ROTORDYNAMIC FORCES GENERATED BY
DISCHARGE-TO-SUCTION LEAKAGE FLOWS
IN CENTRIFUGAL PUMPS

ABSTRACT

This paper reviews the current state of knowledge of rotordynamic forces caused by the discharge-to-suction leakage flows in centrifugal pumps. The indications that these flows could contribute significantly to the rotodynamics motivated the fabrication of an experiment in which measurements of rotordynamic forces would be made on simulated leakage flows in which the flow rate, clearance, eccentricity and other parameters would be exercised in order to understand the phenomena. Sample data is presented and demonstrates substantial rotordynamic effects which could be potentially destabilizing. The rotordynamic forces appear to be inversely proportional to the clearance and change significant with the flow rate.

1. INTRODUCTION

In turbomachinery, the trend toward higher speeds and higher power densities has led to an increase in the number and variety of fluid-structure interaction problems in pumps, compressors, turbines and other machines. Fundamentally this occurs because the typical fluid forces scale like the square of the speed and thus become increasingly important relative to the structural strength. This becomes particularly acute in rocket engine turbopumps where demands to minimize the turbopump mass may also lead to reductions in the structural strength. This paper focuses on just one such fluid-structure interaction issue, namely the role played by fluid forces in determining the rotodynamic stability and characteristics of a turbopump. More specifically we review the contributions to the rotodynamic forces from the fluid flow through centrifugal pump impellers and the discharge-to-suction leakage flows external to the impeller. Results from an experimental program designed to measure these leakage flow contributions are described and analyzed.

2. BACKGROUND

Rotodynamic forces imposed on a centrifugal pump by the fluid flow through it were first measured by Domm and Hergt (1970), Hergt and Krieger (1969-70), Chamieh et al (1985) and Jery et al (1985). These forces are defined by expressing the instantaneous radial forces, \( F_x^*(t) \) and \( F_y^*(t) \) (figure 1) acting on the impeller in the linear form
\[
\begin{bmatrix}
F_x^* (t)
\end{bmatrix} = \begin{bmatrix}
F_{OX}^* \\
F_{OY}^*
\end{bmatrix} + [A] \begin{bmatrix}
x(t) \\
y(t)
\end{bmatrix}
\] (1)

where \(F_{OX}^*, F_{OY}^*\) are the steady, time-averaged forces in a stationary frame and \([A]\) is the rotordynamic matrix where \(x(t), y(t)\) are the shaft displacements from the mean position. The steady radial forces \(F_{OX}^*, F_{OY}^*\) result from non-axisymmetries and are discussed in detail elsewhere (Iverson et al [1960], Domm and Hergt [1970], Chamieh [1983], Chamieh et al [1985], Adkins [1985]). We focus here on the rotordynamic matrix \([A]\) which will in general be a function not only of the mean flow conditions and pump geometry but also of the whirl motion. In the case of a circular whirl orbit \(x = \epsilon \cos \Omega t, y = \epsilon \sin \Omega t\) where \(\epsilon\) is the eccentricity and \(\Omega\) is the whirl frequency. Then \([A]\) is expected to be a function of both \(\epsilon\) and \(\Omega\). At small, linear amplitudes \([A]\) should be independent of \(\epsilon\) and presented as a function of the whirl ratio \(\Omega/\omega\) where \(\omega\) is the impeller rotation frequency. Then the forces \(F_n^*\) and \(F_\ell^*\) normal and tangential to the whirl orbit (figure 1) are given by

\[
\begin{align*}
F_n^* & = \epsilon (A_{xx} + A_{yy})/2 \\
F_\ell^* & = \epsilon (A_{yx} - A_{xy})/2
\end{align*}
\] (2)

Figure 1. Schematic of the fluid-induced radial forces acting on an impeller whirling in a circular orbit. \(F_x^*\) and \(F_y^*\) represent the instantaneous forces in the stationary laboratory frame. \(F_n^*\) and \(F_\ell^*\) are the forces normal and tangential to the whirl orbit where \(\Omega\) is the whirl frequency.

Figure 2. Schematic showing the impeller/volute arrangement for the experiments of Jery (1986) and Adkins (1985).
Note that if $[A]$ is to be rotationally invariant, then $A_{xx} = A_{yy} = \epsilon^{-1} F^*_n$ and $A_{yx} = -A_{xy} = \epsilon^{-1} F^*_t$. Virtually all of the experimental results confirm the fact that the matrix $[A]$ is rotationally invariant for the flows discussed in this paper (Jery [1986]).

Typical experimental measurements of the dimensionless normal and tangential forces, $F_n$ and $F_t$, ($F^*_n, F^*_t$ non-dimensionalized by $\rho \pi \omega^2 b_2 R_2^2$ where $\rho$ is the fluid density and $b_2, R_2$ are respectively the width and radius of the impeller discharge) from the work of Jery (1986) are shown in figure 3. These particular results are for a typical five-bladed centrifugal pump impeller made by Byron-Jackson for a specific speed of 0.57 (referred to as Impeller X) and installed in a well-matched spiral volute in the manner shown in figure 2 (for more detail see Jery [1986] or Adkins and Brennen [1988]).

Figure 3. Dimensionless normal and tangential forces, $F_n$ and $F_t$, as a function of whirl ratio from Jery (1986). Typical centrifugal impeller/volute combination (Impeller X and Volute A at 1000 rpm and a flow coefficient $\varphi = 0.092$) are shown by $\triangle$; dummy Impeller S results with externally imposed pressure rise are shown by $\times$.

Figure 5. Theoretical predictions from Childs (1986) on the $F_n, F_t$ resulting from the conventional leakage path geometry used in the tests of Bolleter et al (1985). Results are shown for three different inlet swirl velocity conditions in which the swirl velocity is assumed to be 0.5 (---), 0.6 (-----) and 0.7 (--.--.--.) of the shroud inlet rotating velocity.
Figure 4. Comparison of the dimensionless normal and tangential forces according to Adkins (1985) theory (solid lines) with the experimental values for Impeller X at $\varphi = 0.092$.

One of the most significant features of these results is the range of positive whirl ratios within which the tangential force is positive and therefore potentially destabilizing rotordynamically. The data for other flow coefficients, $\varphi$, is very similar. As these results were being obtained it was recognized that contributions to the rotodynamic forces could arise not only from azimuthally non-uniform pressures in the discharge flow acting on the impeller discharge area but also from similar non-uniform pressures acting on the exterior of the impeller front shroud as a result of the leakage flow passing between this shroud and the pump casing. Consequently, Jery (1986) also made measurements using a solid "impeller" (Impeller S) with the same exterior profile as Impeller X. The leakage flow was simulated by a remote auxiliary pump which generated the same discharge to inlet pressure differences as occurred with Impeller X operating at a given flow coefficient. The normal and tangential forces obtained are included in figure 3. If one assumes that the solid impeller experiences the same leakage flow contributions to $F_n, F_t$ as Impeller X but does not experience the main throughflow contributions, the tentative conclusion could be drawn that the leakage flow contribution to the normal force was about 70% of the total and the contribution to the tangential force was about 30% of the total. This tentative conclusion indicating the substantial role of the leakage flow motivated further study.

In parallel work Adkins (1985) (see also Adkins and Brennen [1988]) developed a fluid mechanical model of the complicated unsteady throughflow generated when a rotating impeller whirls. The model allowed evaluation of the pressure perturbations in the impeller discharge which compared well with the experimental measurements of these perturbations. It therefore permitted evaluation of the contribution to the
rotodynamic forces from these pressure perturbations and typical results for a limited range of whirl ratios are presented in figure 4 along with experimental measurements of the total $F_n$, $F_t$ under the same conditions. The conclusions are crudely consistent with the early remarks; the pressures in the main discharge flow contribute about one half of the rotodynamic forces. To confirm this Adkins (1985) made pressure perturbation measurements in both the main discharge and the leakage flow. These allowed evaluation of the rotodynamic "stiffness," namely the rotodynamic forces at zero whirl ratio, $F_n(0)$ and $F_t(0)$. The experiments suggested fractional contributions similar to those in Jery's work, namely that the leakage flow component of $F_n(0)$ was more than 70% while the component of $F_t(0)$ was about 40%. Adkins (1985) also concluded that changes in the geometry of the leakage pathway resulted in significant changes in these rotodynamic contributions. Since the geometry used in these tests was not typical of that in prototype pumps it was also concluded that further work on the rotodynamic characteristics of leakage flows was clearly indicated and this led to the fabrication of the experiment described below.

There are several other indications which suggest the importance of leakage flows to the fluid-induced rotodynamic forces. It is striking that the total rotodynamic forces measured by Bolleter et al (1987) for a conventional centrifugal pump configuration are about twice the magnitude of those measured by Jery (1986) or Adkins (1985). In the light of the results presented below it now seems sensible to suggest that this difference is due to the fact that the clearances in the leakage flow annulus are substantially smaller in Bolleter's configuration. We also note that there have been reports that SSME impellers fitted with anti-swirl vanes in the leakage flow annulus have had noticeably different rotodynamic characteristics (Jackson [1985]).

When it became apparent that leakage flows could contribute significantly to the rotodynamics of a pump, Childs (1986) adapted the bulk-flow model which he had developed for the analysis of fluid-induced forces in seals to evaluate the rotodynamic forces, $F_n$ and $F_t$, due to these leakage flows. The model was applied to several pump geometries; typical results for the conventional centrifugal pump configuration tested by Bolleter et al (1987) are shown in figure 5. The results have been scaled to conform with the non-dimensionalization used in this paper. Data is shown for three different inlet swirl velocity conditions in which the swirl velocity is assumed to be 0.5, 0.6 or 0.7 of the impeller tip speed. Note that Childs (1986) also presents qualitatively similar results for a quite different leakage flow path geometry.

Several general conclusions may be drawn from Childs work. First the magnitude and overall form of the model predictions are consistent with the experimental data. In particular, the model also predicts positive, rotodynamically destabilizing tangential forces (or cross-coupled stiffness to use rotodynamic parlance) over a range of positive whirl ratios. Secondly, a rather unexpected resonance-like phenomenon develops at small positive whirl ratios when the inlet swirl velocity ratio exceeds about 0.5. It remains to be seen whether such "resonances" occur in practice. Childs (1986) points out that a typical swirl velocity ratio at inlet (pump discharge) would be about 0.5 and
may not therefore be large enough for the resonance to be manifest. It is clear that a
detailed comparison of model predictions with experimental measurement remains to
be made and is one of the purposes of the present program.

3. LEAKAGE FLOW TEST APPARATUS

The experimental apparatus sketched in figures 6 and 7 was designed and con-
structed to simulate impeller shroud leakage flow (Zhuang [1989], Guinzburg et al

Figure 6. Schematic of the whirling shroud where $S$ is the center of the stationary casing,
$R$ is the center of the rotating shroud, $W$ is the center of the whirl orbit along which $R$
travels, $WR = \varepsilon$ is the eccentricity, and $WS = \delta$ is the offset.

Figure 7. More detailed structure of the leakage flow test apparatus (Zhuang [1989]).
A rotating shroud is mounted on a spindle attached to the rotating force balance (Jery et al [1985], Franz et al [1989]). The gap between this rotating shroud and the stationary casing can be varied by both axial and radial adjustment of the stationary casing. The initial geometric configuration consists of a straight annular gap inclined at an angle of 45° to the axis of rotation. The flow through the leakage path is generated by an auxiliary pump. The shroud can be driven at speeds up to 3500 RPM. A circular whirl motion with a frequency up to 1800 RPM can be superimposed on the basic rotation. The amplitude of this whirl motion or eccentricity, $\epsilon$, is variable as is the fixed offset, $\delta$. Both the main motor and the whirl motor are driven through position and velocity feedback systems which are coupled to a data acquisition system which records the position in both rotation cycles at which radial force measurements are taken. Descriptions of the force balance, data processing and other details are contained in Jery [1985].

Steady radial forces and rotordynamic forces were obtained from the force balance measurements. In addition, an array of static pressure manometer taps was located along a meridian in the leakage flow passage. By setting the rotating shroud at various offsets this allowed evaluation of the steady forces and zero whirl frequency rotordynamic forces by integration of the measured pressure differences. These could be compared with the force balance measurements from the same experiments (Zhuang [1989]).

The results from these experiments will be presented non-dimensionally by dividing the forces by $\rho \pi \omega^2 L \epsilon R_2^2$. This differs from the factor used to non-dimensionalize the impeller forces presented earlier in that the axial length, $L$, of the leakage flow passage (figure 6) has replaced $b_2$, the impeller discharge width. In most pumps $L$ and $b_2$ are comparable and hence, to evaluate the significance of the results, the dimensionless data from the leakage flow tests may be directly compared with that from the impeller tests.

The forces are presented as functions of the whirl ratio or ratio of whirl frequency, $\Omega$ to rotating frequency, $\omega$. Other dimensionless parameters are the flow coefficient, $\varphi (= Q/2\pi R_2^2 H \omega$ where $Q$ is the leakage flow rate), the gap width ratio, $H/R_2$, the eccentricity ratio, $\epsilon/R_2$, the offset ratio, $\delta/R_2$, and the Reynolds number $\omega R_2^2/\nu$, where $\nu$ is the kinematic viscosity of the liquid.

4. EXPERIMENTAL RESULTS FOR ROTORDYNAMIC FORCES

Preliminary results from this experimental apparatus were obtained for zero whirl frequency using static offsets (Zhuang [1989]). Typical results for zero flow rate and a particular offset are presented in figure 8 which illustrates a number of general features in the data. Note first that the data at rotating speeds of 1000 rpm and 1500 rpm are in good agreement which provides some evidence that the Reynolds number effects are not too significant. Secondly the forces calculated from the measured pressure distributions in the leakage annulus agree well with those measured directly with the
force balance. This confirms the fact that the forces arise from the pressure variations in the leakage flow and not from the viscous shear stresses or the stresses on the other surfaces of the rotating shroud. Finally, figure 8 clearly demonstrates that the forces are a strong function of the clearance, $H$; indeed the dependence is close to inverse proportionality.

More complete rotodynamic results from force balance measurements are shown in figures 9, 10 and 11 for a rotating speed of 1000 rpm, four different leakage flow rates (zero to 30 gpm), two different clearances, $H$, and two eccentricities, $\varepsilon$. All of the data obtained thus far is for inlet swirl velocity ratios (in Childs' sense) which are close to zero though future tests will explore the effect of this parameter by installation of inlet guide vanes.

Note first that the general form and magnitude of the data shown in figures 9, 10 and 11 is very similar to that obtained for impellers by Jery (1986) and Adkins (1985) and to that from Childs' model in the absence of the "resonance." Secondly,
Figure 10. Dimensionless normal and tangential forces at 1000 rpm, an eccentricity $\epsilon = 0.0254$ cm, a clearance $H = 0.424$ cm, offset $\delta = 0$ and various flow rates as follows: $0 \ell/sec = \square$, $0.631 \ell/sec (10 \text{ gpm}) = +$, $1.262 \ell/sec (20 \text{ gpm}) = \Delta$, $1.892 \ell/sec (30 \text{ gpm}) = \times$.

Figure 11. Dimensionless normal and tangential forces at 1000 rpm, an eccentricity $\epsilon = 0.118$ cm, a clearance $H = 0.140$ cm, offset $\delta = 0$ and various flow rates as follows: $0 \ell/sec = \square$, $0.631 \ell/sec (10 \text{ gpm}) = +$, $1.262 \ell/sec (20 \text{ gpm}) = \Delta$, $1.892 \ell/sec (30 \text{ gpm}) = \times$.

since the data of figures 9 and 11 were obtained under conditions which were the same except for the magnitude of the eccentricity, $\epsilon$, it is reassuring to note the similarity between the two sets of data. Evidently these experiments lie within the linear regime of small eccentricities (note that the assumption of linearity was implicit in equation (1)). Thirdly, we note that the forces are strong functions of both the leakage flow rate and the clearance, $H$. In the case represented by figure 10 the combination of small eccentricity and large clearance led to forces whose magnitudes were rather small and hence the larger scatter in the data presented in that figure.

The effect of flow rate on the normal force is clearer than its effect on the tangential force. Clearly the Bernoulli effect on the normal force increases with increasing flow. It would also appear that the positive tangential forces at small positive whirl ratios are smallest at the highest flow rate and therefore increasing the flow is marginally stabilizing. The effect of the clearance is much larger and it seems that all the forces

are roughly inversely proportional to the clearance, $H$.

Though the functional dependence of $F_n, F_t$ on the whirl ratio, $\Omega/\omega$, is not necessarily quadratic, it is nevertheless of value to the rotordynamicists to fit the data of figures 9, 10 and 11 to the following expressions:

\[
F_n = M (\Omega/\omega)^2 - c (\Omega/\omega) - K
\]

\[
F_t = -C (\Omega/\omega) + k
\]

where $M, C, c, K$ and $k$ are the dimensionless direct added mass ($M$), direct damping ($C$), cross-coupled damping ($c$), direct stiffness ($K$) and cross-coupled stiffness ($k$). The cross-coupled added mass ($m$) has been omitted for simplicity. Table 1 lists the values of these rotordynamic quantities for the data of figures 9, 10 and 11.
The added masses listed in Table 1 could be compared with theoretical values derived as follows. The potential flow added mass for a fluid-filled annulus between two circular cylinders (inner and outer radii denoted by $a, b$ respectively) is $\rho \pi \Delta L a^2 b^2 / (b^2 - a^2)$ where $\Delta L$ is the axial length (Brennen [1976]); this assumes no axial velocities which could relieve the pressures caused by acceleration of the inner cylinder. If this expression is integrated over the length of the leakage annulus shown in figure 6 it leads to an added mass given by

$$M = 0.160 R_2 / H$$

or 3.53 for $H = 0.424$ cm and 10.71 for $H = 0.140$ cm. The fact that the actual values are about 40% of these may reflect the relief allowed by non-zero axial velocity. It is however interesting to note that the above result correctly models the functional dependence on $H$ exhibited by the experimental data.

The data of Table 1 is presented in graphical form in figure 12 where the dimension-

![Graphs showing direct and cross-coupled stiffness, damping and added mass as functions of the flow coefficient, $\phi$, for three geometries: $\epsilon/R_2 = 0.00271, H/R_2 = 0.0149(\times)$, $\epsilon/R_2 = 0.0126, H/R_2 = 0.0149(\Box)$ and $\epsilon/R_2 = 0.00271, H/R_2 = 0.0453(+)$.](image-url)
less rotodynamic parameters are plotted against the flow coefficient, $\varphi$. The similarity of the results for the two eccentricities is clearly manifest. The smaller magnitude generated with the larger clearance is also clearly demonstrated.

5. CONCLUSIONS

A review of the existing experimental and analytical results shows that the discharge-to-suction leakage flow in a centrifugal pump can contribute substantially to the fluid-induced rotodynamic forces for that turbomachine. While the geometry of the impeller shroud/pump casing annulus varies considerably in previous studies the indications are that the contributions from the leakage flow can be of the same order as those acting on the impeller discharge. This motivated the current experimental study of leakage flows and their rotodynamic effects.

Preliminary experimental results for simulated leakage flows of rather simple geometry are presented for different whirl frequencies, eccentricities, clearances and flow rates. The functional dependence on whirl frequency to rotating frequency ratio (term-
ed the whirl ratio) is very similar to that measured in experiments and to that predicted in the theoretical work of Childs. Two sets of results taken at different eccentricities yield quite similar non-dimensional rotodynamic forces indicating that the experiments probably lie within the linear regime. The dimensionless forces are found to be functions not only of the whirl ratio but also of the flow rate and of the clearance. While the dependence on flow rate is not simple, it would appear that the dimensionless rotodynamic forces are roughly inversely proportional to the clearance. Future tests will include the addition of swirl to the inlet flow in order to examine whether the "resonances" predicted by Childs do indeed occur.

6. ACKNOWLEDGEMENTS

The authors are grateful to F. Zhuang, A. Bhattacharyya and F. Rahman for help with the experimental program. We would also like to thank NASA George Marshall Space Flight Center for support under Grant NAG8-118.
