Harmonic Cascading in Bubble Clouds

S. Kumar, Palaiseau, France
C. E. Brennen, Pasadena, CA, USA

ABSTRACT

Nonlinear interactive effects in a bubbly cloud have been studied by investigating the frequency response of a bubble layer bounded by a wall oscillating normal to itself. First, a Fourier analysis of the Rayleigh-Plesset equation is used to obtain an approximate solution for the nonlinear response of a single bubble in an infinite fluid. This is used to solve for nonlinear effects in a semi-infinite layer containing bubbles with a distribution of size.

A phenomena termed harmonic cascading is seen to take place due to presence of distribution of bubble sizes. This phenomena consists of a large response at twice the excitation frequency when the mixture contains bubbles with a natural frequency equal to twice the excitation frequency. The ratio of the amplitude of the second harmonic response to the amplitude of the first harmonic response is observed to increase when the number of small bubbles is increased relative to the number of large bubbles. The response is also seen to be weakened by an increase in the number of bubbles per unit liquid volume at constant void fraction.

1. INTRODUCTION

The purpose of this research is to gain some understanding of the global effects of bubble dynamics in the fluid mechanics of bubbly flows and, in particular, cavitating flows. At the most basic level, bubble-bubble interactions occur because the pressure changes generate rapid bubble volume changes which cause accelerating velocity fields which effect the pressure distribution in the flow. These effects may occur in the kind of bubbly cavitating flow which produce noise, damage, and performance deterioration in ship propellers, hydrofoils and turbomachines. The understanding of flows of bubbly mixtures is also important in the design and operation of sonar systems, cavitation detection devices and in acoustical techniques of flow measurement.

Traditionally, cavitating flows have been studied using single bubble dynamics and assuming no interaction among the bubbles in the flow field. Such an approach ignores the interactive effects that the bubble dynamics have on the global pressure distribution in the flow field and is accurate only in case of extremely dilute bubble concentrations. The experimental results of Arakeri and Shanmuganathan (1985) and Marboe et al. (1986) have shown that noise produced by travelling bubble cavitation can be modified by interactive effects at higher bubble concentrations in ways that can not be explained on the basis of single bubble theories. To model these effects researchers have used continuum models incorporating bubble dynamics to analyze global interactive effects. Early studies treated the bubbly mixture as an equivalent compressible homogeneous medium (Tangen, Dodge and Seifert (1949)). Among the first to focus on the dynamics of bubble clusters was van Wijngaarden (1964) who analyzed the collapse of a large number of bubbles next to a flat wall and found considerable increase in the pressure at the wall as result of the interactive effects. Biesheuvel and van Wijngaarden (1984) used ensemble and volume average of the conservation equations for each phase to develop more general equivalent flow models of dispersed two phase mixtures, including the phenomena of bubble dynamics, relative motion and liquid compressibility. Most of the later research efforts are based on these equations. d'Agostino and Brennen (1988) and Omta (1987) found that the characteristic natural frequencies of a spherical cloud of bubbles can be much smaller than the natural frequency of a single bubble. Chahine (1982) pioneered other approach to solution the flow of bubble clouds which utilises the method of matching asymptotic expansions and sums up the contribution of individual bubbles in the cloud. Birnir and Smereka (1990) have carried out numerical solutions for bubble clouds and investigated the solutions using techniques used to study dynamical systems. They found that the bubble radius, the flow velocity and pressure were bounded and the cloud was seen to posses natural frequencies.

However, most of the recent analyses use linearized models of the bubble dynamics and the flow. It is well known that the dynamics of a bubble can be quite nonlinear (Prosperetti (1975)) which in combination with nonlinear convective effects may produce significant nonlinear effects in bubbly flows. An attempt to understand these nonlinear effects by studying an analytically amenable model problem is presented here. The purpose is to obtain a qualitative understanding of the various mechanisms of frequency dispersion in the bubbly two phase mixtures associated with cavitation. The dynamics of a bubbly liquid next to a flat wall which oscillates normal to its own plane has been studied. Almost all of the work reported in the literature assume the clouds to contain
identical bubbles. A semi-infinite layer with a given bubble size distribution has been examined and reveals new phenomena of harmonic cascading in such clouds.

2. NOMENCLATURE

- \( \phi \): imaginary number
- \( k \): polytropic constant for gas expansion and contraction
- \( j, m, n \): integer indices
- \( l_r \): reference length scale
- \( p \): pressure in liquid flow field
- \( P_{\infty} \): pressure of permanent gas in the bubble at undisturbed condition
- \( P_n \): complex amplitude of pressure oscillation at frequency \( n \phi \)
- \( P_{\infty} \): reference pressure in the liquid volume
- \( P_{\infty} \): pressure inside the bubble at undisturbed condition
- \( R \): radius of the bubble
- \( R_m \): radius of the smallest bubbles in the layer
- \( R_M \): radius of the largest bubbles in the layer
- \( R_o \): radius of the bubble at undisturbed reference conditions
- \( R_0 \): complex amplitude of radius oscillation at frequency \( n \phi \)
- \( S \): surface tension of the liquid
- \( t \): time
- \( T \): Lagrangian time
- \( u \): velocity of the liquid
- \( x \): Eulerian space coordinate normal to the wall
- \( X \): Lagrangian space coordinate normal to the wall
- \( X_n \): complex amplitude of fluid displacement oscillation at frequency \( n \phi \)
- \( \alpha \): volume fraction of bubbly mixture
- \( \alpha_o \): volume fraction of bubbly mixture at undisturbed reference conditions
- \( \delta \): increment in the frequency
- \( \gamma \): ratio of specific heats
- \( \nu \): kinematic viscosity
- \( \omega_b \): natural frequency of the bubble (in radians/sec)
- \( \omega_f \): forcing frequency for pressure or wall oscillation (in radians/sec)
- \( \omega_r \): reference frequency (in radians/sec)
- \( \eta(R_o) \): bubble number density per unit liquid volume
- \( \eta'(R_o) \): bubble number density per unit total volume
- \( \eta' \): number of bubbles per unit liquid volume
- \( \Re \): real part of complex quantity
- \( \rho \): density of the liquid
- \( \rho_o \): density of the vapor in the bubble
- \( \tau \): volume of the bubble
- \( \tau_n \): complex amplitude of the bubble volume oscillation at frequency \( n \phi \)
- \( \tau_o \): volume of the bubble at undisturbed reference conditions

3. SOME TYPICAL APPLICATIONS AND VALUES

Clouds of cavitation bubbles occur in a variety of technological situations. Cavitation clouds are generated by propellers and are an important source of noise and damage. Furthermore, single bubbles in travelling bubble cavitation have been observed to breakup into many smaller bubbles (Blake et al. (1977) and Ceccio and Brennen (1991)) and the dynamics of these small clouds are clearly important. The typical data used for illustration of the present analysis have been selected with these physical situations in mind.

A number of researchers have measured the size of free stream nuclei (Gates and Acosta (1978)) and cavitation bubbles (Maeda et al. (1991)). Typical nuclei range in size from 10 \( \mu m \) to 150 \( \mu m \); the size distribution can usually be approximated by

\[
\eta(R_o) = \frac{N^*}{R_o^m} \tag{1}
\]

where \( \eta(R_o) dR_o \) is the number of nuclei per unit liquid volume with equilibrium radii between \( R_o \) and \( R_o + dR_o \). A distribution of the form given by the equation (1) has been used to describe the size distribution of free stream nuclei in sea water and various water tunnel facilities with \( N \approx 10^{-5} \) and \( m \approx 3 \rightarrow 4 \) (Brennen and Ceccio (1989)). The bubble size distribution in cavitation clouds (Maeda et al. (1991)) can also be approximately described by equation (1) with suitable values of \( N^* \) and \( m \).

The void fraction values due to free stream nuclei are extremely small. Though the void fraction for a cavitation cloud is larger than that of free stream, it is still small at approximately 0.03% (Maeda et al. (1991)). No measurements of the void fraction of a cloud resulting from the breakup of a collapsing bubble exist. For purpose of illustrating the present results, void fractions were estimated from the experiments of Arakeri and Shanmuganathan (1985). The fluid has been chosen to be water at room temperature (20 °C). A bubble subject to periodic excitation oscillates with value of the polytropic constant, \( k \), between 1 and \( \gamma \) (Plesset and Hsieh (1960)) and so, for illustrative purposes, the value of the polytropic constant, \( k \), has been chosen to be 1. When a distribution of bubble sizes is used the form given by equation (1) will be employed and a range of nuclei sizes between 10 \( \mu m \) and 100 \( \mu m \) will be used. The values of ambient pressure have been chosen to be typical values for reduced pressure in the water tunnel (13146 Pa) and atmospheric conditions for cavitation at the ocean surface (101325 Pa). These will be referred to as Water Tunnel and Ocean conditions.

4. NONLINEAR SOLUTION FOR A SINGLE BUBBLE

There exists a substantial body of literature on the nonlinear dynamics of a single bubble in an infinite fluid (Plesset and Prosperetti (1977)). In the present work it is necessary to construct the very simplest nonlinear solution of the Rayleigh-Plesset equation for a single bubble. Later this will be used as a building block for the problems of many bubbles interacting in a flow. The bubble is assumed to be spherical and to contain water vapor and residual permanent gas. The bubble interior is assumed to be uniform with constant vapor pressure, \( P_v \). The permanent gas in the bubble is assumed to behave polytropically with an index, \( k \), between 1 and \( \gamma \) (Plesset and Hsieh (1960)). The liquid compressibility is only included in the radiation damping and this is done by including it in the effective viscosity used for the bubble dynamics (Devin (1959) and Prosperetti (1977)). The bubble growth due to rectified diffusion has been ignored since
that takes place at a much slower time scale than the natural cycle of the bubble (Hsieh and Plesset (1961)). With these assumptions the Rayleigh–Plesset equation describing the bubble dynamics becomes

\[
\frac{D^2 R}{D \tau^2} + \frac{3}{2} \left( \frac{D R}{D \tau} \right)^2 + \frac{4 \nu}{\rho R} \frac{D R}{D \tau} + \frac{2S}{\rho R^2} = \frac{P_c - P_\infty(t)}{\rho} + \frac{P_\infty}{\rho} \left( \frac{R_0}{R} \right)^{3k}
\]  

(2)

In the present solution a Fourier series expansion is used and terms up to second order are retained in order to examine these corrections to the linear solution. The bubble radius, \( R(t) \), and the pressure at infinity, \( P_\infty(t) \), are expanded in the form

\[
R = R_0 + \sum_{n=1}^{N} \Re \left( P_n e^{int \omega_k} \right)
\]

(3)

\[
\frac{P_\infty(t)}{\rho} = P_\rho + \sum_{n=1}^{N} \Re \left( P_n e^{int \omega_k} \right)
\]

(4)

where \( P_n \) and \( R_0 \) are complex quantities and the frequencies \( n \omega_k \) represent a discretization of the frequency domain. These expansions are substituted into equation (2) and all terms of third or higher order in \( R_0/R \) are neglected in order to extract the simplest nonlinear effects. Finally, coefficients of \( e^{int \omega_k} \) on both sides of the simplified equation are equated to yield the following relation for \( P_\rho \) and \( R_0 \):

\[
\frac{P_\rho}{\omega_k^2 R_0^2} = \Lambda(n) \frac{R_0}{R_n} \sum_{j=1}^{n-1} \beta_1(n, j) \frac{R_2}{R_0} \frac{R_n}{R_{n+j}} \sum_{j=1}^{N-n} \beta_2(n, j) \frac{R_2}{R_0} \frac{R_n}{R_{n+j}}
\]

(5)

where the overbar denotes complex conjugate and the bubble natural frequency, \( \omega_k \) is given by

\[
\omega_k = \sqrt{\frac{\nu}{\rho R_0^3} + \frac{2S}{\rho R_0^3}} \frac{1}{2}
\]

(6)

and \( \Lambda(n) \), \( \beta_1(n, j) \) and \( \beta_2(n, j) \) are defined as

\[
\Lambda(n) = \left[ \frac{n^2 \delta^2}{\omega_k^2} - 1 \right] \left( 1 + \frac{4 \nu \delta}{\omega_k R_0^3} \right)
\]

(7)

\[
\beta_1(n, j) = \frac{3k+1}{4} + \frac{3k-1}{2} \frac{S}{\rho \omega_k^3 R_0^3} + \frac{1}{2} \frac{\delta^2}{\omega_k^2} (n-j) (n+j+1)
\]

\[
+ \frac{2 \nu \delta}{\omega_k R_0^3} \frac{(n-j)}{\omega_0 R_0^3}
\]

(8)

and

\[
\beta_2(n, j) = \frac{3k+1}{2} + (3k-1) \frac{S}{\rho \omega_k^3 R_0^3} + \frac{1}{2} \frac{\delta^2}{\omega_k^2} (n^2 - n - j^2) + \frac{2 \nu \delta}{\omega_k R_0^3} \frac{n \delta}{\omega_0 R_0^3}
\]

(9)

For illustrative purposes, we select the values of the parameters \( \nu/\omega_k R_0^3 \) (\( \approx 0.01 \)) and \( S/\rho \omega_k^3 R_0^3 \) (\( \approx 0.10 \)) at the water tunnel condition for a bubble of 14 \( \mu \)m radius. We chose to consider a single bubble subjected to an oscillating pressure at infinity containing a single frequency, \( \omega_f \), such that \( \omega_k/\omega_f = 3.0 \) and several values of \( P_\rho/\omega_k R_0^3 \). Results obtained from equation (5) are compared to a numerical integration of the Rayleigh–Plesset equation (which uses a fourth order Runge–Kutta scheme) in Fig. 1 for \( P_\rho/\omega_k R_0^3 = 0.04 \) and 0.08. It can be seen that present approximate analysis works very well for the smaller amplitude and
obtained for a single bubble of 14 μm radius. The parameters are $P_{\infty}/\omega_{f}^2 R_{0}^2 = 0.08$, $\omega_{s}/\omega_{f} = 6.0$ and $S/\rho \omega_{f}^2 R_{0}^2$ are for the water tunnel conditions.

A comparison of the spectra of $|1 - R(t)/R_0|$ is made in Fig. 2 for the case in which the $P_{\infty}/\omega_{f}^2 R_{0}^2$ and $\omega_{s}/\omega_{f}$ values are 0.08 and 6 respectively. It can be seen that the present approximate solution agrees well with the numerical integration for frequencies at which the magnitude is significant. Note that the radius oscillations occur at harmonics of the frequency of the pressure oscillation, $\omega_f$.

Eller and Flynn (1969) observed that for pressure oscillations with amplitude larger than a threshold value, the bubble radius oscillation will contain a subharmonic of order one half. This can also be seen in Lauterborn’s (1976) numerical calculation of the frequency response of a single bubble and in the 3rd order perturbation solution of Prosperetti (1975). The present solution does not give rise to subharmonics in the domain of its validity, i.e., $|R_m/R_0| < 1$. This is because the subharmonics are generated by nonlinearities at an order higher than quadratic. Thus, the absence of subharmonics from our approximate solution does not invalidate our analysis.

More accurate nonlinear solutions than the one described above (for example Prosperetti (1974)) exist and have been reported in the literature. The value of present solution lies in its simplicity and the feasibility of incorporating it in analysis of the collective response of a cloud of bubbles.

5. A SEMI-INFINITE LAYER WITH BUBBLE SIZE DISTRIBUTION

Most of the research efforts in modelling bubbly mixtures so far have assumed bubbly mixtures of identical bubbles. In most practical circumstances, uniformly sized bubbles are very difficult if not impossible to achieve. Moreover, cavitation nuclei in water have a distribution of bubble sizes ranging over several orders of magnitude (Gates and Acosta (1978)).

In this section, we present a weakly nonlinear model of flows of such bubbly mixtures. Since the flow now has a number of length and time scales in terms of the bubble radii and their natural periods, we can expect different mechanisms causing interactions between the different time scales. We shall find a new mechanism for frequency dispersion called harmonic cascading.

The specific problem addressed in this analysis is shown schematically in Fig. 3. Liquid containing bubbles is bounded by a flat wall which oscillates in a direction normal to itself at a frequency, $\omega_f$. The resulting flow is assumed to be a function of $x$ and $t$ alone. A number of simplifying assumptions are introduced in order to obtain a solvable set of equations. The volume of liquid involved in condensation and evaporation during bubble oscillation has been ignored; this is reasonable in view of large differences in the density of liquid and vapor phases. The liquid has been assumed to be incompressible and the relative motion between the phases has been ignored. Both were found by d’Agostino and Brennen (1988) to have very little effect on important features such as natural frequencies of the flow. The most important feature of these effects is the damping that they cause at the resonant frequencies. This can be incorporated in the present solution by taking an appropriate value of effective viscosity in place of liquid viscosity used in the Rayleigh-Plesset equation.

We assume that the bubble number density distribution, $\eta(R_m)$, is known and that it is piecewise uniform. Then, the number of bubbles per unit liquid volume with equilibrium size between $R_m$ and $R_m + dR_m$ is $\eta(R_m) dR_m$. The volume of bubbles per unit liquid volume is

$$\frac{\alpha}{1 - \alpha} = \int_{R_m}^{R_M} \eta(R_m) dR_m$$

where $\tau$ is the volume of a bubble and $R_m$ and $R_M$ are minimum and maximum equilibrium bubble radii present in the layer. Thus, the number of bubbles per unit total volume with equilibrium radius between $R_m$ and $R_M$ is

$$\frac{\alpha}{1 - \alpha} = \int_{R_m}^{R_M} \eta(R_m) dR_m$$

- 174 -
and \( R_0 + dR_0 \), can be written as

\[
\eta' (R_0) dR_0 = \eta (R_0) (1 - \alpha) dR_0 = \frac{\eta (R_0) dR_0}{1 + \int_{R_0}^{R} \eta (R_0) \tau dR_0}
\]  
(11)

We use a dispersed phase number continuity equation to ensure mass and number conservation. Assuming the liquid to be incompressible, it follows that if the bubbles are neither created nor destroyed then

\[
\frac{D}{Dt} \int_{R_0}^{R} \eta' (R_0) dR_0 + \frac{\partial u}{\partial x} \int_{R_0}^{R} \eta' (R_0) dR_0 = 0
\]  
(12)

Assuming that the number density per unit total volume is conserved, the above equation reduces to

\[
\frac{Dn' (R_0)}{Dt} + \eta' (R_0) \frac{\partial u}{\partial x} = 0
\]  
(13)

The corresponding momentum equation is

\[
\rho (1 - \alpha) \frac{D u}{Dt} = - \frac{\partial p}{\partial x}
\]  
(14)

The solution to the problem represented by (2), (11) (13) and (14) was solved in Lagrangian coordinates, \( X \) and \( T \) using a method parallel to that described in Kumar (1991). The above equations ((13) and (14)) become

\[
\frac{\partial n' (R_0)}{\partial T} + \eta' (R_0) \frac{\partial u}{\partial X} = 0
\]  
(15)

and

\[
\frac{\partial u}{\partial T} \frac{\partial x}{\partial x} = - \frac{1}{1 - \alpha} \frac{\partial p}{\partial X}
\]  
(16)

Consistent with the structure of the solution sought, the relationship between Lagrangian and Eulerian coordinates, \( X \) and \( x \), is written in the form

\[
x = X + \sum_{n=1}^{N} \Re (X_n (X) e^{inT})
\]  
(17)

and the bubble volume, \( \tau \), and pressure, \( P \), are written as

\[
\tau = \tau_0 + \sum_{n=1}^{N} \Re (\tau_n (X) e^{inT})
\]  
(18)

\[
P = P_0 + \sum_{n=1}^{N} \Re (P_n (X) e^{inT})
\]  
(19)

Substituting the expansion (18) into equation (10) we obtain

\[
\int_{R_0}^{R} \eta' (R_0) \tau dR_0 = \frac{\sigma_0}{1 - \alpha_0} + \sum_{n=1}^{N} \Re (A_n e^{inT})
\]  
(20)

where

\[
A_n = \int_{R_0}^{R} \eta (R_0) \tau_n dR_0
\]  
(21)

The above equations ((15), (16) and (20) ) along with the expansions ((17), (18) and (19) ) have been used to yield following governing equation for the pressure oscillations in the layer ( Kumar (1991))

\[
d^2 \left( \frac{P_n}{\omega^2} \right) d (X/\alpha) = \lambda^2 \frac{P_n}{\omega^2} + \sum_{j=1}^{N-n} \psi (n, j) \frac{P_j}{\omega^2} \frac{P_{n-j}}{\omega^2}
\]  
(22)

where

\[
\lambda_n^2 = (1 - \alpha)^2 \left( \frac{\eta' (R_0) \psi' (n)}{\omega^2} \right) \phi' (n)
\]  
(23)

\[
\psi (n, j) = (1 - \alpha)^2 \left( \frac{\eta' (R_0) \psi' (n)}{\omega^2} \right)^2 \left[ (1 - \alpha) \frac{2j - n}{2n} \phi' (j) \phi' (n - j) \right]
\]  
(24)

\[
\theta (n, j) = (1 - \alpha)^2 \left( \frac{\eta' (R_0) \psi' (n)}{\omega^2} \right)^2 \theta' (n, j)
\]  
(25)

\[
\phi' (n) = \int_{R_0}^{R} \frac{3n (R_0) \tau_n \omega R}{\lambda (n) \omega R^2} dR_0
\]  
(26)

\[
\psi' (n, j) = \int_{R_0}^{R} \frac{3n (R_0) \tau_n \omega R}{\lambda (j) \lambda (n - j) \omega R^2} \left[ \frac{1}{\lambda (n)} \right] dR_0
\]  
(27)

\[
\theta' (n, j) = \int_{R_0}^{R} \frac{3n (R_0) \tau_n \omega R}{\lambda (j) \lambda (n + j) \omega R^2} \left[ \frac{1}{\lambda (n + j)} \right] dR_0
\]  
(28)

and \( \omega \), \( \lambda \), and \( \alpha \) are suitable reference frequency and length scales respectively. Equation (22) has the following approximate solution (accurate to the second order, details are given in Kumar (1991))

\[
\frac{P_n}{\omega^2} = \phi (X / \alpha) = \sum_{j=1}^{N-n} \psi (n, j) \frac{P_j}{\omega^2} \frac{P_{n-j}}{\omega^2} \quad \text{and} \quad x = X + \sum_{n=1}^{N} \Re (X_n (X) e^{inT})
\]  
(29)

Using the solution given by equation (29) and the momentum equation (Kumar (1991)) the following relation for the conditions at the wall may be obtained

\[
\left( \alpha_0 - 1 \right) \left( \frac{\eta' (R_0) \psi' (n)}{\omega^2} \right)^2 \frac{X_n (0)}{\lambda_n} = \left( \frac{\lambda_n}{\lambda_n + \lambda_{n+j}} \right) \psi (n, j) \frac{P_j}{\omega^2} \frac{P_{n-j}}{\omega^2} + \sum_{j=1}^{N-n} \left( \frac{\lambda_n}{\lambda_n + \lambda_{n+j}} \right) \theta (n, j) \frac{P_j}{\omega^2} \frac{P_{n+j}}{\omega^2}
\]  
(30)

In the case of identical bubbles, we have

\[
\eta (R_0) = \psi (R_0 - R_0')
\]  
(31)

where \( \psi' \) is the total number of bubbles per unit liquid volume and \( R_0' \) is the radius of the bubbles. It can be seen that above result reduces to the result for identical bubbles given in Kumar (1991).

For purpose of illustration we examine a bubble layer containing bubbles of radii between 10.0 \( \mu m \) and 100.0 \( \mu m \) under the water tunnel conditions.
The largest natural frequency of the bubble and the largest bubble radius present in cloud are convenient choices for the reference frequency, $\omega_r$, and the reference length scale, $l_r$ respectively. In the sample calculations the coefficients, $c'(n)$, $\psi'(n,j)$ and $\theta'(n,j)$ were evaluated using equations (26), (27) and (28) respectively. The integrals were evaluated numerically using the trapezoidal rule and Richardson extrapolation was used to estimate the value of the integral for zero step size. The parameters $\Lambda_n$, $\beta_1(n,j)$ and $\beta_3(n,j)$ were calculated from equations (7), (8) and (9), and $\Lambda_n$, $\psi(n,j)$ and $\theta(n,j)$ could then be calculated using equations (23)-(25). Equation (30) was then solved using a Newton-Raphson scheme to calculate the constants $c_n$ for a given amplitude of wall oscillation, $X_n(0)/l_r$. Knowing $c_n$, the amplitude of pressure oscillation could be calculated from the equation (29). Using this solution, the values of $R_n/R_o$ were calculated for different values of $R_o$ and the amplitude of $R_n/R_o$ is checked to insure that it is less than unity. Note that, equation (30) is similar in structure to the equation (5) and hence the solution is nonzero only at harmonics of the excitation frequency. Once again calculations of up to 20 harmonics were found to be sufficient.

Numerical results were computed for a number of typical cases. For each case the results were obtained for thesize distribution density parameter, $m = 2, 3, 4$ (see equation (1)) and the value of $N^*$ was adjusted to obtain the required value of the void fraction. The results for different cases were obtained in order to investigate the effect of changes in void fraction, ambient conditions and amplitude of wall oscillation.

A typical frequency response of the cloud is shown in Fig. 4 for the water tunnel conditions. This illustrates the features of the frequency response common to all cases. The amplitude of pressure oscillation for the fundamental and the second harmonic, which are marked [L] and [2] respectively, as well as the solution obtained from the linearized analysis which is marked [L], are shown. Amplitudes of higher harmonics were found to be negligible. The frequency ratio is the ratio of the actual frequency at which the response occurs to the reference frequency and thus the abscissa represents $\omega_f/\omega_r$ for the line marked [L] and $2\omega_f/\omega_r$ for the line marked [2]. It is seen that the amplitude of first harmonic pressure oscillation increases with increasing excitation frequency. The reason for this is that there is a larger number of smaller bubbles, for which the natural frequency of the bubble is larger. Thus for larger frequency ratios (excitation frequencies) a larger number of bubbles are excited at their natural frequency thus leading to an increase in the amplitude of the pressure oscillation. The stiff behaviour of bubbles whose natural frequencies are less than the excitation frequency (seen in Kumar (1991) as a response to the super-resonant excitation ($\omega_f > \omega_r$), applied to the cloud of identical bubbles) also contributes to an increase in the amplitude of pressure oscillation.

Fig. 5 shows the natural frequency of the bubble for the water tunnel and the ocean conditions. It is clear that smaller bubbles have larger natural frequencies. When the wall is oscillated at a frequency, $\omega_f$, the bubbles with their natural frequency equal to $\omega_f$ are excited with the largest amplitude. Because of the nonlinearity present in the system, the flow variables oscillate at the harmonics of the excitation frequency, $\omega_f$. Thus, the pressure oscillation at $2\omega_f$ excites bubbles with their natural frequency equal to $2\omega_f$ and since, the number of bubbles with the natural frequency, $2\omega_f$, is larger than the number of bubbles with the natural frequency, $\omega_f$, the response resulting from the bubbles with natural frequency of $2\omega_f$ may be significant and may be larger for larger values of $m$. In other words, the excitation may cascade to higher frequencies. We shall refer to this mechanism as harmonic cascading.

The ratio of amplitude of the second harmonic to the amplitude of the first harmonic increases for larger values of the parameter, $m$ (Fig. 4). This could be expected from the above description of the mechanism.
of harmonic cascading. Note that the linear solution is larger than the first harmonic and the difference between the linear solution and the first harmonic is larger for larger values of \( m \). For excitation frequencies larger than the reference frequency, \( \omega_r \), the amplitude of second harmonic is very small and the difference between the linear and nonlinear solutions is also very small. This could be anticipated since \( \omega_r \) is the highest natural frequency present in the cloud and the effect of harmonic cascading is expected to decrease for wall oscillation frequencies larger than 0.5\( \omega_r \). For excitation frequencies up to 0.5\( \omega_r \), harmonic cascading remains an important effect with the amplitude of second harmonic becoming larger than the amplitude of first harmonic for \( m = 4 \). For excitation frequencies larger than 0.5\( \omega_r \), the increase is due to the collective response of the bubbles to the excitation. It is seen that the pressure oscillation decays rapidly away from the wall, decaying to very small values at a distance of 4\( l_r \) from the wall.

Frequency responses for different values of the size density distribution slope, \( m \), are compared in the Fig. 6. The void fraction is same for all cases. It appears that an increase in the value of \( m \) reduces the amplitude of the first harmonic. For a given value of the void fraction, the number of bubbles is larger for larger values of \( m \) and the reduction in the amplitude of pressure oscillation may be caused by the increased damping in the system due to the larger number of bubbles. The weaker response for increased void fraction (also seen for a layer of identical bubbles (Kumar (1991)) may also be caused by an increase in the number of bubbles. Note that the amplitude of the second harmonic is not strongly effected by change in the value of \( m \).

The effect of changes in ambient conditions on the frequency response of the bubbly layer; \( |P_n|/\omega^2 l_r^2(X = 0) \) for the (a) fundamental and the (b) second harmonic is plotted against the frequency ratio, (a) \( \omega_f/\omega_r \) and (b) \( 2\omega_f/\omega_r \) respectively for \( m = 3 \). The parameters: \( X_n(0)/l_r = 0.0002 \) and \( \alpha_o = 0.05 \).

The effect of changes in ambient conditions on the frequency response are shown in Figs. 7. Clearly the effect is not a strong one. However, it does appear that the ocean conditions do promote a little stronger harmonic cascading. This may be explained as follows. The super-resonant (\( \omega_f > \omega_r \)) excitation of the bubbles which have natural frequencies less than the excitation frequency contributes significantly to the amplitude of the fundamental harmonic and this is not strongly influenced by reduction in the viscous and surface tension parameters for the ocean conditions. However, bubble dynamics play a stronger role in the generation of the second harmonic through harmonic cascading and thus increase in the amplitude of the second harmonic (with reduced effect of viscosity and surface tension at the ocean conditions) may be expected. Hence, stronger harmonic cascading can be expected for the ocean conditions.

The effect of changes in the void fraction on the layer is shown in Fig. 8. It is clear that higher void fraction reduces the magnitudes of both the first and the second harmonic. As explained earlier, this may be due to larger damping due to increased number of bubbles.
Figure 8. The effect of variation in void fraction on the frequency response of the bubbly layer; $|P_{in}/\omega_n^2|^{1/2}(X = 0)$ for the (a) fundamental and the (b) second harmonic is plotted against the frequency ratio, (a)$\omega_f/\omega_n$ and (b)$2\omega_f/\omega_n$, respectively for $m = 3$. The parameters: $X_n(0)/U = 0.0002$ and the ambient conditions are for the water tunnel. Values of void fraction, $\alpha_v$, of 0.01, 0.05 and 0.10 are used.

6. LIMITATIONS

In this section we shall examine the various limitations of the present model. The limitation imposed by the continuum mechanics model have been discussed in detail by d'Agostino and Brennen (1988) and so we focus here on additional considerations necessary in the present analysis.

First the amplitude of the radius oscillation is required to be small; in particular, $|R_n/R_0| \ll 1$ must be satisfied. This is also required to avoid the following instability in the bubble dynamics. For pressure oscillations exceeding a threshold value, the bubbles larger than a critical size are known to grow to a large size and then collapse violently (Flynn(1964)). This will not occur if the ratio of the maximum size of the bubble to the equilibrium bubble radius is less than 2.0 (Flynn(1964)). Moreover, the effect of damping is also reduced for large bubbles. These restrictions place an upper limit on the excitation for the present analyses. In practice, $|R_n/R_0| \ll 1$ is expected to dictate the maximum applicable excitation for which the theory remains applicable.

The range of void fraction, for which present theory may be applied, is also bounded by an upper and a lower limit. The lower limit of the void fraction is determined by maximum bubble separation required under continuum assumption as well as requirement of maximum permissible amplitude of radius oscillation, $|R_n/R_0|$. The upper limit on void fraction is determined by the requirement of local pressure disturbance to be negligible in comparison to the global pressure oscillation (d'Agostino and Brennen (1988)).

The phenomena of rectified diffusion results in slow growth of the equilibrium size of a bubble (Hsieh and Plesset (1961)). Thus, the theory can be applied to the bubbly layers subject to steady state oscillation for long periods only if the equilibrium size, $R_0$ is tracked and the values appropriate to a particular time are employed.

7. SOME PRACTICAL OBSERVATIONS

Though limited to small amplitude oscillations and thus to a small excitation, the qualitative phenomena uncovered here are valuable to bear in mind when interpreting some of the practical observations of the response of bubbly mixtures. In particular, harmonic cascading should be present in many practical situations. Measurements of spectra reported by Mellen (1954) and Blake (1986) appear to contain peaks which may be due to harmonic cascading. The results of Arakeri and Shanmuganathan (1985) do not exhibit harmonic cascading. However, that may be due to lack of variation in the size of bubbles generated by electrolysis. It may be important to keep this in mind while designing experiments for evaluating interactive effects in bubbly mixtures. It is particularly important to note that most of the spectra reported in the literature have been made using half octave frequency resolution. Clearly, a finer spectra resolution in the spectra measurement is required in order to unambiguously resolve harmonic cascading.

8. SUMMARY AND CONCLUSIONS

In this work we have studied the nonlinear effects which can occur when a plane wall bounding a bubbly liquid oscillates in a direction normal to itself.

The phenomena of harmonic cascading is seen to take place in a bubbly mixture containing bubbles of different sizes. Harmonic cascading occurs when a low frequency excitation applied to the layer at a frequency, $\omega_f$, results in a large amplitude of oscillation at the frequency of $2\omega_f$ due to presence of a large number of bubbles with natural frequency of $2\omega_f$. The ratio of the amplitude of the second harmonic to the amplitude of the first harmonic defines the extent of harmonic cascading. This ratio increases with an increase in the number of small bubbles relative to the number of large bubbles. It is noteworthy that the phenomena of harmonic cascading can only be modelled by a nonlinear model because the linearized models do not allow for such harmonic generation.

Larger values of the void fraction cause a reduction in the amplitude of pressure oscillation in all cases. This may imply reduced acoustic noise in the bubbly mixtures (observed experimentally by Arakeri and Shanmuganathan (1985)) and damage potential in cavitating flows. Furthermore, the larger number of bubbles present at larger void fractions may cause stronger dissipation and a reduced amplitude of oscillation.
