(Received 30 June 2008; published 24 October 2008)

We examine bosons hopping on a one-dimensional lattice in the presence of a random potential at zero temperature. Bogoliubov excitations of the Bose-Einstein condensate formed under such conditions are localized, with the localization length diverging at low frequency as $\ell(\omega) \sim 1/\omega^\alpha$. We show that the well-known result $\alpha = 2$ applies only for sufficiently weak random potential. As the random potential is increased beyond a certain strength, $\alpha$ starts decreasing. At a critical strength of the potential, when the system of bosons is at the transition from a superfluid to an insulator, $\alpha = 1$. This result is relevant for understanding the behavior of the atomic Bose-Einstein condensates in the presence of random potential, and of the disordered Josephson junction arrays.

Equation (1) holds for $\alpha = 2$.

$\ell(\omega) \sim 1/\omega^\alpha$, \hspace{1cm} (1)

$\alpha = 2$. \hspace{1cm} (2)

This result, in particular, formed the basis of the analysis in Refs. [6,7]. Using the renormalization group analysis of Ref. [17] and the study of random elastic chains of Ref. [20], we show that Eq. (2) does not apply everywhere in the superfluid regime. In a finite region of parameter space on the superfluid side near the superfluid-insulator transition, Eq. (2) fails, and is replaced by the law

$\alpha = g$, \hspace{1cm} (3)

where $1 \leq g \leq 2$. The meaning of the parameter $g$ will be elucidated later in the Letter. Furthermore, as the system approaches the transition to the insulating regime, $g$ decreases. Exactly at the transition $g = 1$, and Eq. (1) acquires a correction to scaling

$\ell(\omega) \sim (\ln^2 \omega)/\omega$. \hspace{1cm} (4)

Equations (3) and (4) are the main result of our Letter.

Our analysis begins by considering a one-dimensional disordered Bose-Hubbard model with many particles per site. Its Hamiltonian is

$H = \sum_k \left[ \frac{U_k}{2} \left( -i \frac{\partial}{\partial \phi_k} + n_k \right)^2 - J_k \cos(\phi_k + 1 - \phi_k) \right]$. \hspace{1cm} (5)

This Hamiltonian describes a chain of sites, connected to their nearest neighbors by a Josephson hopping with a random strength, $J_k$. $U_k$ is the strength of the on-site repulsion, and $n_k \in \left[ -\frac{1}{2}, \frac{1}{2} \right]$ are random offset charges. The hopping, charging, and offsets are randomly distributed with probability densities $P_j(J)$, $P_U(U)$, and $P_n(n)$.

In the strong-disorder limit, a real-space renormalization group analysis can be employed to gradually eliminate sites with anomalously large $J_k$ or local charging gap, $\Delta_k = U_k(1 - 2|n_k|)$ [17,18]. The remaining sites are de-
scribed by the same Hamiltonian but with the renormalized probability distributions. The system of Eq. (5) then emerges as either a superfluid or an insulator; the latter could be either a Mott insulator, a Mott glass, Bose glass, or random-singlet glass, depending on the strength, relative and absolute, of various types of disorder present. If the bosonic system is a superfluid, the distribution of $J$ renormalizes towards the universal limiting function

$$P_J(J) = CJ^{x-1},$$

with $C$ providing normalization. The superfluid is described by $g \geq 1$ with its value decreasing as the critical point at $g = 1$ is approached; in particular, as disorder increases, $g$ decreases. At the same time,

$$P_U(U) \sim \frac{1}{U^2} \exp\left(-\frac{\Omega f}{U}\right),$$

where $f$ flows to 0 along the renormalization group trajectories, and $\Omega$ is the decreasing UV cutoff scale of the renormalized Hamiltonian, i.e., its largest hopping or gap. We now proceed to show that the same parameter $g$ appearing in the distribution (6) controls the localization length of low-frequency phonons, as expressed in Eq. (3).

At the final stages of the renormalization, as long as $g \geq 1$, the system is a superfluid and the possibility that the system is a superfluid and the possibility that the uniform-$U$ treatment leading to Eqs. (11) cannot be considered a derivation of the localization length results in our problem: the random boson problem has charging energies $U_k$ which are also randomly distributed. Below, we show that the results given in Eqs. (10) and (11) are valid even if $U_k$ are random, as long as the probability of observing anomalously small $U_k$ is not too large. In addition, we show that the uniform-$U$ results for $g = 1$ exhibit strong corrections to scaling [see Eq. (31)].

Let us first confirm that the fully random Bosonic chain, Eq. (8), also has a finite constant density of states at low frequencies, as in (10). Consider the classical ground state of a system of $N + 1$ sites described by Eq. (9), where the first grain's phase $\phi_0$ is kept fixed at $\phi_0 = 0$, and a force $h$ is applied conjugate to the phase $\phi_N$ of the last grain. The equilibrium values of the variables $\phi_k$ can be found by minimizing the energy

$$E = \frac{1}{2} \sum_{k=0}^{N-1} J_k (\phi_k - \phi_{k+1})^2 - h \phi_N,$$

which yields $\phi_k = h \sum_{l=0}^{k-1} J_l^{-1}$, \hspace{1em} $0 \leq k \leq N$. (13)

Alternatively, $\phi_k$ can be computed in the following way. Introducing the variables $\psi_k = \phi_k/\sqrt{U_k}$, we can find $\psi_N$ by inverting the matrix $\mathcal{H}_{kl}$ defined by the expression

$$\frac{1}{2} \sum_{k=0}^{N-1} J_k (\psi_k \sqrt{U_k} - \psi_{k+1} \sqrt{U_{k+1}})^2 = \frac{1}{2} \sum_{k=1}^{N} \mathcal{H}_{kl} \psi_k \psi_l.$$

(14)

Then $\phi_k = \sqrt{U_k U_N} G_{kn} h$, (15) where $G$ is a matrix inverse to $\mathcal{H}$. In particular, we are interested in $k = N$ case when Eq. (15) can be rewritten as

$$\phi_N = h \sum_n \frac{C_n [\phi_n^{(n)}]^2}{\omega_n^2}, \hspace{1em} C_n = \left[ \sum_{k=0}^{N} \frac{[\phi_k^{(n)}]^2}{U_k} \right]^{-1}.$$ (16)

Here, $\phi_k^{(n)}$ are the normalized solutions to the eigenmode equation Eq. (9) with the boundary conditions $\phi_0 = 0$ at the beginning of the chain, and with the frequency $\omega_n$, labeled by the index $n$.

Next, we compare the two expressions for $\phi_k$ at $k = N$, Eqs. (13) and (16). We observe that for the probability distribution $P(J) = J^{x-1}$, as long as $g > 1$,

$$\langle \phi_N \rangle = h \left( \sum_{k=0}^{N-1} \frac{J_k^{-1}}{2} \right) \sim N.$$

(17)
On the other hand,  
\[ \phi_{N} = N \int d\omega \rho(\omega) C(\omega) \frac{[\phi_N^{(\omega)}]^2}{\omega_0^2}, \]  
(18)

where \( \phi_N^{(\omega)} \) refers to the eigenmode at frequency \( \omega \), and \( \rho(\omega) \) is the density of states. Clearly, unless the density of states is strongly suppressed at small \( \omega \), the integral (18) diverges due to small \( \omega \) contributions. At small \( \omega \), the localization length exceeds the system size, thus \( \phi_N^{(\omega)} \sim 1/\sqrt{N} \). At the same time, \( (1/U_k) \) is finite, which means that \( C(\omega) \) is both \( \omega \) and \( N \) independent. Suppose \( \rho(\omega) \sim \omega^\gamma \), where \( \gamma < 1 \). Then,  
\[ \phi_N \sim \int d\omega \rho(\omega) \omega^{\gamma} \sim \rho(\omega_0) \omega_0, \]  
(19)

where \( \omega_0 \) is the smallest frequency of the system, which can be found by  
\[ \int_0^{\omega_0} d\omega \rho(\omega) \sim \frac{1}{N}, \quad \omega_0 \sim \frac{1}{N^{\gamma/(1+\gamma)}}. \]  
(20)

This in turn gives  
\[ \phi_N \sim \frac{1}{N^{(1-\gamma)/(1+\gamma)}}. \]  
(21)

Comparison with (17) reveals that \( \gamma = 0 \), i.e., Eq. (10).

We now return to the localization length. First, consider the case of weak random \( J_k = J_0 + \delta J_k \) and \( U_k = U_0 + \delta U_k \). Treating \( \delta J_k \) as a perturbation, it is easy to find the localization length following Refs. [21,22]. Indeed, the mean free time can be found by the Fermi golden rule, to go as \( \tau^{-1} \sim \omega^2 \), while the mean-free path goes as \( \sqrt{J_0 U_0 \tau} \).

The localization length is proportional to the scattering length in 1D, thus \( \ell(\omega) \sim \omega^{-2} \).

This calculation, however, ignores the possibility of the wave scattering off the anomalously small \( J_k \) or \( U_k \). Indeed, suppose we have a “weak link” in Eq. (9) where \( J_{\text{weak link}} = J \) on that link is much smaller than \( J \) on other links, \( J \ll J \). It is straightforward to check that the phonons with wave vector \( q \gg j/J \) get reflected off this weak link, while those with wave vector \( q \ll j/J \) pass straight through. This is easiest to see if we solve Eq. (9) with the assumptions that all \( J_k \) are equal to \( J_0 \), while that of the weak link is \( J \ll J_0 \), and all the \( U_k \) are equal to \( U_0 \). Then, the transmission coefficient through the weak link is  
\[ T = \frac{1}{1 + q^2 \frac{J}{J}}. \]  
(22)

where \( q \) is the dimensionless wave vector which is assumed to be small, or \( |q| \ll \pi \). \( T \) tends to 1 at small \( q \), and to 0 at large \( q \gg j/J \).

It thus follows that a phonon with wave vector \( q \) cannot have a localization length bigger than the average distance between the “weak links” with the strength of their couplings no bigger than \( q \) divided by the density of states. Using Eq. (6), we can estimate the average separation between such weak links. We find  
\[ \int_0^\ell dJJ^{\gamma-1} \sim \frac{1}{\ell}, \]  
(23)

where \( \ell \) is the average distance between the weak links \( j \). This gives \( \ell \sim 1/j^\gamma \). Since \( j \sim q \), and \( q \sim \omega \) due to Eq. (10), the localization length is bounded from above by \( \ell \sim 1/\omega^\delta \); thus, we arrive at our result, Eq. (3).

Scattering off the small \( U_k \) can also reflect the short wavelength waves. Taking all \( U_k \) equal to \( U_0 \), while the “heavy link” (recall that the “masses” are inversely proportional to \( U_k \)) \( U_k \) equal to \( u \ll U_0 \), and taking all the \( J_k = J_0 \) gives the transmission coefficient  
\[ T = \frac{1}{1 + \frac{u^2}{\omega^2} q^2}, \]  
(24)

equivalent to (22). This, however, does not lead to any corrections to Eq. (3). Indeed, using the same arguments as preceding Eq. (23), we find  
\[ \int_0^\ell dU \exp(-\Omega f) \sim \exp(-\Omega f/\ell) \sim 1/\ell. \]  
(25)

Here, \( \ell \) is the typical distance between these “heavy” links. Again taking \( u \sim q \sim \omega \), we find  
\[ \ell \sim \exp\left(\frac{\Omega f}{\omega}\right). \]  
(26)

This estimate is much bigger than Eq. (3), and thus the real localization length Eq. (3) remains unaffected. This concludes the derivation of Eqs. (10) and (2)–(4). 

The analysis of \( \ell(\omega) \) above assumed that we probe the phonon modes of the superfluid in the very end of the renormalization group flow, once the power law that controls the distribution \( P_f(J) \sim J^{-1} \), has already attained its fixed-line value. While this is valid in the limit of \( \omega \to 0 \), corrections to scaling may arise near the critical point. References [17,18] allow us to consider the corrections to this analysis arising from the flow to the SF fixed line. The RG flow for the generic-disorder case is given by  
\[ \frac{df}{dT} = f(1 - g), \quad \frac{dg}{dT} = -\frac{1}{2} fg, \]  
(27)

where \( \Gamma \) is the logarithmic RG flow parameter. In the region close to the critical point, \( f = 0, g = 1 \), we can solve these equations approximately to give  
\[ g \approx 1 + \epsilon + \frac{2\epsilon}{e^{\epsilon \Gamma} - 1}, \quad f \approx \epsilon^2 \frac{4e^{\Gamma}}{(e^{\Gamma} - 1)^2} \]  
(28)

for disorder realizations that flow to \( g = 1 + \epsilon \) with \( \epsilon \ll 1 \). Flows that terminate at the critical point, however, are given approximately by  
\[ g \approx 1 + \frac{2}{\Gamma}, \quad f \approx \frac{4}{\Gamma^2}. \]  
(29)

To find the corrections to scaling in the form of \( \ell(\omega) \), we first note that it is given by the bare length scale of renormalized sites once the RG scale reaches \( \Gamma = \ln^{\omega_0}_\omega \).
Integrating Eq. (30) using Eq. (29) gives the correction to scaling at the critical point. At the critical point, we expect the length of the system to be averaged over 40 realizations of chains with Gaussian initial conditions with $g = 10$. Off criticality, we find by the same analysis that the RG flow of the effective site and bond length is given by the following equation:

$$\frac{d\ell}{d\Gamma} = \ell(f + g).$$

At the critical point, we expect $\ell(\omega) \sim 1/\omega$; let us first derive the correction to scaling at the critical point. Integrating Eq. (30) using Eq. (29) gives $\ln \ell = \Gamma + 2 \ln \ell_0 / \ell_0 + O(1/\ell)$, and thus we find the localization length at criticality having a logarithmic correction

$$\ell(\omega) \sim \left[ \ln^2(\omega/\omega_0) \right] / \omega.$$

Off criticality, we find by the same analysis

$$\ell(\omega) \sim \left[ (1 - (\omega/\omega_0)^\epsilon) / \epsilon \right]^{1+\epsilon}.$$ 

In summary, localization properties at low frequency are determined by the parameter $g$. Its value cannot be calculated directly in closed form from the initial disorder distribution, but we can estimate it by following the RG flow using the techniques of Refs. [17,18]. In Fig. 1, we demonstrate how initial distributions evolve into the exponents $\Delta$. Then, they are expected to mimic (5), and the rest of the analysis of this Letter applies. Experimental observation of the excitation’s localization length could, for example, follow the techniques of Ref. [23], where two crossing laser beams imprint a certain momentum at a certain frequency into the condensate. This technique creates excitations, which can subsequently be detected, only if their momentum deviates from the momentum of a clean-system phonon by no more than the inverse localization length.

FIG. 1 (color online). An example of the correspondence between initial distributions and the exponent $g = \alpha$ at the end of the flow. Main plot: terminal $g$ as a function of the parameter $\delta$ for initial Gaussian coupling distributions $P_U(U) \sim e^{-(U-\langle U \rangle^2)/\langle U \rangle^2}$, and $P_J(J) \sim e^{-(J-\langle J \rangle^2)/\langle J \rangle^2}$, truncated for $J, U < 10^{-4}$. The transition (terminal $g = 1$) occurs at $\delta \approx 1.05$. Inset: example of the flow of $g$ vs the RG flow parameter $\Gamma$ for Gaussian initial conditions with $\delta = 1.125$. The localization exponent $\alpha$ coincides with $g$ at the large $\Gamma$ plateau. Each point is averaged over 40 realizations of a chain of $5 \times 10^6$ sites.
