LETTER TO THE EDITOR

HIFI observations of water in the atmosphere of comet C/2008 Q3 (Garradd)*,**

(Affiliations are available in the online edition)

Received 31 March 2010 / Accepted 13 May 2010

ABSTRACT

High-resolution far-infrared and sub-millimetre spectroscopy of water lines is an important tool to understand the physical and chemical properties of cometary atmospheres. We present observations of several rotational ortho- and para-water transitions in comet C/2008 Q3 (Garradd) performed with HIFI on Herschel. These observations have provided the first detection of the 212−101 (1669 GHz) ortho and 111−001 (1113 GHz) para transitions of water in a cometary spectrum. In addition, the ground-state transition 101−101 at 557 GHz is detected and mapped. By detecting several water lines quasi-simultaneously and mapping their emission we can constrain the excitation parameters in the coma. Synthetic line profiles are computed using excitation models which include excitation by collisions, solar infrared radiation, and radiation trapping. We obtain the gas kinetic temperature, constrain the electron density profile, and estimate the coma expansion velocity by analyzing the map and line shapes. We derive water production rates of 1.7−2.8 × 1028 s−1 over the range ν = 1.83−1.85 AU.

1. Introduction

Comets spend most of their lifetime in the outer Solar System and therefore have not undergone considerable thermal processing. Line emission is useful to study the physical and chemical conditions of cometary atmospheres, and their relation to other bodies in the Solar System (Biver et al. 2002; Bockelée-Morvan et al. 2004).

Water molecules in cometary atmospheres are excited due to collisions with other molecules and radiative pumping of the fundamental vibrational levels by the solar infrared flux. The 101−101 ortho-water transition at 557 GHz is one of the strongest lines in cometary coma, but it cannot be detected directly from the ground due to absorption in the Earth’s atmosphere (Bockelée-Morvan 1987). Water vapour production has been estimated previously from the ground through measurements of its photodissociation product, the OH radical (see e.g. A’Hearn 1982), and water high vibrational bands (Bockelée-Morvan et al. 2004). The 101−101 rotational transition of ortho-water at 557 GHz has been observed using heterodyne techniques by the HIFI observations of water in the atmosphere of comet C/2008 Q3 (Garradd)

* Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

Notes. The observations were conducted using standard frequency switching (FSw), position switching (PSw) and on-the-fly spectral maps (OTF) observing modes. The error bars in line intensity, velocity shift and production rate are the statistical errors.

2. Herschel HIFI observations

Comet C/2008 Q3 (Garradd) was observed with HIFI about one month post-perihelion in the period July 20–27 2009, when the comet was at r₉ ≈ 1.8 AU from the Sun and Δ ≈ 1.9 AU from Herschel (Table 1). HIFI’s submillimetre high-resolution heterodyne spectrometer is designed to have noise levels close to the quantum limit (de Graauw et al. 2010). The spectral resolution is 1.1 MHz and 140 KHz provided by the wide band spectrometer (WBS) and the high-resolution spectrometer (HRS), enabling HIFI to resolve spectrally cometary line shapes.

We present a summary of the HIFI observations in Table 1. These HIFI observations constitute the first detection of the 212–103 transition of ortho-water at 1669.9 GHz, and the 111–000 transition of para-water at 1113.3 GHz in cometary coma. In addition, the ground-state transition 101 transition of ortho-water at 556.936 GHz in comet C/2008 Q3 (Garradd) obtained by the HRS on July 20.94 UT in FSw mode. The velocity scale is given with respect to the comet rest frame. The dashed line shows a synthetic profile computed with the Monte Carlo model for isotropic outgassing at vₑxp = 0.55 km s⁻¹, T = 15 K, and xₒ = 0.2.

3. Data analysis

3.1. Water line emission

Figure 1 shows the spectrum of the 110–010 ortho-water line, corresponding to a long integration in frequency switching mode with a throw of 18 MHz. Here the signal-to-noise ratio is very high. This line is optically thick and slightly asymmetric due to self-absorption effects in the coma. From the width of the non-self-absorbed redshifted side of the line we obtain an estimate of 0.55 km s⁻¹ for the coma expansion velocity. Values in the range vₑxp = 0.5–0.8 km s⁻¹ are typical for relatively weak comets with total water production rate Qₜ₂,0 < 10²⁵ s⁻¹ at r₉ > 1.2 AU.

Figure 2 shows the water spectrum of the 111–000 para-water line at 1113.3 GHz observed in frequency switching mode. We averaged over two dates to increase the signal-to-noise ratio. The

The radial gas density profile for water was obtained using the standard spherically symmetric Haser distribution (Haiser 1957). The expansion velocity is assumed to be constant in the coma. We use a constant neutral gas kinetic temperature throughout the coma and the electron temperature profile given by Biver (1997) (see also Bensch & Bergin 2004). We assume an ortho-to-para water abundance ratio of 3 (see e.g., Crovisier et al. 1997). The few number of observed water lines, their non-simultaneity, and the different beam sizes for each line prevented us to derive useful constraints on the ortho-to-para ratio. Molecular data for ortho- and para-water have been obtained from the current version of the LAMDA database2 (Schöier et al. 2005).

The electron density profile is derived from the 1P/Halley in situ measurements scaled to the water production rate and heliocentric distance of comet C/2008 Q3 (Garradd) (Biver 1997; Bensch & Bergin 2004). A scaling factor to this electron density profile, $x_e$, is introduced as a free parameter to the model (Biver 1997). Observations of the 557 GHz line in comets with Odin have shown that the radial profiles of the line brightness are best explained with $x_e = 0.2$ (Biver et al. 2007). For the Monte Carlo code, the water-electron collision rates from Faure et al. (2004) are used.

Infrared pumping of vibrational bands by solar radiation contributes to the excitation in the outer coma where the gas and electron densities are low (Bockelée-Morvan 1987). We use the effective pumping rates for the lowest rotational levels of the ground vibrational state of ortho-water from Zakharov et al. (2007). Effective pumping rates for para-water were computed as described in Zakharov et al. (2007).

The relative level population of the lowest levels of para-water is shown in online Fig. 5. In the inner coma, frequent collisions between water molecules lead to a thermal equilibrium distribution, and electrons are cooled down close to the neutral gas temperature (e.g. Bensch & Bergin 2004). Given the beam sizes (between 17 000 and 51 000 km projected on the comet), molecules from the outer coma contribute to the detected emission. The line excitation in this region is dominated by water-electron collisions and infrared fluorescence.

Once the level populations are calculated, we solve the radiative transfer equation along different lines of sight through the comet atmosphere covering $2.5 \times \text{HPBW}$, and compute the beam averaged emission at the distance of the comet. By comparing to the observed line emission, we deduce the water production rate.

### 3.3. Water production rates

Mapping observations shown in Fig. 4 can be used to constrain the neutral gas kinetic temperature and the electron density scaling factor $x_e$. We constrained these model parameters by minimizing the radial variation of the water production rate deduced from the intensity at different offset positions. Hence, deviations from the Haser law due, e.g., to sublimating grains or structures induced by the rotation of the nucleus are not considered. We used the HRS data with the two orthogonal polarisations. We averaged radially the line intensity using bins of 10$''$ to 20$''$. In Fig. 6, we show the retrieved water production rate as a function of offset for an isotropic model with an expansion velocity $v_{\text{exp}} = 0.55 \text{ km s}^{-1}$, $T = 15 \text{ K}$, and $x_e = 0.2$ and 1. We found that a constant production rate is obtained for excitation parameters in the range $T = 15$–25 K and $x_e = 0.1$–0.2. The best-fit synthetic line profile computed using the Monte Carlo code

Fig. 6. Apparent water production rates as a function of offset deduced from the 557 GHz map shown in Fig. 4. Isotropic outgassing at $v_{\text{exp}} = 0.55$ km s$^{-1}$ is assumed. Results for $x_{\text{eq}} = 0.2$ and 1 are shown with black and red symbols, respectively. The dashed horizontal line shows the mean water production rate.

Fig. 7. 557-GHz line Doppler shift as a function of position offset for models considering isotropic outgassing (black line) and anisotropic outgassing concentrated in a $\pm130^\circ$ cone (red line). The blue squares indicate the observed line Doppler shift.

with $v_{\text{exp}} = 0.55$ km s$^{-1}$, $T = 15$ K, and $x_{\text{eq}} = 0.2$ is shown in Fig. 1. This model explains satisfactorily the observed line shape. A similar spectrum is obtained with the escape probability method. Both models differ by less than 5% in the calculated line intensities.

We also investigated an anisotropic model with the outgassing restricted to a $\pm130^\circ$ cone centered in the direction towards the Sun and expansion velocity of 0.60 km s$^{-1}$. The anisotropic model provides a better fit to the evolution of the line mean Doppler shift (Fig. 7). This suggests a day/night asymmetry in the comet outgassing which may affect production rate determinations.

The water production rates derived from different lines are in the range $1.7\sim2.8 \times 10^{28}$ s$^{-1}$. Those derived from the 1113 and 1669 GHz lines observed on the same day are consistent. A decrease of the comet activity from July 20.9 to 27.8 UT is suggested. However, this needs to be confirmed from a proper consideration of the outgassing asymmetry and possible pointing offsets related to the comet ephemeris.

4. Conclusions

The Herschel Space Observatory provides unique new capabilities for the detection of water in the Solar System. HIFI's spectral range and high resolution allowed for the direct detection of several water lines almost simultaneously. High spectral resolution is crucial to resolve the line shape and asymmetries due to self-absorption.

On 20–27 July 2009, comet C/2008 Q3 (Garradd) was observed with HIFI. The high-resolution spectra of HIFI allows us to detect for the first time several rotational water lines in cometary spectra. A water production rate of $\sim2 \times 10^{28}$ s$^{-1}$ was derived at heliocentric distance of 1.8 AU using radiative transfer numerical codes which include collisional effects and infrared fluorescence by solar radiation.

In future studies, HIFI will be able to detect water isotopes, and determine the D/H ratio in active comets.
