Detection of molecular gas in a distant submillimetre galaxy at $z = 4.76$ with Australia Telescope Compact Array

ABSTRACT

We have detected the CO(2–1) transition from the submillimetre galaxy (SMG) LESS J033229.4$-$275619 at $z = 4.755$ using the new Compact Array Broadband Backend system on the Australian Telescope Compact Array. These data have identified a massive gas reservoir available for star formation for the first time in an SMG at $z \sim 5$. We use the luminosity and velocity width (full width at half-maximum, FWHM, of $\sim 160 \text{ km s}^{-1}$) of the CO(2–1) line emission to constrain the gas and dynamical mass of $M_{\text{gas}} \sim 1.6 \times 10^{10} M_{\odot}$ and $M_{\text{dyn}}(\lesssim 2 \text{kpc}) \sim 5 \times 10^{10} (0.25/\sin^2 i) M_{\odot}$, respectively, similar to that observed for SMGs at lower redshifts of $z \sim 2$–4, although we note that our observed CO FWHM is a factor of $\sim 3$ narrower than typically seen in SMGs. Together with the stellar mass we estimate a total baryonic mass of $M_{\text{bary}} \sim 1 \times 10^{11} M_{\odot}$, consistent with the dynamical mass for this young galaxy within the uncertainties. Dynamical and baryonic mass limits of high-redshift galaxies are useful tests of galaxy formation models: using the known $z \sim 4$–5 SMGs as examples of massive baryonic systems, we find that their space density is consistent with that predicted by current galaxy formation models. In addition, these observations have helped to confirm that $z \sim 4$–5 SMGs possess the baryonic masses and gas consumption time-scales necessary to be the progenitors of the luminous old red galaxies seen at $z \sim 3$. Our results provide a preview of the science that ALMA will enable on the formation and evolution of the earliest massive galaxies in the Universe.

Key words: galaxies: evolution – galaxies: formation – galaxies: high-redshift – galaxies: individual: LESS J033229.4$-$275619 – submillimetre: galaxies.
1 INTRODUCTION

Blank field surveys at millimetre and submillimetre (submm) wavelength have uncovered a population of extremely luminous, highly optically obscured star-forming galaxies, so termed submm galaxies (SMGs; e.g. Smail, Ivison & Blain 1997; Barger et al. 1998; Hughes et al. 1998; Coppin et al. 2006; Weiß et al. 2009). SMGs are IR luminous ($L_{\text{IR}} \gtrsim 5 \times 10^{12} L_{\odot}$) and have high inferred star formation rates (SFRs) in excess of $1000 M_{\odot} \text{yr}^{-1}$, and the redshift distribution of radio-identified 850-μm selected SMGs (representing ≈60 per cent of the SMG population; e.g. Ivison et al. 2007) peaks at $z \sim 2.2$ (Chapman et al. 2005). There are indications that SMGs are strongly clustered (Webb et al. 2003; Blain et al. 2004; Weiß et al. 2009), while molecular gas observations of SMGs have demonstrated that they contain the massive compact gas reservoirs needed to form a luminous spheroid (Greve et al. 2005, hereafter G05; Tacconi et al. 2006, 2008, 2010). The combination of these properties makes them attractive candidate progenitors of today’s most massive elliptical galaxies (e.g. Lilly et al. 1999; Genzel et al. 2003; Swinbank et al. 2006).

While the bulk of SMGs lie at $z \sim 2$, recently the first examples of submm-selected SMGs at $z \sim 4$–5 have been uncovered (Capak et al. 2008; Schinnerer et al. 2008; Coppin et al. 2009, hereafter C09; Daddi et al. 2009a,b; Knudsen et al. 2010), reviving the potential worry that significant numbers of SMGs could lie at $z > 4$ and are missed from current spectroscopic surveys (e.g. Chapman et al. 2005; Pope et al. 2005). The presence of even a small number of galaxies at $z \gtrsim 4$ forming stars at a rate of $\sim 10^3 M_{\odot} \text{yr}^{-1}$ could pose a serious problem for current hierarchical models, which predict a $z > 4$ SMG surface density which is barely consistent with highly incomplete current observational estimates ($\sim 10^{-2}$; see C09). However, the galaxy luminosities are not robust predictions of the models, since they depend upon the adopted initial mass function (IMF) and dust properties (e.g. Swinbank et al. 2008). Much stronger and more reliable constraints on the models are provided by comparisons of the baryonic (gas+stars) and dynamical masses for these young galaxies (e.g. Genzel et al. 2003; Baugh et al. 2005, hereafter B05).

Here we report on the detection of CO(2–1) emission from a luminous SMG, LESS J033229.4–275619 (LESS J033229.4 hereafter), discovered in the deep 870-μm LABOCA ECDF-S Survey (LESS; Weiß et al. 2009). LESS J033229.4 has a deboosted 870-μm flux density of $5.1 \pm 1.4 \text{mJy} (4.6\sigma$ significance), a faint radio and mid-IR counterpart, and optical spectroscopic and photometric observations identifying it as an ultraluminous far-IR galaxy at $z = 4.76$ (C09). This is currently the highest redshift SMG known, suggesting that intense star formation was occurring in galaxies when the Universe was just over 1-Gyr old (see also Riechers et al. 2009).

We use observations of CO(2–1) to (i) confirm the counterpart identification and redshift of the source; (ii) to investigate the $L_{\text{CO}}$–$L_{\text{IR}}$ relation for SMGs at $z \sim 5$; (iii) to determine if $z > 4$ SMGs have the baryonic and gas consumption time-scales necessary to be the progenitors of luminous red galaxies found at $z \sim 3$ (Marchesini et al. 2007, 2009) and (iv) to derive a total baryonic mass for the system by combining our stellar and gas mass estimates, in order to test the B05 galaxy formation model. We adopt cosmological parameters of $\Omega_M = 0.73$, $\Omega_{\Lambda} = 0.27$, and $H_0 = 71 \text{km} \text{s}^{-1} \text{Mpc}^{-1}$. At $z = 4.76$, the angular scale is 6.5 kpc arcsec$^{-1}$, and the Universe is 1.3-Gyr old.

2 OBSERVATIONS AND DATA REDUCTION

The $^{12}\text{CO}(2–1)$ line ($v_{\text{rest}} = 230.538 \text{GHz}$) tracing cold molecular gas in LESS J033229.4 ($\alpha_{2000} = 03^h 32^m 29^s.30$, $\delta_{2000} = -27^\circ 56' 19''.40$) was observed in 2009 September over a period of six nights with the ATCA and CABB (Ferris & Wilson 2002). For improved ($u, v$)-coverage, we employed a combination of the two most sensitive and compact five-antenna hybrid configurations, H75 and H168. We utilized the maximum available CABB 2.048-GHz bandwidth (ensuring that the CO line of interest would lie well within the spectral window), with 2048 channels across the intermediate-frequency (IF) band, corresponding to a 1-MHz spectral resolution. Assuming a source redshift of $z = 4.762$, we tuned the 7-mm IF1 receiver to a central frequency of 40.010 GHz, resulting in a frequency coverage of 39.035–40.984 GHz, covering CO(2–1) emission between $z = 4.625$–$4.906$. The system temperature was 90–160 K over the observing run. Phase, amplitude and bandpass calibration were acquired by short observations of PKS 0402–362 every 10 min, with pointing performed on the same source every hour. Flux-density calibration was performed using short observations of Uranus each night (and Mars in one instance), the recommended standard ATCA calibrator source, and we estimate the calibration uncertainty to be $\lesssim 20$ per cent based on the currently available standard Miriad model for Uranus (Sault & Killeen 1999; see Emonts et al., in preparation).

The data were calibrated, mapped and analysed using the standard Miriad (Sault & Killeen 1999) and Karma (Gooch et al. 1996) packages. The corresponding synthesized beam adopting a natural weighting is $\sim 12 \times 9$ arcsec$^2$. Overall 35 hr of observations were obtained, including 25 hr of on-source integration time. The resultant $1\sigma$ rms channel noise in the 1-MHz-wide channel spectrum (corresponding to $\lesssim 7 \text{km} \text{s}^{-1}$) is $\approx 0.44 \text{mJy beam}^{-1}$, which is consistent with sensitivities reached by other 7-mm ATCA/CABB experiments (e.g. Emonts et al., in preparation).

3 OBSERVED MOLECULAR GAS PROPERTIES

Inspection of the combined data cube reveals the presence of a relatively narrow emission line near the phase centre, blueshifted by $\sim 400 \text{km} \text{s}^{-1}$ from the central frequency. To test the reality of the detection, we split the visibility data into two halves and find that the line persists in the data cubes at lower signal-to-noise ratio. To quantify the significance and parameters of the CO(2–1) line emission, the visibilities were resampled to a velocity resolution of 90 km s$^{-1}$ (chosen to yield optimal line signal-to-noise ratio), providing a 1$\sigma$ rms channel sensitivity of $\gtrsim 0.14 \text{mJy beam}^{-1}$, revealing a $\gtrsim 5\sigma$ detection (see Fig. 1), the brightest peak in the entire data cube with this binning. In Fig. 2, we plot contours of the emission for the line at the brightest 90 km s$^{-1}$ channel overlaid on a true-colour near-IR HAWK-I image of LESS J033229.4 from Zibetti et al. (in preparation). A Gaussian profile fit to the CO spectrum indicates a FWHM of $160 \pm 65 \text{km} \text{s}^{-1}$, and a velocity integrated line flux of $F_{\text{CO}(2-1)} = 0.09 \pm 0.02 \text{Jy km} \text{s}^{-1}$. The uncertainties on the CO line parameters have been estimated by rebinning the data cube to several different spectral channel resolutions from 50 to 200 km s$^{-1}$ and finding the $1\sigma$ spread of each parameter, which are comparable to the individual parameter fit uncertainties. We determine a best-fitting CO(2–1) redshift of $z = 4.755 \pm 0.001$, corresponding to an offset of $-370 \pm 30 \text{km} \text{s}^{-1}$ with respect to the optical redshift.
4.76 L105

Figure 1. CO(2–1) spectrum of LESS J033229.4 binned into 90 km s$^{-1}$ channels, extracted through the brightest pixel from Fig. 2, showing a $\pm 5\sigma$ line detection overlaid with a best-fitting Gaussian with an FWHM of 160 $\pm$ 65 km s$^{-1}$. The upper axis indicates the redshift of the CO(2–1) transition, from which the line fit indicates $z = 4.755 \pm 0.001$. The CO emission line is blueshifted by $\approx 370$ km s$^{-1}$ from the optical Ly$\alpha$ redshift (dotted vertical line and error bar) and consistent with a redshift of $z = 4.751 \pm 0.005$ derived from a VLT [O II] emission spectrum (Alaghband-Zadeh et al. in preparation). We have zoomed in on the central $\sim 5000$ km s$^{-1}$ of the spectrum for clarity, although for completeness we also show the entire 2-GHz wide spectrum as an inset.

Figure 2. CO(2–1) intensity contours of the line peak 90 km s$^{-1}$ wide channel in the ATCA spectrum overlaid on a true-colour ground-based HAWK-I JK image of LESS J033229.4. The CO(2–1) solid line contours begin at 2.5$\sigma$ and increase in steps of 0.5$\sigma$, where $\sigma = 0.14$ mJy (the channel rms). Equivalent negative contours are shown by dotted curves. The CO source appears to be spatially unresolved with the $\approx 12 \times 9$ arcsec$^2$ beam ($\approx 380 \times 60$ kpc FWHM, shown in the bottom right-hand corner). The CO centroid is consistent with the radio-identified optical V-band dropout counterpart of the SMG (encircled in green and featured as an inset in the top right-hand corner) within the $\lesssim 2.3$-arcsec positional uncertainty.

derived by Vanzella et al. (2006) of $z = 4.762 \pm 0.002$ determined from the asymmetric Ly$\alpha$ emission, N $\gamma$ and a continuum break (see C09). Note that this apparent redshifting of Ly$\alpha$ compared to the systemic redshift of the source (as measured from the nebular emission) is routinely seen in samples of 2 $\lesssim z \lesssim 3$ star-forming galaxies with offsets of $\Delta V_{LB} \approx 450$ km s$^{-1}$ compared to the systemic redshift (Steidel et al. 2010). The CO redshift also corresponds to the redshift of the [O II] emission at $z = 4.751 \pm 0.005$ from a VLT spectrum (Alaghband-Zadeh et al. in preparation). The CO detection provides definitive proof that the previously identified counterpart at $z = 4.76$ for this SMG is correct.

Averaging the remaining channels in the $\sim 1.6$-GHz (129-channel) line-free region of the spectrum reveals no significant continuum detection down to a 1$\sigma$ sensitivity of 0.013 mJy.

4 INFERRED GAS, DYNAMICAL AND TOTAL BARYONIC MASS OF THE SYSTEM

We calculate the line luminosity and the total cold gas mass (H$_2$+He) from the integrated CO(2–1) line flux following Solomon & Vanden Bout (2005), in order to determine the amount of available fuel for the current star formation episode. We find a line luminosity of $L_{CO(2–1)} = (2.0 \pm 0.4) \times 10^{40}$ K km s$^{-1}$ pc$^2$, where we then assume both that the gas is thermalized for the $J = 2$–1 transition [i.e. assuming a constant line temperature brightness ratio, $L_{CO(2–1)} = L_{CO(1–0)}$] and a CO-to-H$_2$ conversion factor of $\alpha = 0.8 M_\odot (K \text{ km s}^{-1} \text{pc}^2)^{-1}$ (which is appropriate for ultraluminous IR galaxies and SMGs; e.g. Downes & Solomon 1998; Tacconi et al. 2008), yielding a total cold gas mass of $M_{\text{gas}} = (1.6 \pm 0.3) \times 10^{10} M_\odot$. This CO(2–1) gas mass is comparable to that derived for SMGs from higher-$J$ transitions (typically $J = 3$–2 or $J = 4$–3). If LESS J033229.4 is a typical SMG, these CO $J = 2$–1 observations suggest that we are unlikely to be missing massive reservoirs of molecular gas around SMGs (see also e.g. Carilli et al. 2010; Ivison et al. 2010; cf. Hainline et al. 2006; Papadopoulos et al. 2010).

We calculate a dynamical mass of the system based on the observed CO(2–1) linewidth following Solomon & Vanden Bout (2005): $M_{\text{dyn}} \sin i = 233.5 \Delta V_{\text{FWHM}} R(M_\odot)$, where $i$ is the inclination of the gas disc, $\Delta V_{\text{FWHM}}$ is the CO FWHM (in km s$^{-1}$) and $R$ is the radius of the CO emitting region (in pc). As we do not have a direct constraint on the spatial extent of the CO emission from our unresolved detection, we assume that the CO traces the stellar light (as seems an appropriate assumption for $z \sim 2$ SMGs; Swinbank et al. 2010), which has a seeing-corrected FWHM of 0.5 $\pm$ 0.2 arcsec in the HAWK-I K-band imaging (or equivalently an FWHM $\approx 4$ kpc at $z = 4.76$). The best-fitting Gaussian FWHM of (160 $\pm 40$) km s$^{-1}$ implies a strict lower limit on the dynamical mass of $M_{\text{dyn}} < 2$ kpc $\sin i = (1.2 \pm 0.6) \times 10^{10} M_\odot$, assuming a 2-kpc radius. As we do not have any constraints on $i$, here we assume $i = 30^\circ$ (appropriate for randomly inclined discs in a sample of galaxies) and explicitly include the $i$ and $R$ dependency in our derived value: $M_{\text{dyn}} < 2$ kpc $\approx (4.8 \pm 2.4) \times 10^{10} (0.25/\sin i)/(R/2$ kpc) $M_\odot$. We caution that $M_{\text{dyn}}$ carries significant uncertainties which will require higher resolution observations to reduce. For instance, we note that the CO FWHM is a factor of $\sim 3$ narrower than typically observed for $z \sim 2$ SMGs (G05), although there are examples of SMGs and high-redshift Lyman-break galaxies with CO emission as narrow as our observed FWHM (e.g. Frayer et al. 1999; Baker et al. 2004; Coppin et al. 2007; Stanway et al. 2008). QSOs typically have narrower linewidths than SMGs by a factor of $\approx 2$–3, consistent with the optically selected QSOs being more closely inclined to the sky plane (showing its central AGN more clearly) than typical SMGs (G05; Carilli & Wang 2006; Coppin et al. 2008).

Thus the CO line narrowness of LESS J033229.4 (whose Hubble Space Telescope rest-frame UV compact morphology and strong N$\gamma$ emission indicate that it hosts an AGN; C09) compared with other SMGs could indicate that $i \approx 10^\circ$. Assuming that LESS J033229.4 is more face-on, adopting $i \geq 10^\circ$, yields $M_{\text{dyn}} < 2$ kpc $\approx (4.0 \pm 2.0) \times 10^{11} M_\odot$. However, the linewidth differences could also indicate that LESS J033229.4 is at a later stage of a merger or has
a different galaxy mass or size than typical $z \sim 2$ SMGs, which could be explored with high-resolution imaging of the gas distribution (e.g. G05; Carilli & Wang 2006). If instead we assume that the gas configuration is spherical (with a uniform distribution) rather than disc-like, then the implied enclosed dynamical mass would be $M_{\text{dyn}}(<2\text{kpc}) = (1.1 \pm 0.6) \times 10^{10} M_\odot$.

The combination of the gas and stellar mass estimates for LESS J033229.4 can be used to calculate the total baryonic mass of the system. The stellar mass of the system from C09 has been reconfirmed by Wardlow et al. (2010) to be $\lesssim 1 \times 10^{11} M_\odot$. Wardlow et al. (2010) has included the new HAWK-I J- and K-band photometry, and adjusted the derived mass for a Salpeter (1955) IMF for compatibility with the IMF assumed in deriving the SFR in Section 5.1. We caution that this quantity has an uncertainty of a factor of $\lesssim 5$ even before considering a potential AGN contribution to the rest-frame near-IR emission and so should be considered an approximate upper limit. Taken together, these estimates imply a total baryonic mass within 2 kpc of $M_{\text{gas}} + M_{\text{stars}} = 1.2 \pm 0.3 \times 10^{11} M_\odot \simeq 1 \times 10^{11} M_\odot$, which is consistent with the dynamical mass estimated above from the CO emission given the considerable uncertainties.

5 DISCUSSION AND CONCLUSIONS

5.1 $z \sim 4-5$ SMGs are higher redshift analogues of $z \sim 2$ SMGs

How representative is LESS J033229.4 of the few known $z \sim 4-5$ submm-selected sources and the more abundant $z \sim 2$ SMG population? Based on the photometric constraints for LESS J033229.4 which trace an SED consistent with local star formation dominated ULIRGs, C09 derive a dust mass of $M_d \sim 5 \times 10^9 M_\odot$ and a far-IR luminosity of $L_{\text{IR}} \simeq 6 \times 10^{12} L_\odot$, implying an SFR of $\gtrsim 1000 M_\odot$ yr$^{-1}$, close to the median luminosity of the $z \sim 2$ and $z > 4$ SMG populations (e.g. Kovács et al. 2006). When combined with our gas mass estimate, it follows that LESS J033229.4 has a star formation efficiency (SFE) of $\sim 250 L_\odot$ (K km s$^{-1}$ pc$^{-2}$)$^{-1}$, a gas-to-dynamical mass fraction of $f = M_{\text{gas}}/M_{\text{dyn}} \sim 0.3$ (sin $i/0.25$), and a gas-to-dust mass ratio of $\sim 30$. Assuming that the star formation follows the K-band light, we estimate a star formation surface density of $\Sigma_{\text{SFR}} \sim 100 M_\odot$ yr$^{-1}$ kpc$^{-2}$, which is similar to the intense central starburst mode inferred for SMGs at $z \sim 2$ (e.g. Smail et al. 2003).

The source properties of LESS J033229.4 derived from the CO line emission are very similar to those of the numerous SMGs at $z \sim 2$ ($M_{\text{gas}} \sim 3.0 \times 10^{10} M_\odot$, $M_{\text{dyn}} \sim 1.2 \times 10^{11} M_\odot$, $f \simeq 0.25$, with SFE $\sim 450 L_\odot$ (K km s$^{-1}$ pc$^{-2}$)$^{-1}$ and $M_{\text{gas}}/M_{\text{dust}} \sim 60$; G05; Kovács et al. 2006) and also the rarer emerging $z > 4$ SMGs (Schinnerer et al. 2008; Daddi et al. 2009a,b). Combining the CO-detected $z > 4$ SMGs, it follows that they lie within the scatter of the $L_{\text{IR}} - L_{\text{CO}}$ relation from G05 for $z \sim 2$ SMGs (assuming a constant line brightness ratio), with $z \sim 4-5$ SMGs spanning a range of $L_{\text{IR}} \sim 0.6-3 \times 10^{11} L_\odot$ and $L_{\text{CO}} \sim 2-6 \times 10^{10} K$ km s$^{-1}$ pc$^2$. It thus appears that within the $z \sim 1-5$ SMG population, $L_{\text{IR}}/L_{\text{CO}}$ is constant with redshift, indicating that SMGs at $z \sim 4-5$ are consistent with being higher redshift analogues of SMGs at $z \sim 2$, forming stars with similar efficiencies.

Overall this comparison suggests that SMGs at $z \sim 2$ and $z > 4$ are equally evolved, have similar reservoirs of gas, similar SFEs and similar fractions of baryons in cold gas as stars.

5.2 The potential descendents of $4 < z < 5$ SMGs

LESS J033229.4 appears to be a luminous massive starburst, forming stars at a rate of $\sim 1000 M_\odot$ yr$^{-1}$, with $M_{\text{dust}} \sim 1 \times 10^{11} M_\odot$, with properties representative of SMGs at $z \sim 2-4$. Its compact morphology and high SFR are potentially consistent with the small sizes of $\lesssim 1-2$ kpc claimed for a population of massive extremely dense old quiescent $z \sim 2$ galaxies (e.g. Daddi et al. 2005; Toft et al. 2007,2009; Zirm et al. 2007; Buitrago et al. 2008; Cimatti et al. 2008). Such compact dense galaxies at $z \sim 2$ have implied formation redshifts of $z \sim 4-5$ and are consistent with being the descendents of a population of gas-rich, highly dissipative mergers, such as $z > 4$ SMGs.

A critical question we can now address is whether LESS J033229.4 has the baryonic mass and gas consumption timescale necessary to be a ‘prototypical’ progenitor of the luminous ‘red and dead’ galaxy population at $z \sim 3$. The baryonic content of LESS J033229.4 is roughly equivalent to the typical stellar mass of a giant elliptical galaxy ($1 \times 10^{11} M_\odot$; Marchesini et al. 2009), given the large uncertainties in some of our mass estimates. Assuming that the molecular gas reservoir is fueling the star formation within LESS J033229.4, it will be able to sustain the current star formation episode for $\tau_{\text{depletion}} \sim M_{\text{gas}}/SFR \sim 1.6 \times 10^{10} M_\odot/1000 M_\odot$ yr$^{-1}$ $\sim 16$ Myr, assuming 100 per cent efficiency. We also compare $\tau_{\text{depletion}}$ with the time to form the current stellar mass of the system. At the current SFR, we estimate a formation time of $\sim M_{\text{gas}}/SFR \sim 1 \times 10^{11} M_\odot/1000 M_\odot$ yr$^{-1} \sim 100$ Myr, which is comparable to the assumed age of the stellar population and burst in the model used in C09. Although the gas consumption time-scale appears to be relatively short, it is similar to the gas depletion timescale of $\sim 100$ Myr for SMGs (e.g. Tacconi et al. 2008). It follows that we are catching this SMG approximately half way through its current star formation episode, with the majority of the galaxy mass already in the form of stars, representative of a major stage in galaxy formation. It thus seems plausible that LESS J033229.4 would display the observed properties of being ‘red and dead’ by $z \sim 3$, since the current stellar population would age another $1$ Gyr between $z = 4.76$ and 3, assuming that no further star formation occurs.

5.3 Observed mass constraints of $4 < z < 5$ SMGs on galaxy formation models

The presence of even the small observed (and likely still incomplete) volume density of the five $z \sim 4-5$ SMGs, $2 \times 10^{-7}$ Mpc$^{-3}$ (conservatively assuming a selection function that is uniformly sensitive across $z = 4-8$ due to the negative $K$-correction; e.g. Blain et al. 2002), poses a challenge to current hierarchical models (see C09). However, the prediction of submm fluxes from the models depends on the assumed IMF and dust properties in the galaxies, making a straightforward comparison between the observed and model SMGs fundamentally problematic. A much more straightforward and reliable test is provided by comparisons of the total baryonic (cold gas+stars) or dynamical masses for these young galaxies (e.g. Genzel et al. 2003), which we now investigate using the five CO-detected $z > 4$ SMGs, with a range of $M_{\text{dust}} \sim 1-3 \times 10^{11} M_\odot$ and $M_{\text{dyn}} \sim 0.5-9 \times 10^{11} M_\odot$. In Fig. 3 we compare the observational and theoretical cosmic volume density of galaxies with...
Figure 3. A comparison of the theoretical predictions and observational constraints of the cosmic comoving volume density of $M_{\text{bary}} \gtrsim 1 \times 10^{11} M_{\odot}$ galaxies, an approximate baryonic mass lower limit observed for the five CO-detected $z > 4$ SMGs discovered to date (the square is positioned at the mean redshift of the sample, and the horizontal line indicates the assumed redshift range $4 < z < 8$; see text). The solid curve represents galaxies from the B05 GALFORM semi-analytic model with $M_{\text{bary}} > 1 \times 10^{11} M_{\odot}$. The dashed curve represents the same mass cut from the model with an additional submm flux cut applied of $S_{\text{850}} > 3$ mJy (appropriate for our SMG sample), although this curve is difficult to compare directly with the observational constraints since the extraction of the submm fluxes from the model depends on the precise assumed IMF and dust properties of the model SMGs. Thus, the solid curve demonstrates that the detailed theoretical models are consistent with current observational constraints.

$M_{\text{bary}} \gtrsim 1 \times 10^{11} M_{\odot}$, using high-redshift SMGs as examples of massive baryonic galaxies with a uniform selection function out to $z \sim 8$. This exercise demonstrates in a less-biased way that the B05 semi-analytic GALFORM model is consistent with our current observed limits on the volume densities of $M_{\text{bary}} \gtrsim 1 \times 10^{11} M_{\odot}$ SMGs at $z > 4$.

These observations provide a view of a massive gas reservoir in a galaxy forming just 1 Gyr after the big bang, giving a sneak preview of the capabilities of ALMA for studying the formation and evolution of the earliest galaxies. However, statistically significant samples of spectroscopically confirmed SMGs are required to determine the true incidence of SMGs at $z > 4$, and far-IR and (sub)mm continuum surveys are first needed to identify large samples of SMGs that can become the targets of interferometric follow-up efforts as those described here. Deep multiwavelength near-IR imaging and sensitive (preferably) low J-transition CO mapping campaigns are necessary for deriving accurate stellar and gas masses, respectively: the key to determining the contribution of SMGs to the baryonic mass of the Universe at $z > 4$.
