ABSTRACT
We present smoothed particle hydrodynamic models of the interactions in the compact galaxy group, Stephan’s Quintet. This work is extension of the earlier collisionless N-body simulations of Renaud et al. in which the large-scale stellar morphology of the group was modelled with a series of galaxy–galaxy interactions in the simulations. Including thermohydrodynamic effects in this work, we further investigate the dynamical interaction history and evolution of the intergalactic gas of Stephan’s Quintet. The major features of the group, such as the extended tidal features and the group-wide shock, enabled us to constrain the models reasonably well, while trying to reproduce multiple features of the system. We found that reconstructing the two long tails extending from NGC 7319 towards NGC 7320c one after the other in two separate encounters is very difficult and unlikely, because the second encounter usually destroys or distorts the already-generated tidal structure. Our models suggest that the two long tails may be formed simultaneously from a single encounter between NGC 7319 and NGC 7320c, resulting in a thinner and denser inner tail than the outer one. The tails then also run parallel to each other as observed. The model results support the idea that the group-wide shock detected in multiwavelength observations between NGC 7319 and NGC 7318b and also the starburst region north of NGC 7318b are triggered by the high-speed collision between NGC 7318b and the intergalactic gas. Our models show that a gas bridge is formed by the high-speed collision and clouds in the bridge continue to interact for some tens of millions of years after the impact. This produces many small shocks in that region, resulting in a much longer cooling time than that of a single impact shock.

Key words: shock waves – methods: numerical – galaxies: evolution – galaxies: groups: individual: Stephan’s Quintet – galaxies: interactions – intergalactic medium.

1 INTRODUCTION
In investigating the evolution of an interacting galaxy system, multiwavelength observations and dynamical modelling are complementary. On the one hand, high-resolution observations in different wave bands reveal important physical quantities and information about various physical processes occurring in the system. By interpreting these quantities and the possible causes of the processes, we can learn about the dynamical state and deduce a plausible interaction history of the system. On the other hand, a well-constrained numerical model not only provides the direct testing of the plausible interactions and helps to interpret observational results, but it may also yield additional constraints or information such as the halo profiles of the system. Ever since Toomre & Toomre (1972) successfully simulated the stellar morphologies of several interacting galaxy pairs, explaining the formation of their peculiar structures, numerical simulations have become more popular and important means of studying interacting systems.

Compact groups (compact and relatively isolated systems of several galaxies) often show highly distorted features of interactions. Because of the dense environment, galaxy interactions occur more frequently in more complex ways in compact groups than binary...
systems. These groups are thus important environments for studying various interaction and merger effects and also the evolution of galaxies at higher redshifts where interactions are more frequent (e.g. Gottlöber, Klypin & Kravtsov 2001).

However, unlike binary systems where computer simulations have often been used to interpret observations, simulations for compact groups have not been frequently attempted, especially to model specific groups. Constraining models is much more difficult or sometimes not doable if the system has experienced multiple strong interactions involving multiple members and the structural or kinematical evidence of interactions has been largely erased.

For some special compact groups, however, numerical modelling is feasible. For example, if a system maintains characteristic tidal features or collisional ring structures, then it is possible to limit the plausible interactions to a few cases. The presence of recent interaction is also helpful, since there can be unique evidence preserved from the ‘young’ interaction. In addition, even though a group appears to have experienced multiple interactions, if each interaction involved mainly two galaxies rather than three or more members (i.e. a sequence of ‘two-at-a-time’ interactions), then modelling interpretations could be more tractable.

Stephan’s Quintet (hereafter SQ; also known as HCG 92, Arp 319 and VV 288; see Fig. 1), one of the first compact galaxy groups identified (Hickson 1982), has many of these properties. It shows strongly disturbed structural and kinematical features, such as extended tidal tails, disturbed arms and ring-like features, and rich intergalactic medium (IGM) with little gas remaining in the central region of every member galaxy (e.g. Sulentic et al. 2001; Williams

![Figure 1.](image-url)
H I gas observed in Stephan’s Quintet (from Williams, Yun & Verdes-Montenegro 2002; reproduced by permission of the AAS). Most of the gas is found outside of the galaxies, within five physically distinct components and in three discrete radial velocity bands. Three H I clouds, ‘Arc-N’, ‘Arc-S’ and ‘NW-HV’, are detected in the highest radial velocity band, 6475–6755 km s$^{-1}$. An H I cloud ‘NW-LV’ is found in the intermediate velocity band 5939–6068 km s$^{-1}$, and a diffuse H I feature ‘SW’ is detected in the low-velocity band 5597–5789 km s$^{-1}$.

et al. 2002; see Fig. 2). Moreover, the group is thought to be experiencing a high-speed collision between a member (NGC 7318b) and its IGM; multiwavelength observations, including radio continuum (e.g. Allen & Hartsuiker 1972; Xu et al. 2003) and X-rays (e.g. Trinchieri et al. 2003, 2005; see Fig. 3a), have consistently shown a huge elongated feature ($\sim 40$ kpc) in the IGM which has been widely interpreted as a shock front triggered by an ongoing or very recent collision.

More recently, Appleton et al. (2006) discovered strong almost pure-rotational H$_2$ line emission along the X-ray-emitting shock front. In follow-up observations (Cluver et al. 2010; see Fig. 3b), the line emission in the main shock region was detected over $\sim 480$ kpc$^2$ with a luminosity exceeding that of the X-rays from the shock. Guillard et al. (2009) modelled the H$_2$ excitation in a multiphased medium overrun by a high-speed shock caused by the intruder. These models, which dealt with H$_2$ formation and destruction, X-ray emission and the survival of dust grains in the shock, showed that the H$_2$ power seen in the Spitzer Space Telescope (Spitzer) observations could be explained in terms of the dissipation of mechanical energy through turbulence. Although these models involve a sophisticated treatment of the microphysics, this paper attempts to place this work in the context of the group dynamics as a whole. This coupling between the large-scale gas dynamics and the detailed astrophysics of the shocked regions provides a strong motivation for this study.

Given all these interesting features and observational constraints available from the literature, we have performed smoothed particle hydrodynamics (SPH) simulations of SQ, taking into account up to four strongly interacting members. Previously, two of us started modelling of this system with a purely gravitational N-body code and examined interaction history and large-scale stellar morphology (Renaud, Appleton & Xu 2010). [Hereafter we distinguish the previous work (code, models, etc.) with the term ‘N-body’; if not specified, the reference is to the current SPH code, models, etc.] In this paper, we extend the N-body work adding thermohydrodynamic effects to model the shocks. With new models, we further investigate the origins of the large-scale features and the dynamical evolution of the intergalactic gas of the system. In future work, we will examine the star formation history and future evolution of the group in more depth using SPH models.

In Section 2, we first briefly review the members and the large-scale features characterizing SQ and consider the group’s plausible interaction history and model constraints. Then we explain the simulation code and model details in Section 3 and present model results in Section 4. Finally, we summarize and discuss our main results in Section 5.

2 OVERVIEW OF SQ PROPERTIES AND MODEL CONSTRAINTS

2.1 The members and the large-scale features

The optical morphology of SQ is presented in Fig. 1. By apparent proximity, SQ traditionally denotes the group of five galaxies,
NGC 7317, NGC 7318a, NGC 7318b, NGC 7319 and NGC 7320. However, NGC 7320 is a foreground galaxy which has a considerably smaller redshift than others (Burbidge & Burbidge 1961) without any indications of interactions with the group. Actually, NGC 7320c, located far east of NGC 7319, is considered to be linked to the group, particularly to NGC 7319. As we conduct numerical modelling of SQ, we treat the five physically related galaxies, excluding NGC 7320 and adding NGC 7320c, as the members of the quintet.

SQ is a relatively close (\(\sim 94\) Mpc away, assuming a Hubble constant of \(70\) km s\(^{-1}\) Mpc\(^{-1}\) and a systemic velocity of \(6600\) km s\(^{-1}\) for the group; Appleton et al. 2006) and isolated system among the Hickson compact groups (HCGs). Four members, NGC 7317, NGC 7318a, NGC 7319 and NGC 7320c, have a similar recession velocity of \(\sim 6600\) km s\(^{-1}\). In contrast, NGC 7318b has a lower recession velocity than the others by \(\sim 900\) km s\(^{-1}\); this galaxy (‘high-speed intruder’) is thought to be coming towards us with the large relative velocity, having collided with the material placed between NGC 7319 and NGC 7318a and triggered the group-wide shock shown in Fig. 3.

The large spiral galaxy NGC 7319, whose nucleus is known to be a Seyfert 2 (Durret 1994), has a strong central bar, disturbed arms and two long tails (hereafter the parallel tails, or the inner and outer tails; see Fig. 1). Both inner and outer tails appear in the optical to extend from NGC 7319 towards NGC 7320c, a small spiral or ringed galaxy. The outer tail is seen in the south of the inner tail, although the outer one is harder to see as it is more diffuse and passes behind the foreground galaxy NGC 7320, running nearly parallel to the inner one. The inner tail, which is optically brighter than the outer one, is active in star formation. Many tidal dwarf galaxy candidates have been found along the inner tail (e.g. Hunsberger, Charlton & Zaritsky 1996), including ‘SQ-B’ marked in the figure. Star formation activity in the outer tail has not been well studied because the foreground galaxy blocks a large portion of the tail. In ultraviolet (UV), the inner tail is far more extended towards north than in optical and shows a loop-like structure (Xu et al. 2005).

To the west of NGC 7319, a pair of galaxies NGC 7318a/b is seen with complex features around them, including ‘SQ-A’, ‘SW-arm’ (Fig. 1). NGC 7318b, the high-speed intruder, has barred spiral morphology and its optical core looks relatively intact (in contrast, its interstellar medium (ISM) has been well removed as shown in Fig. 2). NGC 7318a is the most difficult member for type determination. Even whether it is an elliptical or a spiral is unclear, due to the complex features around the pair. Most of the features are thought to be related to NGC 7318b; however, some of the arm-like structures might be associated with NGC 7318a (e.g. Shostak, Sullivan & Allen 1984). On the other hand, the photometric data of NGC 7318a show a smooth light distribution like an elliptical (Moles, Márquez & Sulentic 1998). The galaxy is listed as an E2.P in the Third Reference Catalogue of Bright Galaxies (RC3; de Vaucouleurs et al. 1991). It was also classified as Sc (Hickson, Kindl & Auman 1989) and SB0 (Hickson 1994). Features in the north of the pair appear to cross each other, and near the crossing a starburst region SQ-A has been found (Xu et al. 1999), together with many young (<10 Myr) star cluster candidates (SCCs) over a large area (Fedotov et al. 2011). The feature SW-arm looks like a tidal tail, and some H\(\alpha\) clumps between NGC 7318a and NGC 7317 (e.g. Xu et al. 1999) might be related to SW-arm.

The fifth galaxy NGC 7317 is located to the south-west of the pair NGC 7318a/b. This elliptical member does not show direct signs of interaction with others (thus we do not include the galaxy in the models). However, the diffuse optical and X-ray haloes lying over the regions of NGC 7318a/b and NGC 7317 (e.g. Moles et al. 1998) indicate that the galaxy is a member of the group.

The neutral hydrogen distribution of the system is very interesting. As shown in Fig. 2, a Very Large Array (VLA) H\(\alpha\) observation (Williams et al. 2002) found most of the gas outside optical boundaries of the members, within five distinct components (‘Arc-N’, ‘Arc-S’, ‘NW-HV’, ‘NW-LV’ and ‘SW’) and in three discrete radial velocity bands (6475–6755, 5939–6068 and 5597–5789 km s\(^{-1}\)); with a Hubble constant of \(75\) km s\(^{-1}\) Mpc\(^{-1}\); and a recessional motion of \(6480\) km s\(^{-1}\) for the centre of mass of the quartet NGC 7317, NGC 7318a/b and NGC 7319). The gas with the highest radial velocity (6475–6755 km s\(^{-1}\)) is detected in two large arc-like clouds (Arc-N and Arc-S) tracing the optical inner and outer tails (see fig. 6 of Williams et al. 2002 for the view of each arc-like cloud separately) and in a relatively compact cloud (NW-HV) centred near SQ-A. Another kinematically distinct cloud (NW-LV) centred near SQ-A is observed in the intermediate velocity band (5939–6068 km s\(^{-1}\)); this cloud coincides with the high-velocity cloud but is more extended (see figs 8 and 9 of Williams et al. 2002 to see NW-HV and NW-LV separately). The low-velocity (5597–5789 km s\(^{-1}\)) gas is found between NGC 7318a/b and NGC 7317 in a diffuse feature (SW).

The shock seen in X-rays in the central region of SQ is shown in Fig. 3(a; cyan), as a narrow elongated feature in the IGM between NGC 7319 and NGC 7318b. As noted earlier, it is widely accepted that the hot X-ray-emitting gas in the elongated feature has resulted from the shock-heating triggered by the present-day high-speed collision between NGC 7318b and the IGM. The fact that the main shock occurs in a region where the cold neutral hydrogen is missing also supports this idea.

The white contours in Fig. 3(b) represent the 0–0 S(1) 17-\(\mu\)m rotational H\(_2\) line emission detected in the central area of the group (see also figs 2 and 3 of Cluver et al. 2010). The strong line emission in north–south direction (‘main shock’) follows the X-ray-emitting shock shown in Fig. 3(a); strong line emission also comes from the starburst region SQ-A and from the region associated with the active galaxy NGC 7319. There is another H\(_2\) structure (‘H\(_2\) bridge’) which runs eastwards from the main shock. The structure is also discernible in the X-ray emission. Overall, the warm molecular gas shows a distribution similar to that of the hot X-ray-emitting gas. The line luminosity of the H\(_2\) in the main shock was measured to be about three times stronger than the X-ray luminosity from the hot shocked gas, implying that H\(_2\) lines are a stronger coolant than X-ray emission (Cluver et al. 2010).

H\(\alpha\) emission in the central region of the group has also been detected, with two different components of the emission, \(\sim 5700\) km s\(^{-1}\) (which is in the velocity range of the high-speed intruder) and \(\sim 6600\) km s\(^{-1}\) (Xu et al. 1999; see also Xu et al. 2003). It is shown that the shock feature appears in the 6600 km s\(^{-1}\) component, but not in the 5700 km s\(^{-1}\) component; this indicates that the shock front is associated with the 6600 km s\(^{-1}\) component.

### 2.2 Interaction history and model constraints

The parallel tails associated with NGC 7319 are one of the most characteristic features resulting from past interactions in the group. Based on the shape and probable age of each tail, three different formation scenarios of the tails have been considered: (A) both tails could be generated simultaneously by an encounter of NGC 7320c with NGC 7319 (Moles, Sulentic & Márquez 1997), (B) the outer and inner tails might be produced one after the other in at least
two passages of NGC 7320c around NGC 7319 (Moles et al. 1997; Sulentic et al. 2001), and (C) the outer tail might be produced by an encounter of NGC 7320c with NGC 7319 and then the inner tail by a different encounter of NGC 7318a with NGC 7319 (Xu et al. 2005).

Scenario A implies the same formation ages for both tails; a bridge and a counter tail of NGC 7319 which were supposed to be pulled out after a closest approach of NGC 7320c could later develop into the inner and outer tails, respectively. The outer tail, however, has often been interpreted to be ‘older’ (formed earlier) than the inner tail as it is optically fainter and broader than the inner one, so this scenario has not been favoured over the other two where the outer tail formed earlier. Recently, Fedotov et al. (2011) suggested that the inner and outer tails would be formed \( \lesssim 200 \) Myr and \( \sim 400 \) Myr ago, respectively, by the age determination of the SCCs. However, we note that although the northern inner tail appears to contain more recent star formation than the southern outer tail, this does not preclude the possibility that the two were formed together but suffered different star formation histories (because the outer tail is more farther out, i.e. more spread out or in a lower density environment). Moreover, the age determination of the outer tail is estimated by the clusters in only one part of the tail (inevitably, a part which is well away from the foreground galaxy) and that of the inner tail is based on the blue clusters (but it also contains some old clusters with an age of \( \sim 500 \) Myr as well; Fedotov et al. 2011). We also note that the age determination of the outer tail versus the inner tail is based on a systematic shift in \( B_{188} \sim V_{606} \) colour of 0.1 mag between the two sets of clusters (Fedotov et al. 2011) which could potentially result from differences in extinction between the two regions (as the authors point out, such extinction would have to be a uniform screen since the points in both clusters are quite well clustered around their respective means – but the proximity of the foreground galaxy to the ‘old’ tail makes this at least plausible). Thus, we consider the formation of both tails together to not be completely ruled out by observations, and is still a plausible hypothesis. Further observational work will be needed to confirm a strong age difference between the two tails.

Scenario B considers common origins, but at different times, for both tails. It suggests that an earlier passage of NGC 7320c would produce the outer tail and then the recent passage (considering a bound orbit of NGC 7320c) would produce the inner tail, because both of the optical parallel tails point to NGC 7320c but the more diffuse outer tail might be formed earlier. Until about a decade ago, the radial velocity difference between NGC 7319 and NGC 7320c had been (incorrectly) thought to be \( \sim 700 \) km s\(^{-1}\). So, assuming a fast encounter, Moles et al. (1997) estimated that the recent encounter might have occurred as recently as \( 1.5 \times 10^8 \) yr ago and an earlier encounter at \( 5 \times 10^8 \) yr ago or earlier. However, later measurements of the radial velocity of NGC 7320c came out to be nearly equal to that of NGC 7319 (e.g. Sulentic et al. 2001), which implies the recent encounter would be slow rather than fast (assuming that the difference between the transverse velocities of the two galaxies is comparable to that between the radial velocities). It is thus argued that if NGC 7320c had encountered NGC 7319 producing the inner tail and moved to its current position then, with a slow passage, it would take at least \( 5 \times 10^8 \) yr (Xu et al. 2005), which is much older than the previously estimated age of the inner tail but close to that of the outer tail.

In scenario C the outer tail also formed earlier than the inner tail, as in the second scenario. The two scenarios agree on the origin of the outer tail, but not on that of the inner tail. As a solution to some of the problems raised in the second scenario regarding the age and non-optical morphology of the inner tail (e.g. the UV inner tail is extended towards north rather than points NGC 7320c as mentioned in Section 2.1), scenario C suggests that an encounter of NGC 7318a might generate a tidal tail looking like the UV inner tail, and the estimated age of the inner tail by the encounter would then be about three times younger than that produced by NGC 7320c, due to the shorter distance between NGC 7318a and NGC 7319 than between NGC 7320c and NGC 7319 (Xu et al. 2005).

As described above, the origins of the inner and outer tails are not yet clearly understood. However, no matter how the parallel tails have been generated, NGC 7319 would have undergone one or more strong prograde encounters to have pulled two substantial tails out of the disc. The system appears to be strongly disturbed during the interaction, as most of gas in NGC 7319 (and the other involved galaxies) has been stripped off and huge amount of gas put into the parallel tails (Fig. 2).

At the time when the parallel tails were produced, NGC 7318b (the high-speed intruder) is thought to be far behind the rest of the group and not to be involved in the generation of the tails (e.g. Moles et al. 1997). The galaxy seems to enter the group in the relatively recent past and is currently passing through the material that has been placed west of NGC 7319 with the large relative radial velocity \( \sim 900 \) km s\(^{-1}\) triggering the group-wide shock.

There have been some arguments about whether or not NGC 7318b had interacted with the group (most likely with NGC 7318a) between after the production of the parallel tails and before the current collision. The optical core of the high-speed intruder looks still intact, which leads to the idea that the galaxy might be entering the group for the first time (Moles et al. 1997; Sulentic et al. 2001). However, the gas disc of NGC 7318b has already been well stripped and some tail-like and ring-like features are seen around the pair NGC 7318a/b; these suggest that NGC 7318b had interacted before (perhaps undergone a partial head-on collision with NGC 7318a), because the removal of outer discs and the development of tidal features occur after the closest encounter (Williams et al. 2002; see also Xu et al. 2005).

It is very difficult to understand clearly the origins of each of the features around the pair NGC 7318a/b, due to the complex interaction involving the high-speed intruder, perhaps multiple interactions from the (relatively recent) past through the present; the features might be influenced by some hydrodynamical effects and/or tidal effects. In particular, the features in the eastern side of the high-speed intruder would require more careful interpretations as the arms of the high-speed intruder and the main shock are very close.

The extra-nucleus starburst region SQ-A may be influenced by some hydrodynamical processes due to the current high-speed collision, because according to He data the star formation in the region occurs not only in the ISM of the high-speed intruder but also in the IGM, \( 6600 \) km s\(^{-1}\) component, and the \( 6600 \) km s\(^{-1}\) component would not be detected if SQ-A is triggered by tidal effects (Xu et al. 2003). It is worth noting that SQ-A lies nearly at the northern end of the shock ridge seen in radio continuum, and at the southern end there is also a star-forming region (i.e. ‘7318b-south’ in Cluver et al. 2010) but in the ridge itself shows little star formation (e.g. Xu et al. 2003; Cluver et al. 2010). Our models can, in principle, address the question of whether the existence of two major star formation complexes at either end of the shock structure is a coincidence or whether they are regions which, unlike the main shock, have less turbulent conditions more conducive to the onset of star formation.
3 NUMERICAL MODELS

We have constructed an SPH code for numerical simulations of SQ. As mentioned earlier, before this hydrodynamic modelling, two of us used an N-body code, based on primarily the NEMO stellar dynamics package (Teuben 1995), and performed about 3000 exploratory runs to test various interaction hypotheses and examined the gravitational aspects of the group (see Renaud et al. 2010 for details). In this new SPH modelling, all of the relatively successful N-body models have been re-tested and some additional ideas of interactions have been tried. We ran about 170 simulations with the SPH code. In this section, we first explain the details of the SPH code and then describe our models including the modelling strategies and the differences among the models.

3.1 The SPH code

The SPH code used in this work has been produced by modifying the SPH code of Struck (1997), which was originally designed for studying collisions between two disc galaxies (see Struck 1997 for details), so that the code can be applied to systems with more than two galaxies. In the SPH code for SQ, four strongly interacting members NGC 7318a/b, NGC 7319 and NGC 7320c have been considered, excluding NGC 7317 (and the unrelated foreground galaxy NGC 7320), since we simulate the group from the generation of the parallel tails to the near future, and when the effect of NGC 7317 on the group is considered to be small (e.g. Moles et al. 1997; Fedotov et al. 2011). It is also because we do not have observational constraints to include the galaxy into the simulations.

Each model galaxy consists of discs containing gas and collisionless star particles and a rigid dark matter halo. The elliptical looking member NGC 7318a is also initialized with discs, but we adjust some initial parameters (such as decreasing the angular and increasing the random velocities of its test particles) to model it as an elliptical galaxy.

In the SPH code, hydrodynamical forces are calculated with a spline kernel on a grid. A constant smoothing length and fixed unit cells in a grid are used. Local self-gravity is calculated between gas particles in adjacent cells. A standard artificial viscosity formulation and a simple leapfrog integration method are used. The large-scale dynamics of interactions are simulated with a restricted three-body approximation. The specific form of the halo acceleration of a particle is

\[ a = \frac{GM_\text{h}}{\epsilon^2 \left(1 + r^2/\epsilon^2 \right)^{3/2}}, \]

where \( M_\text{h} \) is a halo mass scale, \( \epsilon \) is a core radius and the index \( n_\text{h} \) specifies the compactness of the halo.

Simple treatments of heating and cooling are included for gas particles using an adiabatic equation of state. (For pressure calculation, adiabatic equation of state was assumed. Heating and cooling were calculated separately. Constant cooling time-scales were used in three temperature ranges as described in Struck 1997.) Star formation is assumed to occur when the local gas density exceeds a constant threshold density and the gas temperature goes below another constant threshold temperature. The density and temperature thresholds are arbitrary and can be normalized to give realistic star formation rate for the system. Dynamical friction is not included for the current models. We will add the effects of dynamical friction in the future runs, with which we will study SQ’s future evolution.

The code uses the non-inertial reference frame of a ‘primary’ galaxy. (The model galaxy for NGC 7319 has been chosen to be the primary.) All masses and lengths in the code are scaled to the halo mass-scale (\( M_\text{h} \) in equation 1) and the core radius (\( \epsilon \) in equation 1) in the halo potential of the primary galaxy. There is a characteristic sound speed in the code, which is used as a unit velocity. These code units are dimensionless and have been converted into the physical units after simulations.

There are fixed spatial boundaries imposed in the code. The boundaries are large enough to include almost all particles but not too large for efficient computing performance. A few distant particles reach the boundaries and are excluded from the simulations in most runs.

3.2 Model differences and initial conditions

Most of our simulations run from just before the production of the parallel tails to shortly after the current high-speed collision. We divided the modelling efforts into three major stages, each with a specific goal: (1) to reproduce the inner and outer tails accurately, stripping much of gas off the involved members; (2) to test the occurrence of any intermediate interaction before the present, especially between the high-speed intruder and NGC 7318a; and (3) to make a high-speed present-day collision between NGC 7318b and the IGM of the group. (These three stages do not have strict boundaries and can overlap; they are more like conceptual categories, although several interactions in the group do indeed seem to occur sequentially.) We will henceforth refer to the model galaxies for NGC 7319, NGC 7318a, NGC 7318b (the high-speed intruder) and 7320c as G1, G2, G3 and G4, respectively (from the most massive model galaxy to the least massive one) to avoid the confusion between the model galaxies and the real ones.

Various interactions have been attempted at each stage. In particular, we spent more time in the first stage, trying many different models, than the other two, in order to generate the two tidal tails (which are supposed to develop as the parallel tails) in the correct configuration out of the disc of G1. The parallel tails are one of the most distinctive features resulting from the past interactions in the group, so a good model of SQ should be able to reproduce them, and the outcome of the first stage would directly affect the interactions in the later stages. The models attempting to reproduce the parallel tails in the first stage were evaluated depending on how reasonably they reproduced the two tails, and those models that successfully generated the tails were evolved further. Once we had any complete model that reproduced the overall morphology of the system relatively well throughout the entire stages, we then made several similar models changing the values of a few model parameters and ran them again to determine how the models are affected by particular parameter values.

We tried a number of models to produce the parallel tails as suggested in both scenarios A (with one encounter of G4) and C (with an encounter of G4 and then an encounter of G2), but not in scenario B (with at least two encounters of G4) as the previous N-body simulations (which included the effects of dynamical friction; Renaud et al. 2010) already found that scenario B does not work properly. (We will hereafter describe complete models as ‘models A’ or ‘models C’ depending on which model scenario is referred to for the production of the inner and outer tails.) The reason why the N-body models with scenario B failed was that after one tail (the outer tail) had been produced by the earlier encounter, G4 had to encounter G1 again very closely to be able to generate another tail (the inner tail), but then G4 could not leave G1 far enough towards its current position (actually, G4 collapsed into the larger member...
G1 in most cases) due to the strong gravitational attraction and the dynamical friction.

In the N-body simulations, one of models C was chosen as the best model in reproducing the general stellar morphology of SQ. In the SPH simulations, however, models A came out generally better than models C. The differences between the N-body and the SPH modelling are primarily because of the different halo potentials used in each simulation code and, in addition, our models are evaluated on the basis of not only the stellar but also the gas features. We will explain more about models A and C, including the advantages and disadvantages of each type, in the next section when we present the model results.

We conclude this subsection by stating initial parameters used in one of our best model A runs (the fiducial model). Many details of the fiducial model are summarized in Table 1. The values in the table were derived from observational data or modelling experiences with many trials. Those values are presented in physical units. To scale the SPH code, the length and velocity code units have been converted into 1.0 kpc and 5.0 km s$^{-1}$ in all models, then the time code unit becomes 200 Myr. The mass code unit, which is the halo mass-scale $M_h$ for G1 (see equation 1), has been scaled to $4.7 \times 10^{10} M_\odot$ in most models including the fiducial model; $M_h$ for G2, G3 and G4 relative to that of G1 have been chosen to be 0.78, 0.62 and 0.22, respectively. Note that $\epsilon$ and $\eta_h$ in equation (1) for all members have been set to 1.0 kpc and 1.4 in the fiducial model. There has been a halo cut-off radius assigned to each member in the fiducial model as 135 kpc (G1), 55 kpc (G2), 80 kpc (G3) and 45 kpc (G4), which is five times larger than either the gas disc radius (for G1, G3 and G4) or star disc radius (for G2, which has been set with a smaller gas disc than its star disc). The halo mass, with the given potential (equation 1), for each member out to the cut-off radius, in the unit of $10^{10} M_\odot$, is 12.6 (G1), 8.2 (G2), 7.1 (G3) and 2.4 (G4). No group halo has been assigned. The initial gas disc of each member in the model, from G1 to G4 in order, were set to 27, 8, 16 and 9 kpc, and the initial stellar disc to 18, 11, 11 and 7 kpc. So, the stellar and gas disc sizes of the least massive member G4 were chosen to be about one-third of those of the most massive member G1. G2 and G3 were selected to be comparable in mass and stellar disc size, but not in gas disc size. G2 was set to have smaller gas disc with much fewer gas particles compared to G3. In all models, all galaxies were initialized in the x−y plane (which was chosen to be equivalent to the plane of the sky) with disc spins in either clockwise or counterclockwise directions, and then rotated around any of the three orthogonal axes as necessary. In the fiducial model, G1 and G4 were set with counterclockwise directional spins, while G2 and G3 with clockwise directional spins. All members in the fiducial model were not tilted in any direction. (The members may not be all exactly face-on, but tilts were ignored in the fiducial model; different tilts particularly for G3, the high-speed intruder, were tested in several similar models to the fiducial model for comparison.)

4 SIMULATION RESULTS

In this section, we present the results of our models. We first describe the general evolution of the fiducial model, as a representative for models A, focusing on the generations of the large-scale structural features in the system. Then, we compare our models A to models C, discussing the advantages and disadvantages of the models. Finally, we analyse the gas properties of the fiducial model and compare with observations.

4.1 Evolution of the fiducial model

The fiducial model is designed first to generate the inner and outer tails simultaneously by a close encounter of G4 with G1 (as suggested in scenario A in Section 2.2), then in the second stage to have a collision between G2 and G3 relatively far behind the plane of G1, and finally in the third stage to make a high-speed collision between G3 and the material found west of G1 (see Section 3.2 for the description of the modelling stages). The initial parameters

The given halo mass is that contained within a halo cut-off radius. Gas and star disc masses are negligible in this model; see the text.

Physical units are used in this table. Conversion from code units is described in the text.

In this model, the halo cut-off radii for G1, G3 and G4 are set to five times their gas disc radii, for G2, five times its star disc radius. No group halo is applied.

All galaxy discs are initialized in the x−y plane with counterclockwise directional spins as seen from the positive z-axis and then rotated as necessary. In this model, G1 and G4 are set in the x−y plane with counterclockwise directional spins, and G2 and G3 are flipped around the z-axis so that they have clockwise directional spins. No additional tilts are applied in this model.

Coordinates are defined in a conventional, right-handed frame, with the origin fixed at the centre of the primary, G1. The x−y plane is defined as the plane of the sky, and positive z as the direction towards the observer.

Positive z-velocities mean motions towards us in the non-inertial reference frame of G1.
Figure 4. The trajectories of the four model galaxies in the fiducial model. The left, middle and right panels show the trajectories projected on to the x–y plane (i.e. plane of the sky), the x–z plane and the y–z plane, respectively. Red, green, blue and cyan are used to represent the centre positions of the halo potentials of G1, G2, G3 and G4, respectively. G1 is fixed at the origin (marked with a red plus sign) throughout the simulation. Near the initial positions of the other three members (see also Table 1), the model galaxy names (G2, G3 and G4) are indicated. Little knots marked in the orbital trajectories of G2, G3 and G4 represent the positions of the model galaxies at every 0.4 time unit (∼80 Myr in the representative scaling). The closest approach between G1 and G4 is indicated with a cyan line. The axes are marked in code length units (∼1 kpc in the representative scaling).

and the subsequent orbits of the model galaxies are presented in Table 1 (and also in Section 3.2) and Fig. 4, respectively. The distributions of star and gas particles of the model galaxies at four times are shown in Figs 5 and 6, respectively. (See also Fig. 7 for a better view of the gas distribution from the model near the present, displaying it in three discrete velocity bands separately.)

As mentioned earlier, we use the coordinate system that moves with the halo centre of G1 (the most massive and largest member in the model), so the galaxy appears fixed at the origin throughout the simulations and set the x–y plane as the plane of the sky. The discs in the fiducial model initialize with star and gas particles as described in Table 1. The adopted scaling is 1 kpc for the length unit, 5 km s\(^{-1}\) for the velocity unit, and 200 Myr for the time unit in all models. Note, however, that this (representative) scaling is not unique and can be scaled, e.g. with the total system mass.

The fiducial simulation starts shortly before G4 makes its closest approach to G1. As shown in Fig. 4, G4 starts south-west of G1 seen in the sky plane, swings closely around G1 in a counterclockwise direction and moves towards east. Seen from the sides, G4 starts slightly above G1, turns quickly around G1 (penetrating G1) going downwards, and then slows in the vertical (z) direction as it moves towards east. On the other hand, G2 starts far from G1 and moves towards west going deeper behind G1. (This orbit of G2 has been chosen in such a way that G2 has little to no effect on the development of the parallel tails, which were supposed to be generated by an encounter of G4 with G1, staying relatively far from both tails until they grow well, and then G2 can encounter with G3 well below the plane of G1.) G3, the high-speed intruder, has been started far below all the others, set to move nearly vertically (in z-axis) towards the rest of the group, meet with G2 on its way up, and then pass through between G1 and G2 at a high speed.

The top rows of Figs 5 and 6 show the early development of the inner and outer tails, in the x–y view (left panels) and the x–z view (right panels), at about \(t = 1.95\) units or 390 Myr (in the representative scaling) after the closest encounter of G4 with G1. (We measure time from the instant of the closest approach between G1 and G4 throughout this paper for convenience; the start of the model is at about \(-1.0\) in code time units. As we noted earlier, the scaling is not unique, and there could be up to a factor of 2 or so change possible in the scaling.) By this time, G4 has swung around G1 in a counterclockwise direction passing through the large disc of G1 from front to behind and has pulled two massive arms (a bridge and a counter-arm) out of the disc of G1. Since the initial disc spin of G1 was also set in counterclockwise direction (Table 1), G1 experiences the encounter as prograde. (For the initial disc spin of G4, we have tried in both counterclockwise and clockwise directions. With the counterclockwise spin, as in the fiducial model, G4 also experiences the encounter as prograde. In this case, much more gas is scattered to the northeast than the other case; with sensitive enough observations, this could be used to determine whether G4 experienced the collision as prograde or retrograde.) The early encounter of G1 and G4 in this model is somewhat similar to that between M51 and NGC 5195 proposed by Toomre & Toomre (1972) in their numerical model. In our model, however, the small companion G4 directly contacts the larger member G1, bringing stronger tidal damage to both galaxies. As seen in the first snapshots in the two figures, both galaxies have strongly been disturbed by the collisional encounter; many test particles of the galaxies have been stripped off or transferred to the other galaxy. In general, gas tends to be affected more by an encounter than the stars. As a related difference, many more gas particles from G4 than star particles are seen to be captured by G1 (compare the top row of Fig. 5 with that of Fig. 6). The accreted gas in the central region of G1 during the encounter might play a role in the development of G1 as an active galaxy (as NGC 7319 is known to have found a type 2 Seyfert nucleus).

The two arms drawn out of G1 continue to grow through the time shown in the second rows of both figures 5 and 6 (\(t = 670\) Myr), forming a parallel configuration. As intended in this model, G2 does not distort the tails while they develop since it stays far from them; meanwhile, G3 continues to approach the group. At the instant of the second snapshots, G3 is about to collide with G2 at \(z \sim -70\) kpc in the adopted scaling. Here G2 is placed slightly to the west (the positive x-direction) of G3 at the onset of the collision. This is intended to make a partial head-on collision between G2 and G3, and to stabilize the orbit of G3 between G1 and G2, keeping G3 from being attracted too much towards G1 afterwards, even though the effect would be small because of the high z-speed of G3. Note that we are not completely certain whether the collision between G2 and G3 does in fact occur (and in the manner described in the model). We attempt the collision in the second stage in the model.
Figure 5. Four snapshots from the fiducial model of star particles projected on to the $x$–$y$ plane (left-hand column) and the $x$–$z$ plane (right-hand column). In all panels, particles originating from G1, G2, G3 and G4 are plotted with red, green, blue and cyan dots, respectively (the red dots were plotted at first and then green, blue and cyan dots in order). The orbital trajectories (Fig. 4) of the members are overlaid in the same colours used for the particles. Time indicated in the left-hand panel of each row is measured from the closest approach between G1 and G4. In the left-hand panel of the first row, the star particles of G2 and G3 are not displayed in order to show the bridge and counter-tail pulled out of G1 shortly after the encounter with G4 more clearly (instead, the centre positions of G2 and G3 are indicated by crosses). In the right-hand panel of the top row, G3 is not shown as it is at $z \sim -163$. The second row is at the onset of the collision between G2 and G3. The third and bottom rows are at times near the present, when G3 passes the mid-plane of the disc of G1, colliding with the particles placed between G1 and G2, and when G3 has passed through the plane of G1, respectively.
Figure 6. Four snapshots from the fiducial model of gas particles projected on to the $x$–$y$ plane (left-hand column) and the $x$–$z$ plane (right-hand column). These snapshots are taken at the same times as those in Fig. 5, showing the distribution of gas particles. Colours are used in the same ways as in Fig. 5 (red for G1, green for G2, blue for G3 and cyan for G4). In the left-hand panel of the first row, the gas particles of G2 and G3 are not displayed in order to show the early configuration of the bridge and counter-tail pulled out of G1 from the encounter with G4 more clearly (instead, the centre positions of G2 and G3 are indicated by crosses). In the right-hand panel of the top row, G3 is not shown as it is at $z \sim -163$. The second row is at the onset of the collision between G2 and G3. The third and bottom rows are at times near the present. At the time of the third row, G3 passes the mid-plane of the disc of G1, making a strong impact colliding with many gas particles west of G1. By the time of the bottom row, G3 has passed through the plane of G1 above $\sim 65$ kpc; still a number of gas particles are seen between G1 and G3 (in the $x$–$z$ view) forming a gas bridge.
based on the interpretation (described in Section 2.2) that some of the disturbed features observed around the pair NGC 7318a/b could be the result of the earlier interaction between the two galaxies. It is thought that some features, such as SW-arm and stripped gas of G3, might have tidal origin that requires some time (a few 100 Myr) to develop to the presently observed state.

The third and bottom rows of both Figs 5 and 6 show the model system at the times near present, when the high-speed intruder is passing the mid-plane of G1 colliding mainly with the outer tail and some other particles placed west of G1 ($t = 900$ Myr $\equiv t_3$; between shortly before the present and the present) and when the intruder has passed the mid-plane of G1 after the strong impact ($t = 1080$ Myr $\equiv t_4$; between the present and shortly after the present), respectively. Since G3 collided with G2 earlier, it has been evolving tidal structures. G3 in this model develops moderate tidal tails by the onset of the current collision, so the disc and the eastern tidal arm pulled out of it both hit the IGM at a high speed (the $z$-velocities of the model galaxies will be discussed in Section 4.3).

The morphology of the model at $t_3 - t_4$ looks generally similar to that of SQ. First, the positions of the four model galaxies projected on to the $x$-$y$ plane are close to those observed. The parallel tails also look similar to the observed features. Note that even though the inner and outer tails in the model were generated simultaneously, the inner tail appears stronger than the outer tail in stellar features. Some of the features around NGC 7318a/b were generated very roughly in the model. The two tails drawn out of G3 (by the collision with G2) do not match with the real optical features very well. However, the tail extracted from the eastern side of the disc looks similar to the feature SW-arm, although the curvature and orientation are not quite right. A feature like SQ-A is produced in the north of G3; the feature began to be formed just after the impact and has

---

**Figure 7.** Gas particles of the fiducial model at $t = 1080$ Myr in three $v_r$ ranges. The top to bottom rows show the gas particles in high-, intermediate- and low-$v_r$ ranges (see the text how to divide the three ranges). The left- and right-hand columns show the gas particles projected on to the $x$-$y$ and $x$-$z$ planes, respectively. Red, green, blue and cyan dots represent the particles originating from G1, G2, G3 and G4, respectively (red dots are plotted first and then green, blue and cyan in order; the dots are expressed smaller in this figure than those in Fig. 6). The centre position of G1 is indicated by a plus sign and those of G2, G3 and G4 with crosses.
grown with time (it is quite small at $t_1$, but larger at $t_2$; see also Fig. 7). Note that a gas bridge is formed (seen in the bottom right panel of Fig. 6) after the strong impact of G3 with the IGM. (We use the term ‘gas bridge’ for the gas feature running mainly in the north–south direction formed in the shock region between G1 and G3 and distinguish it from ‘H$_2$ bridge’ which indicates specifically the thin dusty bridge running in the east–west direction shown in Fig. 3b.) We will discuss and compare the gas structure further in Section 4.3.

4.2 Models A versus models C

The fiducial model described above is one of the models of type A (which are designed to generate the inner and outer tails simultaneously by an encounter of G4 with G1 as suggested in scenario A in Section 2.2). The observations of the inner and outer tails in SQ suggest a younger age of the inner tail than the outer tail (e.g. Fedotov et al. 2011). We thought in the beginning of this work that models C (which intend to generate the outer tail first by an earlier encounter of G4 with G1 and then the inner tail by the recent encounter of G2 with G1 as suggested in scenario C) would be more appropriate for the system. However, as we proceeded with the simulations, we found difficulties with models of type C.

First, reconstructing two long tails one after another in a good configuration following scenario C was much more complicated than we expected. In such models, producing the outer tail first from G1 by an encounter of G4 and letting G4 leave towards east (to its current position) are easy, however, because the scenario assumes that the inner tail is formed sufficiently later than the outer tail, G2 has to encounter G1 closely (to produce the inner tail) after the previously generated outer tail has already been grown. Then, even though G2 could manage to pull the inner tail out of the already disturbed G1, creating a relatively good configuration with the outer tail, G2 at the same time strongly distorts the outer tail. This ‘dilemma’ (G2 has to pass G1 closely to produce the inner tail but then it also destroys the outer tail) occurred in the earlier $N$-body models as well, so a very inclined orbit of G2 with which G2 would not disturb the outer tail was used (see Renaud et al. 2010 for details). We applied the similar orbits for G2 in models C, but the effect of G2 on the outer tail was still too strong because of the extended halo potentials used in the SPH code (equation 1). To decrease the effect of G2 on the outer tail, we tried particularly smaller cut-offs for the halo potentials of the model galaxies; the effect was still not eliminated. (We cut off each halo potential at 2–3 times the maximum initial disc extent for models C, and 5 or more times that for models A.)

Another disadvantage of models C is that it is difficult to adjust the orbit of G2 after it encounters G1 to best fit later developments. We prefer to place G2 relatively far below in the second stage so it collides with G3 (like in the fiducial model) and so G3 has time to develop tidal features (assuming that some features of NGC 7318b have tidal origins). However, when G2 is placed on an inclined orbit to make the inner tail without destroying the outer tail in the first stage, it is difficult to put G2 sufficiently far down in the second stage and then let G2 slow down in its vertical motion (in $z$-axis) in the third stage (as it should have a small $z$-speed relative to G1 near the present). In addition, apart from the possibility of the collision between G2 and G3 well below the plane of G1, it is difficult to evolve sufficiently many particles to the western side of G1 to be hit and shocked by G3 in the third stage in these models.

Models of type C do have some advantages. One is that the observed gas distribution near the parallel tails could also generally be well reproduced. Another is that a transient feature like the observed H$_2$ bridge could be relatively well generated by the encounter of G2 with G1 in models C. We, however, have not tried to optimize models C as thoroughly as with models A. Thus, although they do not look promising, we cannot entirely rule out the models of scenario C.

4.3 Gas properties

We first compare the kinematical and structural features of gas formed in the fiducial model at $t_4$ (the time of the bottom rows of Figs 5 and 6) to the H$_1$ features observed in three different velocity ranges (Fig. 2; Williams et al. 2002). At that time, the $z$-velocities of the centres of the model galaxies G2, G3 and G4 (relative to G1) are $-3.6, 64.7$ and $-3.3$ in code units, respectively. (G3 has much higher $z$-velocity than the others; however, its relative $z$-speed is not yet comparable to the observed value ($\sim$900 km s$^{-1}$) with the representative scaling. We found that other models with different $z$-velocities for G3, ranging from slightly lower to twice higher than that in the fiducial model, have similar results as long as G3 has a much higher $z$-velocity than the others.) We will hereafter use ‘$v_z$’ for the $z$-velocity of a test particle in the non-inertial reference frame of G1 (used in all SPH models), and ‘$v_r$’ for either an observed radial velocity or the velocity of a test particle expressed as the radial velocity. To compare with the H$_1$ features in each $v_r$ range, we roughly divide the gas particles from the model with $v_r$ into three ranges (Fig. 7): $v_r < 20$ (high-$v_r$), $20 \leq v_r < 55$ (intermediate-$v_r$) and $v_r \geq 55$ (low-$v_r$). ($v_r = 0$ for test particles means the particles have the same $z$-velocities to that of the centre of G1; positive/negative values of $v_r$ indicate motions towards/away from us relative to G1. While for the observed H$_1$ gas, $v_r$ values less/greater than that of NGC 7319 ($\sim$6600 km s$^{-1}$) mean motions towards/away from us relative to NGC 7319). In contrast to the H$_1$ observation, where almost no gas was detected in the central regions of all members, our models (both types of models A and C) did not remove most of the gas from the members. (Specifically, the percentage of the gas particles of G1 remaining within the initial stellar disc radius of G1 at $t_4$ is 39 per cent in number of particles; similarly, the percentages of the remaining gas particles of G2, G3 and G4 are about 96, 45 and 49 per cent, respectively.) However, some other structural features of gas were reproduced relatively successfully in the fiducial model, as described in the following paragraphs. It is yet unclear why the galaxies contain no H$_1$ within them. Some members appear to be of quite early type, and might have lost their gas long before the recent encounters. The case of NGC 7319 is more mysterious. Perhaps the bar has funnelled much gas to the centre. Unveiling the origins of the H$_1$ deficiency in the members is one of the problems that we need to keep investigating.

As shown in the top row of Fig. 7, the gas corresponding to the high-$v_r$ range consists of particles originating mostly from G1, G2 and G4 (which have a similar high radial velocity) as expected (note that G2 was initially set with the smallest number of gas particles as indicated in Table 1). A few particles originating from the high-speed intruder G3 (3.5 per cent of G3 gas particles) which are captured by the others or scattered into the intergalactic space are in this $v_r$ range. Many high-$v_r$ gas particles are found between G1 and G4, tracing the stellar parallel tails (shown in the bottom row of Fig. 5). These groups of gas particles in the model look quite similar to the two huge arc-like H$_1$ clouds observed along the optical inner and outer tails in high-$v_r$ range (Arc-N and Arc-S in Fig. 2, respectively). Arc-S extends well beyond the southern tip of the optical outer tail, and the gas feature formed in the model
along the outer tail extends farther than the corresponding stellar feature. Arc-N curves towards north (as the UV inner tail; see Section 2) rather than towards NGC 7320c. In the model, many gas particles distributed along the inner tail seem to be curved towards G4; however, there is a trail of gas curved far to the north like the observed cloud Arc-N. Another notable high-\(v_r\) gas feature is seen in the top-left panel of the figure, at west of G1 and north of G3. We interpret this gas as the compact high-\(v_r\) H\(_i\) cloud (NW-HV) detected near SQ-A, although the model feature should be separated more from both G1 and G3. (We tried to refine the feature in some similar models by using different values of \(v_r\) and/or tilt for G3. However, with the limited resolution, the feature did not come out noticeably differently.)

Gas particles in the intermediate-\(v_r\) range (middle row of Fig. 7) appear mostly at north of G3 (left panel). Most of these gas particles have come from either G1 (35 per cent) or G3 (63 per cent) (note that the percentages vary depending on the criteria for dividing the \(v_r\) ranges; it is also affected by the number of gas particles set for each member). The observed intermediate-\(v_r\) H\(_i\) cloud (NW-LV) coincides with the high-\(v_r\) cloud (NW-HV) near SQ-A, but is more extended. The intermediate-\(v_r\) gas particles in the model are distributed over a larger area than the high-\(v_r\) gas particles at north of G3.

The gas particles in the low-\(v_r\) range are presented in the bottom row of the figure. Almost all (99 per cent) of the particles originate from G3 (87 per cent of G3 gas particles are in this range). The H\(_i\) observation found low-\(v_r\) gas in south of NGC 7318a/b diffusely distributed (the feature SW in Fig. 2), and no gas in the central area of NGC 7318b. As pointed out earlier, in contrast to observations, many gas particles in the model remain in the G3 disc and the spiral features look somewhat different. However, some of the particles found south of G3 appear more or less similar to the diffuse H\(_i\) gas.

Next, we briefly describe the hot gas distribution from the fiducial model when G3 hits the IGM. The particles shown in the top panel of Fig. 8 are those of hot gas (which is more like H\(_X\) gas than hot X-ray gas) exceeding a certain (arbitrarily chosen) common temperature cut-off, in the high-\(v_r\) range at \(t_h\) (about 17 per cent of the total gas particles have higher temperatures than the cut-off at the time, and it decreases to about 6.6 per cent at about 0.35 time unit (70 Myr) before and after \(t_h\) with the same cut-off). In the bottom panel of the figure, we display the star-forming gas particles of the model at \(t_h\) to compare the distribution of the hot gas to that of the star-forming gas. Even though the model results in the figure are too rough to be able to specifically compare to observations, due to the simplified treatment of heating and cooling in our code, we can see an elongated feature of hot gas particles (top panel), with little star formation in the area of the elongated feature (bottom panel). This implies that the elongated feature in the model would be heated by the collision with G3 rather than by star formation, in agreement with the observations. The model does not provide any insights into the structure and formation mechanisms of two major star formation complexes at either end of the shock structure.

In Fig. 9, we show the average of the internal energy of the shock-heated gas particles in the fiducial model with respect to time (black solid line). For the internal energy per particle, we include all of the gas particles of G1 and G3 which appear near the shock and the gas bridge formed shortly after the strong impact of G3 with the IGM in the fiducial model. Specifically, the particles within the region of \(0 \leq x \leq 30, -40 \leq y \leq 10\) and \(10 \leq z \leq 30\) at \(t = 5.0\) (1 Gyr in the representative scaling) in code units were chosen. The centre position of G3 at the time is about \(x = 17, y = -20\) and \(z = 40\). To compare to the fiducial run, we built a similar model, setting no gas particles for G3 and keeping all the other parameters of the fiducial model. The average internal energy of the gas particles of G1 that appear within the same region at the same time in the comparison model is also presented in the figure (red dashed line). (In the fiducial model, a total of 2779 gas particles, 1447 from G1 + 1332 from G3, met the above selection criteria. While in the comparison model, 170 gas particles of G1 met the same criteria. For the internal energies per particle represented in the y-axis in the figure, these 2779 and 170 gas particles are considered in the fiducial and comparison models, respectively.) In both models, G3 collides with the IGM at about \(t = 4.45\), which corresponds to 890 Myr in the adopted scaling. (G3 in these models collides first with G2 at about \(t = 3.38, 700\) Myr.) As expected, a strong peak occurs in the fiducial model but not in the comparison model during the impact, when G3 hits the outer tail and some other stripped materials west of G1. In the fiducial model, the average internal energy of the gas particles in the shock region decreases rather slowly after the impact, showing a nearly power-law form as might be expected from decaying turbulence in the interacting flows. We checked the trajectories of some of the gas particles (clouds) and found that many of the particles’ trajectories in the gas bridge in the fiducial model were redirected by collisions with other particles, after G3 has already passed through the plane of G1, for tens of millions of years. This amounts to decaying turbulence with many small shocks of various strengths in that region and we think that it can account for the observed emission without much star formation. The time-scale is much longer than the cooling time of a single impact shock (e.g. Guilland et al. 2009), and so makes...
it easier to understand how we happen to see a phenomenon that would otherwise be extremely short-lived.

5 SUMMARY AND DISCUSSION

Motivated by the disturbed structure of SQ, including the remarkable group-wide shock seen at the IGM between NGC 7319 and 7318b, and using published high-quality observations for the system in various wavebands, we have attempted to model the interaction history and the evolution of the large-scale structure of the group.

Despite the complex interactions expected in the compact group, some of its major features allow us to constrain the models reasonably well. First, the appearance of the parallel tails provides important clues to track how they were formed, narrowing down the possibilities to encounters of NGC 7320c and/or NGC 7318a with NGC 7319. In addition, the fact that such delicate tidal features extend large distances onwards justifies the supposition that members might not pass close to the tails after they were produced, otherwise they would have been destroyed or greatly modified. Some of the other complex disturbed features around the pair NGC 7318a/b, such as the tail-like feature SW-arm and the stripped gas disc of the high-speed intruder, suggest that NGC 7318b might have interacted with NGC 7318a earlier. At present, it is known from many observations that the high-speed intruder, NGC 7318b, has hit the IGM giving rise to the large-scale shock.

The interactions described above seem to take place one after another, involving mainly two members at a time, which simplifies the modelling. Thus, we divided each of our models in three major stages and simulated a series of plausible interactions in order. In the first stage, we tried a collision between NGC 7319 and NGC 7320c to produce both of the parallel tails simultaneously in models (models A), or via an encounter between NGC 7319 and NGC 7320c to generate the outer tail first and then an encounter between NGC 7319 and 7318a to pull out the inner tail later (models C). Then, in the second stage, we attempted an interaction between NGC 7318a and 7318b of varying intensity, and in the final stage a collision between NGC 7318b and the IGM.

Models A were generally more successful than models C. Even though generating the parallel tails one by one from two different interactions seems conceptually reasonable, in models C it turned out to be very difficult to pull another substantial tail (the inner tail) in a second close encounter, while at the same time preserving the outer tail. This latter encounter usually destroyed the outer tail in models with extended halo potentials, and with very limited halos it still disturbed the outer tail, yielding a poor tail morphology. On the other hand, a single strong encounter, as in models A, could generate two substantial tails nicely with different stellar intensity.

We note that the fact that the two tails do not have the same star formation history does not have to mean that they were not born in the same tidal event.

In the fiducial model (one of the best models of type A), the inner and outer tails are generated simultaneously by an encounter of NGC 7320c, and the high-speed intruder experiences an earlier collision with NGC 7318a, the galaxy slightly to its west, below the plane of NGC 7319. This early collision induces spiral waves in the intruder, one of which later collides with the outer tail and the IGM.

We think that the fiducial model is generally successful in reproducing the large-scale morphology and kinematics of SQ. Specifically, the current relative positions (projected on to the sky plane) and relative radial velocities of the members, the long parallel tails with thinner and brighter inner tails in the stellar feature, the huge amount of high-\(v_r\) gas along both the parallel tails, the features looking like SW-arm and SQ-A, the high- and intermediate-\(v_r\) gas to north of the high-speed intruder and some scattered low-\(v_r\) gas to the south-west of the high-speed intruder that were produced in the model resemble more or less the real features. However, the detailed inner structures of the spiral members, the many disturbed structural features around NGC 7318a/b, and the gas removal from each disc (which may also have resulted from the earlier interactions than the start of our simulations) were not reproduced in our models. The location of SQ-A and the orientation of SW-arm in the model do not match the observations well either. The gas temperature and star formation history of our models are not accurate enough for detailed comparison to observations. The shortcomings of the models are the result of limited resolution and the approximate treatments of heating and cooling in the current code. None the less, the model shows the shock-heated gas, by the impact of the high-speed intruder with the IGM, in an elongated feature with little star formation. A gas bridge is formed in the shock region and particles in the bridge continue to interact for some tens of millions of years after the impact. Dynamical friction has been neglected in this work. Though the effect would not change our main results, it becomes particularly significant for modelling the future of the system.

Finally, we note some general implications of this work. Constructing numerical models of a compact group could be very difficult as the system might have experienced multiple interactions. However, if a group possesses very extended features, the model could be relatively well constrained. This is because not only do the rich features provide important clues to the formation, developing and maintaining these delicate extended features also could eliminate the possibilities of strong interactions occurring in the vicinity.
of the features after the production. We found a very interesting result in SQ, with collisions occurring mostly two-at-a-time. This result may be general (although it is not necessarily so), because flyby or the final merger together time would be short compared to the total orbital time.

SQ appears to be unusual in the population of compact groups in that the system possesses prominent, extended features and the intruder seems to be actively colliding with previously known tidal material. This might be due to the unique interaction history of the system or result from the short time-scale during which such features can be observed. SQ seems to exhibit a wide variety of galaxy interaction indicators, ranging from clear stellar and gaseous tidal features to group-wide shock structures. This kind of diversity may be special to the compact group environment, but SQ may be a snapshot in time of what many compact groups may go through if we wait long enough. The question of how commonly powerful shocks are found in the compact group environment is being explored by a major Spitzer survey of HCGs by Cluver et al. (in preparation). We expect that our main result can be extended to other similar groups in studying the evolutionary histories or finding initial conditions of collisions. Detailed numerical studies on more compact groups would also help to better understand the evolution of high-redshift galaxies.
