In this work we study the effect of thin-film deposition on the quality factor (Q) of silicon nanobeam cavities. We observe an average increase in the in Q of 38 ± 31% in one sample and investigate the dependence of this increase on the initial nanobeam hole sizes. We note that this process can be used to modify cavities that have larger than optimal hole sizes following fabrication. Additionally, the technique allows the tuning of the cavity mode wavelength and the incorporation of new materials, without significantly degrading Q. © 2012 Optical Society of America

1. MOTIVATION

Photonic crystal (PC) cavities provide exciting platforms for photonics applications in addition to fundamental cavity quantum electrodynamics (cQED) experiments. The ability to fabricate cavities with small mode volumes (V) and large Qs leads to large enhancements in light–matter interactions. By placing active emitters such as quantum dots (QDs) into the cavity, it is easy to observe Purcell enhancement of spontaneous emission with only modest Qs. Increasing the Q further leads to the quantum regime of strong coupling, in which energy is able to coherently transfer between the emitter and cavity multiple times before decaying. This regime leads to exciting new physics, such as the Jaynes–Cummings ladder, deterministic single-photon sources, and photon blockades [1–3].

In addition to a high Q and low V, it is important that the cavity and emitter be near resonance with each other. Previous work has shown the ability to reversibly tune cavity resonances by 5 nm using the condensation of gases at low temperatures [4]. Additionally, tuning of 2D photonic crystal systems has been shown using atomic layer deposition (ALD) of hafnium oxide [5] and titanium oxide [6] and plasma-enhanced chemical vapor deposition of silicon nitride [7]. In this work, we observe a shift in cavity resonance of 20 to 29 nm, with a high tuning precision as a result of the multiple-cycle deposition process.

Finally, it is important that one can incorporate an active medium with the cavity. While this can be achieved with QDs and quantum wells in III–V systems, it presents more of a challenge for silicon photonics. In this work, we show the ability to deposit new material on top of a silicon PC cavity with a minimal effect on the Q. This opens up the possibility of incorporating active materials through similar methods. For example, one can dope AlO3 with layers of erbium during the deposition process [8].

2. NANOBEAM CAVITIES

One PC cavity geometry that is becoming popular is the 1D nanobeam, shown in Fig. 1. This design consists of a strip waveguide with an array of etched holes. The holes begin with uniform radius and spacing, creating a Bragg mirror region. The hole radius and spacing are then tapered down to a cavity region where the mode is confined, before tapering back up to another mirror region. The holes confine the light along one dimension, while it is confined by index guiding along the other two. The substrate can be etched from underneath the cavity, leaving it suspended, or in the case of this work, the cavity can remain on the substrate for increased durability. Simulations of unsuspended cavities predict Qs as high as 366,000 with a mode volume of 0.552(λ/n)3. Experimentally, suspended silicon nanobeam cavities have already been measured with Qs of 360,000 [9].

In this work, nanobeams are fabricated on silicon-on-insulator wafers, consisting of a 220 nm silicon layer on top of a 2 μm SiO2 layer. The structure is defined using electron beam lithography and formed using inductively coupled
plasma etching. Each nanobeam is characterized by a lattice constant \(a\), which is the distance between the center of the holes in the mirror region. The value of \(a\) varies from 590 to 455 nm in 5 nm steps, shifting the cavity mode through the range of our measurement ability. In the taper region, the lattice constant varies from 0.98\(a\) to 0.86\(a\), while in the cavity region, the lattice constant is 0.84\(a\). The nominal hole radius is 0.3 times the local lattice constant.

3. CHARACTERIZATION BY MEASUREMENT OF THE CAVITY QUALITY FACTOR \(Q\)

In order to characterize the \(Q\) of silicon nanobeam cavities, we use the tapered microfiber probe technique \([10,11]\). In this technique, an optical fiber is heated and stretched, such that it adiabatically tapers to a region with a diameter on the order of 1 \(\mu\)m. This region of the fiber is then carefully positioned across the nanobeam cavity. A tunable narrowband laser source is coupled into one end of the fiber, and the transmitted power is detected at the other end. As the laser source is tuned into resonance with the cavity, some of the power is coupled into the cavity mode, resulting in a measurable dip in transmission through the fiber.

As a result of the tapered microfiber probe, the cavity experiences an additional amount of loss. This causes an increase in the measured resonance linewidth and thus a decrease in the measured \(Q\) compared to the intrinsic \(Q\) of the cavity. This effect was studied in \([10]\), which found that by positioning the probe near the edge of the nanobeam, coupling to the cavity is minimized, leading to a measured \(Q\) closer to the intrinsic \(Q\). For this study, all \(Q\)s are measured at the edge of the nanobeam cavity. Because of the positioning uncertainty of the probe, which leads to slight changes in the coupling and hence the measured \(Q\), five measurements are taken of each cavity; the maximum value is used for all comparisons.

To determine the intrinsic \(Q\) of a cavity, we use the crossed polarizer resonant scattering technique \([10,12]\). This is a free space method in which a tunable laser source is focused onto the cavity with a microscope objective. The incident light is polarized at 45° with respect to the polarization of the cavity mode. The reflected light is passed through a polarizer at 90° relative to the incident light. Light that simply reflects from the substrate will be blocked by the crossed polarizer. Light that couples into the cavity will scatter out with the polarization of the cavity mode, a portion of which will be able to pass through the final polarizer and be detected. Because of the increased difficulty and low signal-to-noise ratio of this measurement, this technique is used only to determine the intrinsic \(Q\) of the best cavities.

4. ATOMIC LAYER DEPOSITION

Atomic layer deposition is a thin-film deposition process that works through the sequential application of two or more gas phase chemicals. The growth takes place as a chemical reaction at the sample surfaces. The reaction is self-limiting, allowing accurate control of film thickness simply by counting the number of cycles.

Because of the nature of this deposition technique, the resulting film is conformal and grows along the surface normal \([13]\). This effect has already been utilized to grow microlens arrays \([14]\) and planarized optical gratings \([15]\) and to tune photonic crystal waveguides \([7,16]\). The conformal film also reduces surface roughness, and ALD-grown \(\text{Al}_2\text{O}_3\) and \(\text{TiO}_2\) films have been found to significantly reduce propagation losses in silicon strip and slot waveguides \([13,17]\). Because the geometry of the silicon nanobeam cavity is a modified silicon strip waveguide, we believe that this process could lead to decreased losses and higher \(Q\)s in these structures.

For this work, we investigated the thin-film growth of both \(\text{TiO}_2\) and \(\text{Al}_2\text{O}_3\) on nanobeam cavities by ALD. \(\text{TiO}_2\) is deposited at 120 °C using a process with titanium tetrachloride (\(\text{TiCl}_4\)) and water as precursors \([18]\). \(\text{Al}_2\text{O}_3\) is deposited at 200 °C using a process with trimethylaluminum (\(\text{Al}_2(\text{CH}_3)_3\)) and water as precursors \([19]\). Figure 2 shows scanning electron micrograph (SEM) images of a cavity before and after the deposition of 20 nm of \(\text{Al}_2\text{O}_3\), showing a clear reduction in hole size due to the thin film.

5. EXPERIMENTAL RESULTS

For initial tests, two nanobeam samples were fabricated using the same design parameters. They were first characterized using the tapered microfiber technique. While imaging the
cavities, it was noticed that there was residual mask material remaining from fabrication. This material was removed using a 10 min O$_2$ plasma etch. The cavities were recharacterized, and it was noted that the cavity wavelength decreased by 6.5 nm on average, but there was no significant change in cavity $Q$. One sample was then coated with 20 nm of TiO$_2$ (index 2.27 at $\lambda = 1.55$ $\mu$m), while the other was coated with 20 nm of Al$_2$O$_3$ (index 1.62 at $\lambda = 1.55$ $\mu$m). The samples were characterized again, following the same procedure. The TiO$_2$ (Al$_2$O$_3$) coated sample showed a shift in cavity mode of 59.2 $\pm$ 0.7(30.3 $\pm$ 0.8) nm on average. The results of the $Q$ measurements are plotted in Fig. 3. While one TiO$_2$ coated cavity showed an increase in $Q$ of 25%, the average change in $Q$ over all cavities was $-1.3 \pm 16\%$. Every Al$_2$O$_3$ coated cavity showed an increase in $Q$, with an average increase of 38 $\pm$ 31% and a maximum increase of 124%. The large standard deviation for this sample mostly results from 2 of the 19 cavities, which showed an increase of more than 100%. Figure 4 shows a measurement of a cavity from the Al$_2$O$_3$-coated sample before and after deposition. This measurement was performed using the crossed polarizer resonant scattering technique, so the measured $Q$ is that of the intrinsic $Q$. This shows the cavity $Q$ to have increased from 107,000 to 212,000.

While the deposition of 20 nm of Al$_2$O$_3$ on that particular sample resulted in a clear increase in the cavity $Q$, from these initial tests it is not clear what factors contributed to this increase. The fact that the sample coated with TiO$_2$ did not show the same increases suggests that the effect is not exclusively due to a decrease in surface roughness. Finite-difference time-domain (FDTD) simulations of the silicon nanobeam $Q$ [Fig. 5(a)] indicate that the $Q$ is highly dependent on the hole radius, with a peak $Q$ near a radius of 0.3 times the lattice constant. To account for the decrease in hole radius as a result of the ALD coating, a third sample was fabricated with an added offset to the hole radius. For each lattice constant, 13 cavities were defined with offsets ranging from $-30$ to $+30$ nm in 5 nm steps. Four arrays of these cavities were fabricated with varying electron beam dosage, but only two arrays provided useful cavities.

This sample was characterized, coated with 20 nm of Al$_2$O$_3$, and then recharacterized. Fifty-three of the 60 cavities that were characterized on this third sample showed increases in the $Q$, with the average increase being 20 $\pm$ 19%. Figure 5(b) shows a plot of the measured $Q$ prior to ALD coating as a function of hole radius offset. There is a trend toward higher $Q$s for cavities with smaller holes. Unlike the simulation, there is not a clear peak in the $Q$. This suggests that our range of hole sizes did not cover the designed range. Looking at the percent increase in the $Q$ as a function of the hole radius offset (Fig. 6), there is also a clear trend toward a greater increase for cavities with larger holes. Following ALD, these cavities have hole sizes closer to those of the cavities that showed the highest $Q$s prior to ALD. This is consistent with the idea that the increase in $Q$ is due to the shift of hole size closer to the optimal (highest $Q$) design.

Figure 7 shows a plot of the shift in the cavity mode wavelength as a result of the deposition of 20 nm of Al$_2$O$_3$, along with FDTD simulation results. While the wavelength shift showed very little dependence on the lattice constant, it showed a strong dependence on the initial hole radius offset.
The shift also showed some dependence on the dosage used during electron beam lithography. This is likely due to the dependence of the hole size and beam width on electron beam dose. The higher dose array, which should have larger holes due to the increased exposure of the mask, showed wavelength shifts in the range of $21.6 \pm 0.2$ nm for the smallest holes to $28.0 \pm 0.1$ nm for the largest holes. The lower dose array showed wavelength shifts in the range of $20.2 \pm 0.2$ nm for the smallest holes to $27.1 \pm 0.4$ nm for the largest.

The FDTD simulations predict a similar range of wavelength shift. The tuning precision is very high because it is determined by the growth rate of the thin film, which can be very slow. For the ALD technique used in this work, the growth rate was around $0.1$ nm/cycle, with a cycle time of $3.45$ s. This results in a wavelength shift on the order of $0.1 \sim 0.15$ nm/cycle.

In order to investigate the effect of the Al$_2$O$_3$ coating on the mode volume, we use numerical methods. FDTD simulations reveal a nearly linear relationship between the mode volume and hole radius offset. The mode volume increases from $0.410 \lambda/n$ for a $30$ nm offset, to $0.658 \lambda/n$ for a $-30$ nm offset. At the same time, the increase in mode volume as a result of depositing $20$ nm of Al$_2$O$_3$ shows little dependence on the hole radius offset, fluctuating in the range of a $2.06\%$ to $6.45\%$ increase.

6. CONCLUSIONS

We have shown that ALD can be a valuable tool for tuning the resonant wavelength and $Q$ of 1D silicon nanobeam cavities postfabrication. The low index and low deposition rate of Al$_2$O$_3$ allows for very precise control of the wavelength shift. The initial size of the cavity holes also plays an important role in the resonance shift. Cavities with smaller holes to begin with will have modes that are more confined to the silicon and therefore will see less of an effect from the additional dielectric material.

Initial results show that a $20$ nm coating of Al$_2$O$_3$ can increase the $Q$ of 1D silicon nanobeam cavities by $38 \pm 3\%$. While the exact nature of this change in the $Q$ is not fully understood, both simulation and experiment show that the $Q$ is significantly affected by the size of the cavity holes. Therefore, it is likely that the changing hole size resulting from the Al$_2$O$_3$ deposition is responsible for much of the change in the $Q$ observed in this work. There still remains much to be done to determine the contribution of other effects to the change in the $Q$. The conformal nature of the ALD film will lead to decreased surface roughness and decreased scattering losses at the Al$_2$O$_3$–air interface; however, the large index mismatch of Al$_2$O$_3$ and silicon means that scattering at this interface will still be significant. Additionally, the thin film could be causing surface passivation, leading to decreased absorption by surface states. Finally, the film may be affecting the mode profile, pulling the field away from the oxide layer and decreasing losses into the substrate. Repeating these experiments with
various materials and film thicknesses will reveal more detail on these separate effects.

In summary, the ability to deposit AlO$_3$ onto silicon nanobeams without significantly degrading the $Q$ or increasing $V$ is important for the field of silicon photonics and cQED. In addition to being able to tune the cavity resonance, the ability to incorporate new materials, such as erbium, will allow the fabrication of active devices from silicon PC cavities.
