ABSTRACT

Context. The measurement of the anisotropies in the cosmic infrared background (CIB) is a powerful means of studying the evolution of galaxies and large-scale structures. These anisotropies have been measured by a number of experiments, from the far-infrared (AKARI 90 μm) to the millimeter (Planck and the South Pole Telescope at ~2 mm). One of the main impediments to an accurate measurement on large scales (≤1 degree) is the contamination of the foreground signal by Galactic dust emission.

Aims. Our goal is to show that we can remove the Galactic cirrus contamination using Hα data, and thus accurately measure the clustering of starburst galaxies in the CIB.

Methods. We use observations of the so-called extragalactic ELAIS N1 field at far-infrared (100 and 160 μm) and radio (21 cm) wavelengths. We compute the correlation between dust emission, traced by far-infrared observations, and Hα gas traced by 21 cm observations, and derive dust emissivities that enable us to subtract the cirrus emission from the far-infrared maps. We then derive the power spectrum of the CIB anisotropies, as well as its mean level at 100 μm and 160 μm.

Results. We compute dust emissivities for each of the Hα-velocity components (local, intermediate, and high velocity). Using IRIS/IRAS data at 100 μm, we demonstrate that we can use the measured emissivities to determine and remove the cirrus contribution to the power spectrum of the CIB on large angular scales where the cirrus contribution dominates. We then apply this method to Spitzer/MIPS data for 160 μm. We measure correlated anisotropies at 160 μm, and for the first time at 100 μm. We also combine the Hα data and Spitzer total power mode absolute measurements to determine the CIB mean level at 160 μm. We find $B_{160} = 0.77 \pm 0.04 \pm 0.12 \text{ MJy/sr}$, where the first error is statistical and the second one systematic. Combining this measurement with the $B_{100}/B_{160}$ color of the correlated anisotropies, we also derive the CIB mean at 100 μm, $B_{100} = 0.24 \pm 0.08 \pm 0.04 \text{ MJy/sr}$. This measurement is in line with values obtained with recent models of infrared galaxy evolution and Herschel/PACS data, but is much smaller than the previous DIRBE measurements. In contrast to Matsuura and collaborators, we do not find any evidence of a new galaxy population at high redshift or unknown diffuse emission. Part of this discrepancy is likely to be explained by their use of an incorrect template for the Galactic cirrus emission.

Conclusions. The use of high-angular resolution Hα data is mandatory to accurately differentiate the cirrus from the CIB emission. The 100 μm IRAS map (and thus the map developed by Schlegel and collaborators) in such extragalactic fields is highly contaminated by the CIB anisotropies and hence cannot be used as a Galactic cirrus tracer.

Key words. infrared: galaxies – ISM: clouds – dust, extinction – diffuse radiation – large-scale structure of Universe

1. Introduction

Starburst (SB) galaxies are known to have had an important role in galaxy formation and evolution throughout the whole history of the Universe. In the far-infrared (FIR) and sub-millimeter, observations are limited by extragalactic confusion: details on small spatial scales are lost in the noise because of the poor angular resolution of the instruments. As a result, unresolved starburst galaxies form the cosmic infrared background (CIB; Puget et al. 1996; Fixsen et al. 1998; Lagache et al. 1999), which peaks at around 200 μm. In the mid-infrared, a large fraction of the CIB has been resolved into individual sources: Papovich et al. (2004), for instance, resolved 70% of the 24 μm background. In the FIR, before the advent of the Herschel telescope, a smaller fraction has been resolved: with Spitzer, Dole et al. (2004) resolved 23% and 7% of the CIB at 70 and 160 μm, respectively. Frayer et al. (2006b) managed to resolve 60% of the CIB at 70 μm using a very deep but small field, which was thus limited by cosmic variance. More recently, Berta et al. (2010) integrated counts coming from Herschel/PACS data at 100 and 160 μm and resolved ~45% and ~52% of the CIB, respectively. At longer wavelengths, Oliver et al. (2010) directly resolved 15%, 10%, and 6% of the CIB at 250, 350, and 500 μm, respectively, using Herschel/SPIRE data. Confusion can be circumvented by the use of statistical methods. For instance, by stacking 24 μm sources, Dole et al. (2006) were able to resolve a large fraction of the CIB at 70 μm and 160 μm and Berta et al. (2010) increased their fractions from 45% to 50%, and from 52% to 75% at 100 μm and 160 μm, respectively. Using a P(D) approach, Berta et al. (2011) were able to obtain still larger fractions of 65% and 89%.
at 100 and 160 µm, respectively; P(D) derived counts of Glenn et al. (2010) account for 64, 60, and 43% of the CIB at 250, 350, and 500 µm, respectively. These results imply that the sources detected at 24 µm constitute the bulk of the CIB around its peak. Caputi et al. (2006) showed that galaxies that dominate the emission at 24 µm become more and more luminous and massive as the redshift increases starting from luminous infrared galaxies (LIRGs) with $10^{11} L_\odot < L_{IR} < 10^{12} L_\odot$ at $0.8 < z < 1.2$ with intermediate mass, to ultra-luminous infrared galaxies (ULIRGs) with $10^{12} L_\odot < L_{IR} < 10^{13} L_\odot$ that dominate at $z > 2$ and have masses $>10^{11} M_\odot$.

The clustering of galaxies that make up the CIB can be characterized by its anisotropies. This clustering was first detected at 160 µm with Spitzer (Lagache et al. 2007; Grossan & Smoot 2007), and then measured at 250, 350, and 500 µm using BLAST data (Viero et al. 2009). All three of these sets of data enabled the detection of an excess of signal on intermediate spatial scales caused by the clustering of starburst galaxies which enabled them to derive the linear bias parameter $b$ that relates the density fluctuations of luminous matter to those of dark matter (DM). Lagache et al. (2007) measured a value of $b = 2.4 \pm 0.2$ while Viero et al. (2009) obtained $b = 3 \pm 0.3$. The difference may be due to selection effects.

At longer wavelengths, higher redshift SB galaxies are probed (Lagache et al. 2005; Fernandez-Conde et al. 2008) and at these higher redshifts, SB galaxies are a highly biased tracer of the underlying dark matter density field. They indeed formed in very massive DM halos early in the history of the Universe. Magliocchetti et al. (2008) derived the two-point correlation function of 24 µm selected sources divided into two redshift bins ($0.6 < z < 1.2$ and $z > 1.6$). Finding that these SB galaxies are strongly clustered and embedded in DM halos of $\equiv 10^{12.8} M_\odot$ for the high $z$ sample and $\equiv 10^{11.5} M_\odot$ for the low $z$ one. Cooray et al. (2010) computed the angular correlation function with Herschel/SPIRE data. They found that 250 µm sources are embedded in DM halos of $\equiv 10^{12} M_\odot$ at $z \sim 1.7$, whereas bright 500 µm sources reside in more massive halos, $\equiv 10^{13} M_\odot$, at $z \sim 2.6$. The CIB anisotropy measurements in the FIR and submillimeter were followed by those of Hall et al. (2010) at 1.3 mm and 2 mm with the South Pole Telescope and by the Fowlner & Atacama Cosmology Telescope Team (2010) at 1.4 and 2 mm with the Atacama Cosmology Telescope (Dunkley & Atacama Cosmology Telescope Team 2010). More recently, Planck Collaboration (2011b) derived CIB power spectra from 10' to 100' simultaneously at 350, 550, 850, and 1380 µm in six high-Galactic latitude fields. Amblard et al. (2011) extended the measurements to smaller angular scales, using Herschel/SPIRE observations of the Lockman-hole field at 250, 350, and 500 µm. These measurements allow us to start to refine the analysis of the clustering properties of galaxies responsible for the CIB, and its cosmic evolution to high redshift ($z \sim 3-4$).

The FIR and submillimeter emission of the Galactic cirrus interferes with the detection and measurement of the CIB. This emission dominates the power spectrum of the anisotropies on large spatial scales, the exact scale depending on the wavelength and the selected field. To remove the cirrus contribution, data at other wavelengths are usually used. For instance, IRIS maps of reprocessed IRAS maps (Miville-Deschênes & Lagache 2005) at 100 µm can be used to determine the power spectrum of the cirrus on large scales. However, as shown in this paper, these data also contain CIB anisotropy and therefore a clustering signal from SB galaxies. To constrain more accurately the contribution of the Galactic cirrus, an external tracer is needed. The most effective one for dust emission in the diffuse sky is neutral hydrogen. In this paper, we show that HI data can be used to remove the cirrus contamination from the 100 µm and 160 µm maps in order to measure the CIB intensity and the power spectrum of the CIB anisotropy. This method based on template removal to separate the cirrus and CIB components, was also successfully applied to the ~140 square degrees of the very diffuse high-latitude sky observed by both Planck/HFI (350 µm to 3 mm) and the Green Bank Telescope (21 cm HI) (Planck Collaboration 2011b).

The paper is organized as follows: we present the data in Sect. 2. In Sect. 3, we briefly describe the astrophysical components and derive the instrumental noise component of the map power spectrum. In Sect. 4, we compute the Galactic cirrus contamination. The cirrus map is then subtracted from the IR maps to obtain the CIB-dominated maps from which we then estimate the power spectrum at both 100 µm and 160 µm (in Sect. 5). In Sect. 6, we estimate the mean of the CIB at 160 µm using the total power mode (TPM) of Spitzer, and at 100 µm using the $B_{100}/B_{160}$ color of the measured correlated CIB anisotropies. We then present our conclusions in Sect. 7.

2. Data

We focus our analysis on the ELAIS N1 field ($l, b = (85.33^\circ, 44.28^\circ)$), which is part of the Spitzer Wide-Area Infrared Extragalactic Legacy Survey (SWIRE). It covers about ten square degrees and was observed by the Multiband Imaging Photometer for Spitzer (MIPS) at 160 µm, by the GBT at 21 cm and by IRAS at 100 and 60 µm.

2.1. MIPS 160 µm

The MIPS observations at 160 µm were taken as part of the SWIRE legacy program (Lonsdale et al. 2003) in 2004 during two epochs separated by six months (late January and late July). The data were taken using the scan mode and the medium scan rate, in about three-degree long strips and an offset between the return and forward scans of 148'' over. This observing strategy produced a map with a median depth coverage of 8 (times 4 s per frame =32 s integration time). However, owing to the dead read-out of the 160 µm array (Stansberry et al. 2007) the coverage was inhomogeneous, being as low as two or as high as ten in some regions of the map, usually along the scanning direction and overlapping independent regions.

During the observations of the first epoch, the Spitzer Observatory went into stand-by mode (Jan 25th). This meant that some of the 160 µm observations were affected by a slightly warmer telescope during the recovery phase, with a temperature of around 6 K rather than the standard ~5.6 K. We mitigated this effect in the data by applying a small offset determined from the nearby unaffected regions (an overlap correction).

The fact that the 160 µm data were taken during two different epochs makes the processing and creation of the final mosaic relatively straightforward. We used the standard basic calibrated data (BCDs) from the Spitzer Science Center, and removed their prediction of the zodiacal light as a function of time and space from each BCD and carried out an overlap correction (Mizuno et al. 2008). The maps were created using the native pixel scale of 16 arcsec/pixel, which preserves the diffuse emission. These final mosaics show no evidence of any defects other than low intensity stripes left as an artifact of the scanning observation. These stripes introduce two peaks at $k \sim 1$ arcmin$^{-1}$ into the power spectrum of the map, as shown in Fig. 1. The effect of
these stripes was mitigated by applying a destriping filter using ridgelets (Ingalls et al. 2011). Our tests of the photometry of the maps and their sources showed that the destriping method preserves the flux to within 5% of the original values. However, the power spectrum of the destriped map shows a little loss of power on small scales ($k \gtrsim 0.2$ arcmin$^{-1}$), as can be seen by comparing the green line with to the black dotted line in Fig. 1. To investigate whether any astrophysical information had been removed or only power contained in the stripes, we destriped the map using the destriper algorithm developed for IRIS, which was not developed for such high-angular resolution data. We found that the IRIS destriper fails to remove residual stripes as it was not developed for such high-angular resolution data. We therefore use the map destriped with ridgelets. To limit point spread function (PSF) uncertainties (see below) we consider only scales $<0.8$ arcmin$^{-1}$, hence disregard the residual stripe at $k \sim 1$ arcmin$^{-1}$.

The identification of sources and their extraction from the Spitzer long-wavelength images (70 and 160 $\mu$m) has been carried out on filtered mosaics using the standard methods applied to the “deep fields” (see e.g. Frayer et al. 2006a,b, 2009). Filtering has been performed to remove the extended emission, thus enhance the detectability of faint point sources. Since we wish to preserve the background/foreground emission, we carried out the source removal on our original mosaics. The PSF is well-sampled in MIPS data: the full width half maximum (FWHM) of the 160 $\mu$m PSF is 40$''$ compared to the pixel size of 16$''$. We thus selected Starfinder, which uses a PSF fitting algorithm, to perform our source extraction (Diolatti et al. 2000). Starfinder also has the advantage that it evaluates the background over the entire image, in the course of the iterative fitting of the individual sources: this leads to smaller residuals (Marleau et al. 2004), even compared to those of the standard Spitzer source extraction software MOPEX/APEX (Makovoz & Marleau 2005). We detected sources down to $S_{160} = 25 \pm 5$ mJy and removed them from the map. Even though the source catalog is highly incomplete at low fluxes, removing sources down to very faint fluxes allows us to lower the Poisson part of the power spectrum and accurately measure the CIB correlated part. Figure 2 shows the source-subtracted map that we use in our study.

The effective PSF of the observed data is quite sensitive to the observed field. We therefore had to determine it directly in the map rather than use a prior estimate. We computed the PSF by stacking the brightest sources of an oversampled map (7.2 arcsec/pix). The oversampling was necessary to obtain an accurate profile of the PSF. We extracted sources at 5$\sigma$ and retained only those with $S_{160} > 600$ mJy. The left panel of Fig. 3 displays the extracted PSF and the right panel its power spectrum compared to that of the STiny Tim Model$^1$ (Küstner et al. 2005; STinyTim, v1.3; Krist 2002). The discrepancy between the power spectra shows the need to determine the PSF in our data. We estimated the errors in the PSF, using different oversamplings, bright source flux cuts, and other extragalactic fields observed with the same scanning strategy. We found that our measurement is highly reproducible up to $k \approx 0.8$ arcmin$^{-1}$. At higher $k$, we have differences that can be as large as 35% which prevented us from accurately measuring the CIB power spectrum. We will thus analyze the power spectra only for $k \lesssim 0.8$ arcmin$^{-1}$.

2.2. MIPS 160 μm total power modes

In our analysis, we used of TPM MIPS observations. A TPM observation at 70 μm and 160 μm is merely another example of a photometry mode observation in terms of its processing from raw data to calibrated images (basic calibrated data or bcd). As in the case of photometry, the calibration was directly tied to the stim flashes that are measured approximately every two minutes. In the standard photometric observations, the scan mirror places the source/sky on different positions of the array(s), taking an image of a frame at each corresponding position. Each frame is calibrated using the stim flashes, and goes through several steps as described in Gordon et al. (2005), described by Eqs. (4) to (16), with two steps being fundamental and applied to all the source frames, a dark subtraction and an illumination correction, i.e. division by a sophisticated flat. The TPM differs in one fundamental way from the photometry mode, in that instead of using the scan mirror to move only the source around the array, it performs an intermediate step of placing the mirror on an internal dark, an “absolute reference” frame, between the source observations. This internal reference dark is inside the cold instrument, i.e. a temperature of less than 1.5 K (recall that the Spitzer telescope cryogenic minimum temperature was 5.6 K). Laboratory and flight tests have shown that the attenuation is at least a factor ten when the scan mirror was placed at the 160 μm dark position. This “reference” frame is observed in the same way as the sky or source frames i.e. is calibrated using stim flashes and undergoes a dark subtraction and illumination correction. As pointed out by Gordon et al. (2005) in their Sect. 5.2.1, one problem when flashing a stim on the 70 μm and 160 μm Germanium arrays is that of a memory effect (“stim flash latent”) soon after the flash. This latency decays exponentially in a way that depends on the background light, so it can last 5–20 s and has a peak amplitude of less than 3% for 70 μm and 7% for 160 μm. Experiments have shown that for signals of a few MJy/sr, similar to those in this study, the latencies are almost completely reduced. We note that TPM observations were meant to be performed on diffuse signals and relatively dark regions of the sky, hence the design of the observing mode was done by taking into account this memory or latency effect. A standard 160 μm TPM observation places the array between the sky and the “internal reference” (aka “internal dark”), but after each observation the memory effect is allowed to decay by taking a series of seven frames, and using the frames unaffected by the latency of the final measurement. Figures 4 through 7 show the time history, as a function of the frame or Data Collection Event (DCE) number, of the median value for each BCD (i.e. the median over the 2 × 16 160 μm array) from one of photometry and TPM observations carried out at 160 μm for the ELAIS N1 field. These observations were done in a sequence, i.e. one after the other. Figures 4 and 5, show the photometric observation; showing as well the exponential decay, the sky measurement (DCE = 8), small decay, and the next calibration stim.

Fig. 4. The complete data sequence of one photometric observations of the ELAIS N1 field at 160 μm, with the median values of each frame in surface brightness units (MJy/sr) as a function Data Collection Event (DCE) number (essentially time). The highest values correspond to the calibration stim flashes.

Fig. 5. A zoomed image of the first 20 DCEs of the Photometric observation, showing the small exponential decay after a stim flash lasting about 2–3 DCEs.

Fig. 6. As Fig. 4, but for the total power mode observation. Once again the largest values correspond to the stim flashes, with the sky measurement being shown in-between them.

Fig. 7. A zoomed image of the first 20 DCEs of the total power mode observation, showing as well the exponential decay, the sky measurement (DCE = 8), small decay, and the next calibration stim.
where DEC = 0 corresponds to the sky measurement, DCE = 1 the stim, DCE = 2 to 7 to observations in the “internal dark reference” and DCE = 8 is the sky measurement followed by another six DCEs and the next calibration stim (DCE = 15). We note that the level of the DCE = 7 is essentially zero, because in the data reduction pipeline this is the “reference” measurement that is subtracted from each BCD. We also note that the sky itself (DCE = 8) is at ~3 MJy/sr, which is the final TPM measurement. The comparison of the TPM with the photometric observation shows that the light contribution of the telescope at 160 µm is ~1.3 MJy/sr. The level of spurious emission due to the telescope background emission at 160 µm is 1.0 ± 0.2 MJy/sr.

The absolute calibration of 160 µm TPM relies on the standard 160 µm calibration, which is based on asteroids, that is tied itself to the 24 and 70 µm MIPS absolute calibration to be internally consistent (Stansberry et al. 2007). Finally, we stress that a single DCE at 160 µm does not cover the 160 µm beam (40”), hence the TPM mode was designed to move the scan mirror to cover the beam in one cycle. A standard TPM 160 µm observation contains four cycles. The final product for a single 160 µm TPM observation is a 5’ × 5’ small mosaic, and for our measurements we calculated the mean over such an image. The two ELAIS N1 TPM observations at 160 µm took 2386 s with 88 s on source each, while the two photometric observations using the enhanced mode took 671 s with 54 s on each source. These numbers illustrate the efficiency of the two modes; for every second on source at TPM, about seven seconds worth of data are used for calibration and latency decay.

### 2.3. HI data

We used the HI 25 deg² data cube (x, y, velocities) centered on ELAIS N1. These data were obtained in 2006 and 2010 with the 100-meter Green Bank Telescope (GBT). Spectra were measured over a 5’ × 5’ area centered on (ℓ, b) = (85.5°, +44.3°) every 3.5’ in both coordinates. Data were taken by in-band frequency switching yielding spectra with a velocity coverage −450 ≤ V_{LSR} ≤ +355 km s⁻¹ and a velocity resolution of 0.80 km s⁻¹. Spectra were calibrated, corrected for stray radiation, and placed on a brightness temperature (T_b) scale as described in Blagrave et al. (2010) and Boothroyd et al. (2011). A third-order polynomial was fit to the emission-free regions of the spectra to remove any residual instrumental baseline. The final data cube has a root mean square (rms) noise in a single channel of 0.12 K of T_b, and an effective angular resolution of 9.4’ × 9.1’ in ℓ and b, respectively.

We distinguish three velocity components in the HI gas data: the local, intermediate (IVC), and high velocity cloud (HVC). These are shown in Fig. 8. The HVC is centered around −115 km s⁻¹ and the IVC around −23 km s⁻¹, as illustrated in Fig. 9. This figure shows velocity spectra along three lines of sight, each of which is dominated by one component. The IVC and the HVC are clearly seen in the middle and bottom panels.

### 2.4. IRIS/IRAS data

We used IRIS (re-processed IRAS data) maps at 60 and 100 µm to measure the emissivities of the dust correlated to the HI components and derive the CIB power spectrum at 100 µm. This new generation of IRAS images was processed using a more reliable zodiacal light subtraction, from a calibration and zero level compatible with DIRBE and a more reliable destriping (Miville-Deschênes & Lagache 2005). At 100 µm,
the IRIS product also represents a significant improvement on the Schlegel et al. (1998) maps. IRIS keeps the full ISSA resolution, it includes well-calibrated point sources, and the diffuse emission calibration on scales smaller than one degree was corrected for the variation in the IRAS detector responsivity with scale and brightness.

Using IRAS, two full-sky maps (HCON-1 and HCON-2 for hours confirmation) were performed and a last one that covers 75% of the sky (HCON-3). The three of them were processed in the same way, including deglitching, checking of the zero-level stability, visual examination for remaining glitches and artifacts, zodiacal light removal, and gain calibration. The three HCONs were then coadded using sky coverage maps to produce the average map (HCON-0). We return to these HCONs to correct for the variation in the IRAS detector responsivity with scale and brightness.

The IRIS PSF is assumed to be Gaussian following Miville-Deschênes et al. (2002)

\[
P(k) = \exp \left( -\frac{k^2}{2\sigma_k^2} \right),
\]

where \(\sigma_k = 0.065 \pm 0.005 \text{ arcmin}^{-1}\) at 100 \(\mu\)m, which corresponds in real space to a Gaussian function with \(\sigma = 1.8 \pm 0.1\) arcmin. Sources are removed down to a 10\(\sigma\) threshold, following the algorithm described in Miville-Deschênes & Lagache (2005). The source-subtracted map at 100 \(\mu\)m is shown in Fig. 10.

The FWHM of our data are given in Table 1. We convolved the maps when necessary in order to compare consistent data.

The blue one represents the noise-subtracted power spectrum divided by that of the PSF \((P(k) - N(k))/\gamma(k)\). The dashed line shows the level of Poisson noise, which is \(9 \times 10^3\) Jy/sr. For clarity, the error bars are not shown.](image)

3. Power spectrum and error bars

There are several contributions to the power spectrum measured in the FIR. These include the Poisson noise caused by discrete unresolved sources and the clustering of galaxies, which together represent the CIB anisotropies, the Galactic cirrus, and the instrument noise. Assuming that the noise is not correlated to the signal

\[
P(k) = \gamma(k) \left[ P_{\text{sources}}(k) + P_{\text{clus}}(k) + P_{\text{cirrus}}(k) \right] + N(k),
\]

where \(k\) is the two-dimensional wavenumber and \(P_{\text{sources}}(k)\), \(P_{\text{clus}}(k)\), and \(P_{\text{cirrus}}(k)\) are, respectively, the power spectrum of unresolved sources, the clustering, and the Galactic dust emission. The instrumental noise is represented by \(N(k)\), and \(\gamma(k)\) is the power spectrum of the PSF of the instrument.

The noise power spectrum, \(N(k)\) was computed using two independent maps of the ELAIS N1 field. At 100 \(\mu\)m, we used the different HCONs (see Sect. 2.4). At 160 \(\mu\)m, we used the even and odd BCDs to build two independent maps. The power spectrum of the difference in the two maps gives an estimate of \(N(k)\). To take account of the inhomogeneous coverage, we applied the method of Miville-Deschênes & Lagache (2005). We subtracted the estimated \(N(k)\) from the raw power spectrum \(P(k)\). The level of the Poisson noise at large \(k\) is obtained by dividing the power spectrum by that of the PSF.

The result is shown in Fig. 11. We found that \(P_{\text{sources}} = 9013 \pm 100\) Jy\(^2\)/sr. Lagache et al. (2007) found a slightly higher value of 9848 ± 120 Jy\(^2\)/sr with sources removed with a higher flux (200 mJy). In this study, sources are removed to a lower flux cut, which leads to a lower shot noise level.

Statistical errors in power spectra are computed using mock signal plus noise maps that we analyzed with the same pipeline as the data. We derived the covariance matrix of this set of power
spectra. Its diagonal terms give the errors in each \( P(k) \). Errors in the subtraction of the cirrus component are not statistical but systematic and due to errors in the emissivities \( \delta \alpha \) (see Sect. 5.1). Errors in the power spectrum of the cirrus-subtracted map due to the spatial removal are on the order of \( \delta \alpha \times P(k) \), which is negligible compared to the statistical error.

We have seen in Sect. 2.1 that there are uncertainties in the determination of the PSF. We took these into account by using several PSFs (ours, STiny Tim, and one computed from another Spitzer field, the CDFS) in the same pipeline. We derive again the covariance matrix of the set of power spectra. We add these errors in quadrature to statistical errors.

4. The Galactic component

In previous works, the Galactic contribution to the power spectrum was either assumed to be proportional to \( k^{-3} \) (Lagache & Puget 2000), estimated using IRIS at 100 \( \mu \)m on large angular scales in the “\( k^{-3} \)” regime (Lagache et al. 2007), or considered to be negligible (Viero et al. 2009), Matsuura et al. (2011) used the Schlegel et al. (1998) map at 100 \( \mu \)m as a cirrus template. This step was incorrect as, in the extragalactic fields, this map is highly contaminated (even dominated on some spatial scales) by the anisotropies of the CIB, as demonstrated in Sect. 5.2.

The goal here is to examine the accuracy of the cirrus removal using \( H_\text{i} \) data (as done by Planck Collaboration 2011b), with the ultimate aim of obtaining CIB anisotropy maps on fields larger than ELAIS N1, and even for a very large fraction of the sky with Planck data. In this section, we present our power spectrum of the Galactic component using only 100 \( \mu \)m data on large scales. We then characterize the dust properties in our field. This is used in Sect. 5 to qualify the accuracy of the cirrus removal using \( H_\text{i} \) data.

4.1. Constraints on the cirrus contribution using IRIS 100 \( \mu \)m data

The power spectrum of the Galactic component is first assumed to be a power law, as in Miville-Deschênes et al. (2007)

\[
P_{\text{cirrus}}(k) = P_0 \left( \frac{k}{k_0} \right)^\beta,
\]

where \( P_0 \) is the normalization of the power spectrum at \( k_0 = 0.01 \) arcmin\(^{-1}\). The cirrus component dominates the power spectrum on large scales (\( k < 0.01 \) arcmin\(^{-1}\)). The ten square degree field selected at 160 \( \mu \)m does not allow us to probe this regime reliably, therefore a larger map is needed. After removing the sources, we fit the power spectrum of a 225 deg\(^2\) IRIS 100 \( \mu \)m map centered on ELAIS N1 deriving \( \beta = -2.53 \pm 0.03 \) and \( P_0 = (4.93 \pm 0.20) \times 10^6 \text{ Jy/sr} \). To compare this value to previous work (e.g. Lagache et al. 2007) in the Lockman Hole field, we need to rescale \( P_0 \) by the ratio of the cirrus brightness. We note that \( P_0 \) is indeed proportional to the square of the surface brightness of the cirrus \( B_{\text{cirrus}}^2 = (B_{100} - B_{\text{CIB}})^2 \). If we take \( B_{\text{CIB}} = 0.78 \text{ MJy/sr} \) according to Lagache et al. (2000), we obtain \( B_{\text{cirrus}} = 1.25 \text{ MJy/sr} \). Using \( B_{\text{lagache}} = 0.51 \text{ MJy/sr} \), we then have

\[
P_{\text{lagache}}^{\text{0,normalised}} = P_0 \times \left( \frac{B_{\text{cirrus}}}{B_{\text{lagache}}} \right)^2 = 4.20 \pm 0.93 \times 10^6 \text{ Jy/sr}^2
\]

which agree with our measured \( P_0 \).

\begin{table}[h!]

\end{table}

Notes: The last four lines give the cirrus and CIB colors according to Boulanger et al. (1996), Flagey et al. (2009), Bot et al. (2009), and Lagache et al. (2003), respectively.

\(^2\) We therefore did not compare their determination of the CIB with ours as their determination is highly biased owing to an incorrect cirrus removal.

\(^3\) IDL atrou algorithm.
cases, they explained these differences by a variation of the interstellar radiation field and/or the abundance of very small and big grains.

To compare the cirrus power spectrum obtained using IRIS data at 100 μm with our 160 μm power spectrum, we rescale the 100 μm power spectrum by $B_{100,\text{cirrus}}^{10,\deg^2} / B_{100,\text{cirrus}}^{25,\deg^2}$ and then by $(B_{160}/B_{100})^2$ = $(1/0.35)^2$, the large-scale color that corresponds to the cirrus color in our field. We show this comparison in Fig. 12 and observe that they are in good agreement for $k < 0.02$ arcmin$^{-1}$ (i.e. in the "cirrus regime"). Unfortunately, the statistics of the large scales at 160 μm are quite poor and do not allow us to quantify the quality of the argument.

4.2. Dust colors and dust-HI emissivities

The dust that is heated by the interstellar radiation field and emits in the IR is mixed with neutral hydrogen. Thus, the IR emission of the cirrus is strongly correlated with the HI 21 cm line. Boulanger & Perault (1987) showed that this correlation is tight at high Galactic latitudes at 60 and 100 μm. This correlation has often been used to study dust properties, for instance by Boulanger et al. (1996) who derived the dust spectrum associated with H I gas.

In this section, we use GBT data at 21 cm to derive the FIR emission of the cirrus, which is then removed from our data at 100 μm and 160 μm in Sect. 5.

In the ELAIS N1 field, there are three distinguishable HI velocity components: the local component, an intermediate velocity cloud (IVC), and a high velocity cloud (HVC). We first compute their integrated emission by adding all velocity channels with $-14$ km s$^{-1}$ < $V_{\text{LSR}}$ < $43$ km s$^{-1}$ for the local, $-79$ km s$^{-1}$ < $V_{\text{LSR}}$ < $-14$ km s$^{-1}$ for the IVC, and $-163$ km s$^{-1}$ < $V_{\text{LSR}}$ < $-79$ km s$^{-1}$ for the HVC. Second, assuming the optically thin case, we estimate their column density using

$$N_{\text{HI}}(x, y) = 1.823 \times 10^{18} \sum_x T_B(x, y, v)dv,$$

where $N_{\text{HI}}$ is the HI column density in unit of $10^{20}$ atoms/cm$^2$, $T_B$ the brightness temperature, and $v$ the velocity.

The interstellar medium in the ELAIS N1 field seems to be dominated by neutral atomic hydrogen that reaches a peak $N_{\text{HI}} \approx 1.5 \times 10^{20}$ cm$^{-2}$ in each of the three components (Fig. 8). The brightness temperature of the HI line is always ≤8.9 K. Since molecular hydrogen, H$_2$, begins to be seen in directions where $N_{\text{HI}} > 2 \times 10^{20}$ cm$^{-2}$ and $T_B > 12$ K (e.g., Gillmon et al. 2006; Liszt 2002; Lockman & Condon 2005), it is unlikely that there are significant amounts of H$_2$ in our field. Therefore, we can apply the decomposition following Miville-Deschênes et al. (2005)

$$I_i = \sum a_i' N_{\text{HI}}(x, y) + C_i(x, y),$$

where $I_i$ is the infrared map, $N_{\text{HI}}(x, y)$ is the column density of the $i$-th HI component, $a_i'$ is the emissivity of component $i$ at wavelength $\lambda$, and $C_i(x, y)$ is a residual term (offset + CIB). The correlation coefficients $a_i'$ are estimated using a $\chi^2$ minimization$^4$. The error bars given by the IDL function are valid only if the noise of the $I_i$ maps is Gaussian and if the noise affecting $N_{\text{HI}}$ is negligible. This may not be the case as the maps contain the IRIS or MIPS instrumental noise and CIB anisotropies. Planck Collaboration (2011a) carried out Monte Carlo simulations to estimate the errors in $a_i'$ for IRIS 100 and 160 μm and determined the coefficients by which they multiplied the error bars found assuming a Gaussian noise. We multiply our errors by these coefficients at 60 and 100 μm. For MIPS at 160 μm, we take the mean of the 100 and 350 μm coefficients determined by Planck Collaboration (2011a), as these coefficients vary only slightly with wavelength. They are on the order of eight.

The emissivities $a_i'$ are computed at 60, 100, and 160 μm in the ELAIS N1/MIPS field (i.e. ELAIS N1 field restricted to the MIPS coverage) and at 60 and 100 μm only in the ELAIS N1/GBT field (i.e. the entire field covered by HI data, see Fig. 8). Figure 8 shows that ELAIS N1/MIPS does not contain the IVC. Therefore, for this field, we use only two components, the local and the HVC, to avoid any additional noise. Our results are given in Table 3.

The emissivities of the local component are in accordance with those found by Miville-Deschênes et al. (2005) at the three wavelengths. They used HI observations from the GBT (Lockman & Condon 2005) to compute emissivities at 24, 60, 100, and 160 μm in the Spitzer Extragalactic First Look Survey field. They have two IVCs whose emissivities are in agreement with ours at 100 μm. However, there is a discrepancy at 60 μm. For IVC1 and IVC2, Miville-Deschênes et al. (2005) found $B_{60}/B_{100} = 0.50$ and 0.34 respectively, whereas we have $B_{60}/B_{100} = 0.30$. This value is in line with Planck Collaboration (2011a), who found $0.23 < B_{60}/B_{100} < 0.42$ in 14 fields covering 800 square degrees of the sky. They interpreted these differences as a contamination of the emission at 60 μm by non-equilibrium emission due to a higher relative abundance of very small grains compared to big grains at shorter wavelength.

Moreover, the HVC in ELAIS N1 is detected at 160 μm. This confirms the detection of dust in some HVCs. Finally, we note that our results are also in very good agreement with those from Planck Collaboration (2011a), who performed a similar analysis on the same field.

Using emissivities, colors can be computed and compared to previous works. We find that $B_{160}/B_{100}$ = 2.87 for the local component. Bot et al. (2009) removed the mean value of the CIB, 0.78 MJy/sr from their $(B_{100})$, and they observed an increase in the ratio $B_{160}/B_{100}$ with $(B_{100})$ meaning that brighter regions are colder. We subtract the same CIB level of 0.78 MJy/sr from our $(B_{100})$, even though we get a mean CIB

$^4$ We use the IDL function regress.

![Fig. 12. Comparison of the cirrus power spectra computed with the IRIS 100 μm map on large scales with that computed with the 160 μm map. Crosses: cirrus power spectrum at 100 μm computed on a 225 deg$^2$ 100 μm map centered on ELAIS N1 rescaled by the ratio $B_{100,\text{cirrus}}^{10,\deg^2} / B_{100,\text{cirrus}}^{25,\deg^2} \times (B_{160}/B_{100})^2$ is shown by crosses. Squares: power spectrum of ELAIS N1 computed at 160 μm.](image-url)
residual of 0.58 MJy/sr (see Table 3). This results in $\langle B_{100} \rangle = 0.4$ MJy/sr, which is much lower than any of their $\langle B_{100} \rangle$. They kept only regions with $\langle B_{100} \rangle > 2.5$ MJy/sr, in order to be dominated by variations in cirrus emission (and not be contaminated by CIB anisotropies). Their fields have a typical $B_{160}/B_{100}$ of 2, which is very close to our value. Our much lower $\langle B_{100} \rangle$ implies that $B_{160}/B_{100}$ may reach a plateau at a value of $\sim 2$ MJy/sr for $\langle B_{100} \rangle$ lower than 2.5 MJy/sr. The value of $B_{160}/B_{100}$ can also be compared to those given in Table 2, which were computed with a linear regression between the two maps at large scales. We achieve an excellent agreement, finding $B_{160}/B_{100} = 0.35 \pm 0.01$ in the two cases.

The CIB should be the only astrophysical component contained in the residual map. To test this, we can check whether the residual mean value agrees with the mean value of the CIB. This is the case at 160 μm, after the map is corrected by an offset term (see Sect. 6.1). At 100 μm, there is a discrepancy between the prediction and our result, which we attribute to residuals of zodiacal light in the map. The IRIS data were indeed calibrated in the DIRBE data, which contain a residual zodiacal emission that leads to an overestimate of the CIB (see Dole et al. 2006). At 60 μm, we do not try to measure the mean value of the residual because the CIB level is on the order of the residual of the zodiacal light at this wavelength (Renault et al. 2001).

### 4.3. Dust temperatures

The IR/HI emissivities give constraints on the dust temperature. We assume that the emission of big grains at thermal equilibrium with a radiation field is a modified black body

$$I_\nu = \tau_\nu B_\nu(T_{BG}) \ .$$

where $B_\nu$ is the Planck function, $T_{BG}$ the big grains’ equilibrium temperature, and $\tau_\nu$ the optical depth. It can be expressed as $\tau_\nu = N_{HI} e_\nu$, with $e_\nu$ the dust emissivity per H atom that is usually assumed to be a power law $e_\nu = e_\nu(\nu/\nu_0)^\alpha$ where $\alpha$ is the emissivity spectral index. Following Boulanger et al. (1996), we assume that $\alpha = 2$. At wavelengths where the emission is dominated by big grains, the IR/HI correlation coefficients can be written as $\alpha_{HI} = e_{HI}(T_{BG})$. We use the infrared-HI correlation coefficients at 100 and 160 μm to estimate the big grains temperature $T_{BG}$ of each HI component assuming that the contribution of very small grains in the FIR is negligible.

#### 5. Removal of the Galactic component

##### 5.1. Removal of the cirrus either spatially or by considering the power spectra and error bars

The cirrus contribution removal can be done in two ways: spatially in the maps or by subtracting the cirrus power spectrum from that of the infrared map. We first need to know whether these two methods are equivalent. We consider the power spectrum of the CIB, $P_{CIB}(k)$, as an estimator for this test, and compute its variance for the two methods in a naive approximation of Gaussianity. We have two maps A and B, containing, respectively, CIB + Galactic component (GC) and only the GC.

### Notes.

Columns 4–6: emissivities (in units of MJy/(sr cm$^{-2}$)) computed in ELAIS N1/MIPS at 60, 100 and 160 μm compared to those of the literature. Columns 7, 8: emissivities computed in N1/GBT at 60, 100 μm. Uncertainties are 1σ uncertainties that take into account the statistical variance and the instrumental noise. MAMD 2005 stands for Miville-Deschênes et al. (2005). Their emissivities are for the Spitzer XFLS field. Planck 2011 stands for Planck Collaboration (2011a). Their emissivities are for the ELAIS N1/GBT field. The second last line gives the mean values of the residual maps. At 160 μm, the mean value has been corrected for the offset determined in Sect. 6.1, and gives the level of the CIB (although see Sect. 6 for a more accurate determination). At 100 μm, the mean value is strongly contaminated by residual zodiacal emission (see Dole et al. 2006) thus does not give the CIB level. The last line gives the CIB coming from the Béthermin et al. (2011) model. This value has been corrected from an offset that is present in the scanning map (see Sect. 6.1).

Residual of 0.58 MJy/sr (see Table 3). This results in $\langle B_{100} \rangle = 0.4$ MJy/sr, which is much lower than any of their $\langle B_{100} \rangle$. They kept only regions with $\langle B_{100} \rangle > 2.5$ MJy/sr, in order to be dominated by variations in cirrus emission (and not be contaminated by CIB anisotropies). Their fields have a typical $B_{160}/B_{100}$ of 2, which is very close to our value. Our much lower $\langle B_{100} \rangle$ implies that $B_{160}/B_{100}$ may reach a plateau at a value of $\sim 2$ MJy/sr for $\langle B_{100} \rangle$ lower than 2.5 MJy/sr. The value of $B_{160}/B_{100}$ can also be compared to those given in Table 2, which were computed with a linear regression between the two maps at large scales. We achieve an excellent agreement, finding $B_{160}/B_{100} = 0.35 \pm 0.01$ in the two cases.

The CIB should be the only astrophysical component contained in the residual map. To test this, we can check whether the residual mean value agrees with the mean value of the CIB. This is the case at 160 μm, after the map is corrected by an offset term (see Sect. 6.1). At 100 μm, there is a discrepancy between the prediction and our result, which we attribute to residuals of zodiacal light in the map. The IRIS data were indeed calibrated in the DIRBE data, which contain a residual zodiacal emission that leads to an overestimate of the CIB (see Dole et al. 2006). At 60 μm, we do not try to measure the mean value of the residual because the CIB level is on the order of the residual of the zodiacal light at this wavelength (Renault et al. 2001).
In Fourier space, we have $a_k^A = a_{k,CIB} + a_{k,GC}$ and $a_k^B = a_{k,GC}$, where $a_k$ are the Fourier coefficients. The power spectrum can be written

$$\hat{P}_{\text{CIB}}(k) = \{a_k^A\}. \quad (9)$$

The mean values of the power spectrum of the CIB anisotropies are equal for both methods but not their variances. For the spatial removal,

$$\text{Var}(\hat{P}_{\text{CIB}}) = \left(\langle a_k^A - a_k^B \rangle^2 - \langle a_k^A \rangle^2 \right)^2$$

whereas for the removal at the power spectrum level a correlation term between the cirrus power spectrum and that of the CIB appears, in addition in the variance of the CIB power spectrum

$$\text{Var}(\hat{P}_{\text{CIB}}) = \left(\langle a_k^A a_k^A - a_k^A a_k^B \rangle^2 - \langle a_k^A \rangle^2 \rangle^2 \right)^2$$

$$= \text{Var}(P_{\text{CIB}}) + \text{Var}(P_{\text{CIB}}) \times \langle a_k^B \rangle^2.$$ \quad (13)

Thus, from this simple argument we expect error bars to be smaller after the spatial subtraction. We check this by performing simulations using mock data. We generate signal plus noise maps and analyze them in both ways. Error bars are indeed smaller in the spatial subtraction case. The template (spatial) subtraction removes each moment of the statistics, whereas the second method only removes the moment of the power spectrum.

5.2. Contribution of the Galactic component to the power spectrum at 100 μm

We start by comparing the cirrus power spectrum obtained at 100 μm to that computed with HI data in the ELAIS N1/GBT field. To construct a map of the cirrus emission at 100 μm, we take the sum of each component column density weighted by the emissivities determined in Sect. 4.2:

$$B_{100} = a_{\text{local}}^{100} \times N_{\text{HI}}^{\text{local}} + a_{\text{IVC}}^{100} \times N_{\text{HI}}^{\text{IVC}} + a_{\text{HVC}}^{100} \times N_{\text{HI}}^{\text{HVC}}.$$ \quad (14)

The left panel of Fig. 13 shows the map at 100 μm projected onto the GBT map and convolved with the GBT beam, the middle panel shows $B_{100}$ computed from 21 cm data. The right panel shows the 100 μm cirrus-free residual. We can clearly see that most of the contribution of the cirrus is removed and that the residual map contains only the CIB. This is even more visible in Fig. 14, which compares the 100 μm power spectrum to that of $B_{100}$ computed from 21 cm data. They are in very good agreement for $k < 0.02$ arcmin$^{-1}$. The discrepancy observed on smaller scales ($k > 0.02$ arcmin$^{-1}$) is expected, as the clustering of SB galaxies dominates (see Sect. 6.2). Therefore, this shows that using of IR/HI emissivities is a reliable method for measuring the contribution of the Galactic component in the FIR.

We can now subtract this cirrus emission from the original map to get the CIB anisotropy map. Since the FWHM of the GBT is much larger than that of IRIS, the 100 μm ELAIS N1/GBT map must be convolved with the GBT beam (9.1 arcmin). Since the cirrus contamination is primarily on large scales, we can create a hybrid power spectrum using the power spectrum of the CIB anisotropies obtained by removing the HI on large scales, and that of the original map on small scales. We use $k = 0.05$ arcmin$^{-1}$ for the transition between the two power spectra. We note that the power spectrum of the CIB anisotropies on large scales must be divided by the power spectrum of a PSF with $FWHM = \sqrt{(FWHM_{GBT}^2 - FWHM_{IRIS}^2)}$ to take
out the same analysis, we find a Poisson noise power spectrum and removed the fit on all scales. When we carry computed at $100 \mu m$. The contribution of the cirrus has been removed following Sect. 5.2. The power spectrum of the noise has been subtracted and the resulting power spectrum has been divided by the power spectrum of the PSF. The black line is the power spectrum of the map that contains the cirrus contamination. The dashed line shows the level of the Poisson noise which is $8.7 \times 10^3$ Jy$^2$/sr.

5.3. Contribution of the Galactic component to the power spectrum at $160 \mu m$

Using the same method as in Sect. 5.2, we remove the cirrus emission from the ELAIS N1/MIPS map at $160 \mu m$. We compute the hybrid power spectrum with a cut at $k = 0.05$ arcmin$^{-1}$. Figure 16 shows the total power spectrum (black) and the cirrus-free one (red). We clearly see the difference only on the largest scales available with this map. We also plot our fit to the clustering power spectrum from Lagache et al. (2007) in blue, and the shot noise level in black. The green line shows the sum of the two-component fits. We also compare our resulting power spectrum to that of Lagache et al. (2007) in Fig. 17. These power spectra are in very good agreement for $k > 0.03$ arcmin$^{-1}$, where they are dominated by the CIB anisotropies (both clustering and Poisson noise). On scales $< 0.01$ arcmin$^{-1}$, there is more power in the Lagache et al. (2007) power spectrum because it contains the cirrus contribution (the blue dashed line is their estimate of the power spectrum of the cirrus). We can see that using H$^i$ data, we are able to extend the measurement of the correlated fluctuations to large scales. This shows that making use of H$^i$ data at 21 cm is an efficient way of removing the contamination of the Galactic component.

6. Measurement of the CIB mean levels at $100 \mu m$ and $160 \mu m$

### 6.1. CIB mean estimate with Total Power Modes at $160 \mu m$

We can also use our H$^i$ data and emissivity measurements to compute the absolute level of the CIB at $160 \mu m$. We consider the two TPMs of Spitzer archival observations (26961 920 and 26962 432) of the ELAIS N1 field that were designed to cross-check the calibration of the diffuse emission at $160 \mu m$. Even with a cryogenic telescope such as Spitzer, there is a small component of thermal emission at longer wavelengths that contaminates the standard photometric observations. The TPM mode by-passes the effects of this spurious radiation by comparing the emission of the target (sky) with that of an internal dark to provide an absolute measurement (see MIPS Handbook Sect. 3.1.12). This mode was designed precisely
to observe relatively faint extended emission regions. The TPM observations that we used are discussed in Sect. 2.2.

There is an HVC in TPM 1 and only the local component in TPM 2 as shown on Fig. 18. We first compare the MIPS scan map values to the TPMs. By first subtracting the map values from those of the TPMs (zodiacal-light subtracted). Infrared emission of the local and of the HVC are in Cols. 4 and 5. The sixth column gives CIB levels at 160 $\mu$m. The first error is statistical and the second is systematic. It is due to the error on the estimation of the zodiacal light. The offsets between the scan map and the TPMs are given in the last column. All values are in MJy/sr.

Making use of the TPM values and the emissivities previously computed, we determine the absolute level of the CIB at 160 $\mu$m. After subtracting the zodiacal light, the components of the TPM are

$$TPM - Zodiocal = Cirrus + CIB,$$

(15)

where the cirrus brightness is

$$Cirrus = \alpha_{\text{local}} \times N_{\text{HI,local}} + \alpha_{\text{IVC}} \times N_{\text{HI,IVC}} + \alpha_{\text{HVC}} \times N_{\text{HI,HVC}},$$

(16)

and $\alpha$ are the values computed across the whole ELAIS N1/MIPS field, as listed in Table 3. We use emissivities calculated
over the entire field larger than over the TPM regions alone since they are far too small to obtain an accurate measurement.

The zodiacal light, which has a value of $B_{\text{zodi}} = 0.83 \pm 0.12$ MJy/sr, was previously subtracted. It was estimated using the Spitzer background model (Reach 2000; Reach et al. 1995; Kelsall et al. 1998). With our emissivities, we can compute the cirrus brightness of both TPMs (following Eq. (16)) and thus compute the CIB level (following Eq. (15)). Our results are listed in Table 4. The last column gives the CIB levels: they are in excellent agreement, even though they were computed in two regions with completely different cirrus contaminations. We get an average value of $B_{160} = 0.77 \pm 0.04 \pm 0.12$ MJy/sr for the CIB level at 160 $\mu$m. The first error is statistical, and the second is systematic and dominated by the error in the zodiacal light removal. We do not include the calibration uncertainties (that are on the order of 12%, Stansberry et al. 2007) in our quoted errors. The errors are dominated by those of the zodiacal light model.

We can compare the value of the CIB level determined with the TPMs to the mean of the residual map we obtained in Sect. 4.2, as the only astrophysical component that should be present in this map is the CIB. We have first to correct the map for the offset. We use 2.05 MJy/sr and find $B_{\text{zodi, residual}} = 0.76$ MJy/sr. This value is in very good agreement with that obtained using the TPMs. They are very close to the predicted CIB level of $B_{160} = 0.63 \pm 0.02$ MJy/sr by Béthermin et al. (2011) and to the last Spitzer determination using very deep number counts: Béthermin et al. (2010) found $B_{160} = 0.78 \pm 0.12$ MJy/sr. Moreover, our value is also in very good agreement with that of Berta et al. (2011), who carried out a P(D) analysis in addition to a stacking one (of sources detected at 24 $\mu$m) in Herschel/PACS data at 160 $\mu$m to derive the differential number counts. Extrapolating the counts down to very faint fluxes using a power law, they obtained $B_{160} = 0.72 \pm 0.05$ MJy/sr. We can also compare our determinations with Juvela et al. (2009), who derived the CIB using ISOPHOT data. They computed linear fits between FIR and Hi data, by disregarding several velocity components in Hi data and for much smaller fields than ELAIS N1 (roughly 25 times smaller). They found $B_{160} = 1.08 \pm 0.32 \pm 0.30$ MJy/sr in the range 150–180 $\mu$m, where the first error is statistical and the second systematic. Although compatible within the error bars, our determination points to a lower value of the CIB. Our CIB determination benefits from having Spitzer and GBT data that cover a large field, allowing for a more robust measurement of the cirrus contamination and thus of the CIB.

We can now combine our CIB mean level measurement at 160 $\mu$m with our CIB anisotropy measurements to compute the CIB at 100 $\mu$m.

### 6.2. CIB mean estimate at 100 $\mu$m

We combine the cirrus-free power spectra measurements at both 100 $\mu$m and 160 $\mu$m with the CIB mean at 160 $\mu$m to derive the CIB mean level at 100 $\mu$m, following

$$\frac{\sigma^\text{CIB}_{100\mu m}}{B^\text{IB}_{100\mu m}} = \frac{\sigma^\text{CIB}_{160\mu m}}{B^\text{IB}_{160\mu m}} \times \frac{B^\text{IB}_{160\mu m}}{B^\text{IB}_{100\mu m}}. \tag{17}$$

where $\sigma$ is the rms fluctuation in the CIB that can be computed using the measured CIB power spectrum. Knowing $\sigma^\text{CIB}_{100\mu m}$, $\sigma^\text{CIB}_{160\mu m}$, and $B^\text{IB}_{160\mu m}$, we can compute $B^\text{IB}_{100\mu m}$ following Eq. (17). We checked using the model of Pépin et al. (2012) that Eq. (17) is valid.

The two CIB power spectra determined previously at 100 $\mu$m and 160 $\mu$m were measured with a different flux cut for the bright sources removal. Thus, we first recompute the power spectra for the two maps without masking any bright point sources, in order to have the same point source contamination (i.e., consistent Poisson noise levels). We then perform the same analysis as previously (removal of instrumental noise and cirrus, and division by the power spectrum of the PSF). We compute the 100/160 $\mu$m ratio of the power spectrum using the largest common scales available ($0.006 < k < 0.2$ arcmin$^{-1}$), obtaining $\sigma^\text{CIB}_{100\mu m}/\sigma^\text{CIB}_{160\mu m} = 0.31 \pm 0.1$. Multiplying the CIB at 160 $\mu$m derived in Sect. 6.1 by $\sigma^\text{CIB}_{100\mu m}/\sigma^\text{CIB}_{160\mu m}$ leads to a CIB at 100 $\mu$m of $B^\text{CIB}_{100\mu m} = 0.24 \pm 0.08 \pm 0.04$ MJy/sr, where the first error is statistical and the second one is systematic. We note that this value is lower than the mean value of the residual map obtained after the removal of the cirrus component (see Table 3), owing to residual zodiacal emission in the IRIS map. An empirical correction of the Lagache et al. (2000) DIRBE measurements, provided in Dole et al. (2006) gives 0.48 $\pm$ 0.21 MJy/sr. Our determination points toward a lower CIB value. By stacking Herschel/PACS maps at 100 $\mu$m at the positions of all 24 $\mu$m galaxies ($S(24) \geq 20$ $\mu$Jy), Berta et al. (2010) measured a CIB surface brightness of 0.25 $\pm$ 0.02 MJy/sr. Subsequently, Berta et al. (2011) improved on these measurements by carrying out a P(D) analysis that allowed them to reach lower fluxes. Extrapolating their differential number counts using a power law, they obtained $B^\text{CIB}_{100\mu m} = 0.42^{+0.28}_{-0.06}$ MJy/sr, which is barely compatible with our determination.

### 7. Conclusion

We have presented a new method for removing Galactic cirrus contamination from the power spectrum of CIB anisotropies by using an independent tracer of this cirrus, the Hi 21 cm data. We have computed the FIR emission of each velocity component of the cirrus and removed it spatially from the maps. The residual map is thus a map of the CIB anisotropies. We have applied this method to MIPS data at 160 $\mu$m in the ELAIS N1 field and recovered the results of Lagache et al. (2007) on intermediate spatial scales where starburst galaxy clustering intervenes. They had derived a linear bias $b \sim 2.4$ with MIPS data at 160 $\mu$m, which probes mainly galaxies around $z \sim 1$. We similarly applied this method at 100 $\mu$m and detected for the first time the correlated anisotropies at this wavelength. An analysis of these CIB anisotropy power spectra was not an objective of this paper, and we refer the reader to Pépin et al. (2012), who presented a clustering model of star-forming galaxies.

We have shown that the cirrus removal using Hi data is the most efficient available method for removing the cirrus contamination accurately. It has also been successfully applied to Planck data (Planck Collaboration 2011b) and will be applied to Herschel data. We caution the reader that it is incorrect to use the 100 $\mu$m map of Schlegel et al. (1998) as a cirrus tracer as this map contains the anisotropies of the CIB.

We have used absolute measurements of the brightness on small regions of the sky (total power modes) with different cirrus contributions to derive the CIB level. Making use of our emissivities, we were able to compute the cirrus brightness in two of these regions, and derive the CIB level at 160 $\mu$m. We found $B_{160} = 0.77 \pm 0.04 \pm 0.12$ MJy/sr (the first error is statistical and the second systematic). In addition, using our measured CIB correlated anisotropies at 100 $\mu$m we computed the CIB anisotropy color, $B_{100}/B_{160} = 0.31 \pm 0.1$. This color measurement is free of cirrus and zodiacal light uncertainties, since the former had
been removed from both power spectra and the latter is a constant that has no influence on power spectra. Using this color and the CIB measured at 160 µm, we derived the CIB at 100 µm

\[ B_{100} = 0.24 \pm 0.08 \pm 0.04 \text{ MJy sr} \]

where the first error is statistical and the second systematic. These CIB measurements are the most accurate measurements based on a diffuse emission analysis. Comparing those measurements with an extrapolation of galaxy number counts, we have found no evidence of an unknown contribution to the CIB, in contrast to Matsuura et al. (2011).
