Three examples of the inversion of refraction data by downward continuation illustrate the applicability of the method to field data. The first example is a refraction profile from the Mojave Desert, California. These data are spatially aliased and contain clear evidence of lateral inhomogeneity. The inversion in this case produces a broken image in the slowness-depth domain due to the lateral inhomogeneity, but a useful average velocity model is still obtained. The second example is a shallow marine reflection profile. Here, the truncation effects due to the finite horizontal aperture of the recording cable produce artifacts in the slowness-depth domain. The velocity model, however, distinct from these artifacts, and the presence of strong precritical reflections aids in the inversion. The third example is another shallow marine reflection profile. The inversion of these data illustrate the utilization of constraints provided by multiples as well as primary arrivals.

INTRODUCTION

Recently, a downward continuation method was presented for the inversion of densely recorded refraction data [Clayton and McMechan, 1981a, b]. This technique transforms the entire recorded data wavefield from the time-distance (t-x) domain into the slowness-depth (p-z) domain. The resulting velocity-depth locus is a focused image in the p-z domain, and the uncertainty in the solution is indicated by the width and coherence of this image. There are two basic assumptions in the procedure which limit its general applicability. The first is the assumption of lateral homogeneity of the velocity structure, and the second is the assumption that the data are sufficiently well sampled in the spatial dimension so that they can be treated as a wave field.

In this paper we present three examples of the application of this method to real refraction data. The main object of the paper is to illustrate the technique when applied to data which do not rigidly satisfy the assumptions mentioned above. Before considering the data, a brief review of the inversion procedure is given.

The downward continuation method consists of two linear, reversible wave field transformations [Clayton and McMechan, 1981a]. The first transformation is a slant stack of the t-x data [Schultz and Claerbout, 1978; Chapman, 1978, 1981; McMechan and Ottolini, 1980]:

$$ S(t, p) = \int_{-\infty}^{\infty} P(t + px, x) \, dx $$

(1)

Here \( P(t, x) \) is the observed (seismogram) wave field, \( S(t, p) \) is the transformed wavefield, \( p \) is the horizontal slowness, \( t \) is the time intercept, \( x \) is the shot-receiver distance, and \( t = t + px \) is the travel time. Each point in the \( t-p \) plane is obtained by performing the integration in (1) over all points in the \( t-x \) data along a line of slope \( p \) and time intercept \( t \). This operation decomposes the data wave field into plane wave elements. (Strictly, the slant stack transformation is insufficient to generate the plane wave response for a point source [Chapman, 1981], but our results do not depend significantly on this interpretation of the \( p-t \) wave field). The slant stack integral (1)
produces a wave field in which the $p$-$\tau$ curve (the 'tau' curve of Bessonova et al. [1974]) is imaged. This step is done only once. The slant stack itself may be viewed as a mathematical transformation which makes no physical assumptions about the nature of the field. However, to interpret $p$ as the horizontal slowness, it is necessary to assume lateral homogeneity. Also, to produce a reasonable tau curve image, it is necessary that the data be sampled sufficiently densely in $x$ so as to avoid severe aliasing [Brocher and Phinney, 1981].

The second transformation is an iterative downward continuation of $S(\tau, p)$:

$$s(p, z) \equiv S(\tau = 0, p, z) = \int S(\omega, p, z = 0)e^{-i\Psi(p, z)} \, d\omega \quad (2)$$

where

$$\Psi(p, z) = 2 \int_0^z [v^{-2}(z'') - p^2]^{1/2} \, dz'$$

In (2), $s(p, z)$ is the solution wave field, $v(z)$ is velocity as a function of depth $z$, and $\omega$ is the temporal frequency. Implicit in (2) is the assumption of lateral homogeneity of the velocity model because the up and downgoing raypaths are assumed to be identical. This transformation of $S(\tau, p)$ is repeated with successive modifications to $v(z)$ until the downward continued wavefield $s(p, z)$ images the input $v(z)$ function. This condition of stationarity indicates that convergence has been achieved (i.e., the $v(z)$ function that produces stationarity is the solution). A more detailed discussion is given by Clayton and McMechan [1981a].

Fig. 3. Slant stack ($p$-$\tau$) wave field obtained by transformation of the Mojave Desert data in Figure 2 via equation (1). Iterative downward continuation of this wave field produces the velocity-depth model.
The main restrictions on the applicability of the downward continuation approach to inversion are that typical refraction data are spatially aliased and that the earth structure is often laterally inhomogeneous. In the sections that follow, realistic examples are considered that do not rigidly satisfy the assumptions of the method and hence serve to illustrate the robustness and utility of the wave field approach even when the data are not ideal. Three data sets are presented. The first profile is composed of vertical component velocity records from the Mojave Desert, and the other two are suites of acoustic responses recorded by hydrophone cables in shallow marine environments.

THE MOJAVE DESERT PROFILE

In the fall of 1980, the U.S. Geological Survey conducted an extensive refraction project in the Mojave Desert of southern California. Only a portion of these data will be analyzed here. The location of the profile we have chosen is shown in Figure 1, and the data traces are shown in Figure 2. A number of features are evident in the data (Figure 2). The first arrivals do not form a smooth locus of constantly decreasing slope ($p$), as would be observed if the earth structure were laterally homogeneous. Most of these fluctuations can be attributed to surficial sediments [Fuis, 1981]. Others, such as the
Fig. 6. An acceptable but unconverged downward continuation solution. The solid line is a velocity-depth curve that produces acceptable travel times (see Figure 7) but does not correspond to stationarity of the \( p-z \) wave field.

early arrivals near \( x = 37 \) km, are apparently related to changes of structure at faults (see Figure 1). These travel time fluctuations do not prevent analysis of the data by wave field transformation, but as discussed below, they do contribute significantly to the uncertainty associated with the best fit laterally homogeneous model.

Figure 3 shows the slant stack of the data in Figure 2. The desired \( p-r \) locus is an image formed as the envelope of a series of intersecting straight lines. The slope of each line is \(-1/x\), where \( x \) is the corresponding shot to receiver distance. Where the \( t-x \) data are not spatially aliased, destructive interference reduces the amplitude contributions off the \( p-r \) locus. Since many of the data traces in Figure 2 are spaced greater than a half wavelength apart, they are spatially aliased, and consequently, many artificial straight lines can be seen throughout Figure 3. As the data traces are unequally spaced, a weighting that depends on trace separation was employed in slant stacking. A fairly coherent image can be seen traversing this wave field in the \((p, r)\) region from \((0.188, 0.0)\) to \((0.138, 1.6)\). The image does have some 'en echelon' branches beside the main locus and some regions where \( r \) is not monotonically decreasing that are due to the fluctuations in arrival times mentioned above. The consequences of the anomalies can be seen in Figure 4.

Iterative downward continuation of the \( p-r \) wave field in Figure 3 produces the slowness-depth image displayed in Figure 4. The solid line in Figure 4 is the velocity function at the final iteration, and it coincides with the dominant image in

Fig. 7. Comparison of observed travel times with those computed for the unconverged model in Figure 6. The calculated travel times are shown as the solid line.
data is seen in the width of the individual branches of the split. First, the time resolution and frequency content in the original model were not correct solutions primarily for laterally homogeneous media. The second model fits the observed travel times adequately and is only as an average laterally homogeneous approximation to the velocity structure along the profile. The uncertainty in this representation of the structure, which is indicated by the width and incoherence of the image, is ±0.8 km depth. This uncertainty in depth can be attributed to a composite of two effects. First, the time resolution and frequency content in the original data is seen in the width of the individual branches of the split image, which accounts for about half the variation. The multiplicity of branches due to lateral velocity changes accounts for the remainder.

As a check on the adequacy of the model obtained, travel times were computed for the model by ray tracing. (Note that up to this point, travel times have not been directly used to constrain the model.) The resulting travel time curve is superimposed on the wave field obtained by downward continuation with it in Figure 4. In general, the model produces a smooth curve that fits the first arrival observations to within 0.05 s. The fit is early at some distances and late at others, indicating that we have indeed obtained a reasonable average velocity function by downward continuation.

Triplications are evident in the travelt ime curve in Figure 5. The one that occurs at 13 km < x < 31 km is due to the rapid velocity increase near 2.3 km depth (Figure 4). This triplication may be real, as there appears to be an increase in waveform complexity near the first arrivals over this distance range, which is consistent with the existence of a triplication. On the other hand, this feature may be an artifact introduced by fortuitous correlations across the variations in first arrival times due to lateral structure changes in this region. The latter interpretation is supported by the absence of the expected precritical reflection image in Figure 4. The precritical reflection would lie horizontal and touch the main image at the depth of the reflector (2.3 km). Examples of precritical reflections are shown in Figure 11 below.

The second triplication lies at x > 33 km in Figure 5. This feature is clearly due to lateral rather than vertical velocity variations, as the highest velocity branch results from coherence of energy strongly affected by the San Andreas Fault (near x = 37 km). Consequently, the velocities in the model in Figure 4 are not reliable below 6 km depth.

To investigate further the stability of the solution in Figure 4, the model was altered to decrease the velocity gradient near 2.3 km depth. This model is shown as the solid line superimposed on the wave field obtained by downward continuation with it in Figure 6. This model does not give the wave field stationarity required for convergence (note that the shift of the wave field in Figure 6 relative to that in Figure 4); however, as is shown in Figure 7, it fits the observed travel times as well as the convergent model does. To choose between the two models is difficult. The first model has converged, but this is a valid indication of a correct solution primarily for laterally homogeneous media. The second model fits the observed times adequately and is slightly simpler but has not converged. For comparison, Figure 8 shows the two average models discussed here along with a shaded area that corresponds to the estimated range of velocities as determined for the same region by two-dimensional ray tracing [Fuis, 1981]. The velocity in the uppermost 2.5 km, which corresponds to fractured granite, is most variable; at these depths our models generally lie within the shaded region. Below 2.5 km the position and velocity gradient of our converged model (curve 1) correspond closely to those of Fuis; those of the smoothed model (curve 2) do not.

In summary, this analysis of the Mojave Desert data illustrates some of the tradeoffs that occur when structure varies

l laterally. Specifically, an equivalent laterally homogeneous velocity-depth curve can be stably estimated, but the finer details of the curve may be related to lateral rather than vertical velocity variation. These effects are not confined to the wave field analysis, but the wave field approach has the advantage of being relatively unbiased as the significance of any region of coherent energy in the data is not established until convergence is obtained. The identification of the possible triplication near 20 km is an example of this.

A SHALLOW MARINE PROFILE CONTAINING PRECRITICAL REFLECTIONS

In a laterally homogeneous region, data in both the common-shot recording geometry and the common midpoint interpretation coordinates used in seismic exploration can be directly inverted by wave field transformation. In this section we present an example of the analysis of a common midpoint gather containing the acoustic response of the uppermost 1 km of sediments in a shallow marine environment. The data are shown in Figure 9.

Figure 10 shows the slant stack of the data in Figure 9. There are some artifacts visible in this wave field; the most prominent ones (labeled T in Figure 10) are due to the truncation of the data at the two ends of the recording cable and appear as coherent straight lines. The p-t image of interest consists of two types of curves. The first is the main trajectory that lies in the (p, t) region from (0.69, 0.0) to (0.45, 0.6).

The strong precritical reflections in these marine data are useful constraints in the downward continuation of the p-t wavefield to produce the model (the solid line in Figure 11). When the correct velocity function is used, precritical reflec-

Fig. 12. Comparison of observed and calculated travel times. The solid lines superposed on the data are times predicted from the model in Figure 11. Arrivals are labeled to correspond to those in Figures 10, 11, and 13.

Fig. 13. Overlay of velocity model on data section. The solid curve is the two-way travel time equivalent of the velocity-depth function in Figure 11. The wave field upon which it is plotted is a near-offset reflection section. The first (left) trace is the near-offset trace from the common midpoint data used to derive the velocity profile. The reflections are labeled to correspond to those in Figures 10-12.
Marine data recorded over a hard bottom typically contain prominent multiple reflections whose peglegs are confined to the water column. (Note that these multiples are not the same as the PP-type refracted multiples analyzed by Clayton and McMechan (1981b).) Analysis of such data can be accomplished by imaging the multiples concurrently with the primary energy. The purpose of the following example is to demonstrate concurrent inversion. The acoustic data that are shown in Figure 14 contain at least four water multiples, of which the first two are directly included in the wavefield inversion presented below. The result of this inversion consists of three images of the velocity-depth profile down to 0.6 km depth.

Figure 15 shows the slant stack of the data in Figure 14. In this wave field a number of water multiples (labeled $M$) are visible. The precise location of the primary $p\tau$ locus is not as clear as in the previous examples because of interference between the primaries and multiples, but it is located approximately between $(p\tau)$ from $(0.67, 0.0)$ to $(0.40, 0.5)$.

To identify and image the multiples, three $p\tau$ wave fields were concurrently downward continued into $p-z$ space. The first of these is the complete $p\tau$ wave field shown in Figure 15. The second is a new $p\tau$ wave field $(p\tau')$ constructed from the first by shifting each $p\tau$ trace toward smaller $\tau$. The amount of shift at each $p\tau$ is equal to the $\tau$ of the primary water bottom reflection of the same $p$:

$$\tau'(p) = \tau(p) - 2 \frac{h}{v} (1 - p^2 v^2)^{1/2}$$

where $h$ and $v$ are the thickness and velocity of the water layer. Inversion of this modified wave field images the first multiple. Similarly, for imaging the second multiple, another $p\tau$ wave field was constructed by subtracting twice the primary water reflection $\tau$ at each $p$. The result of concurrent imaging of these three $p\tau$ wave fields is the three $p-z$ wave fields in Figure 16. The solid line superimposed on all three $p-z$ wave fields corresponds to the final $p\tau$ locus. The uncertainty in this locus is seen to be of the order of $\pm 0.025$ km. In Figure 16a, $P_1$ is the precritical primary water bottom reflection and $P_2$ is the precritical primary reflection from a discontinuity near 0.35 km depth.
Fig. 16. Concurrent imaging of three p-z wave fields. (a) The inversion based on the primary energy, (b) The first multiple, (c) The second multiple. All three image the same p-z curve (the dotted line that is superimposed on each). In each panel, the successive images are numbered: 1 for the primary image, 2 for the first multiple image, 3 for the second multiple, and so forth. Branches labeled M and P are precritical reflections discussed in the text.

Fig. 17. Comparison of two velocity analyses of the data in Figure 14. Curve 1 is the two-way travel time profile corresponding to the velocity profile plotted in the three panels of Figure 16; 2 is the corresponding rms time profile; 3 is the rms time profile of Schultz [1980]; 4 is the time profile corresponding to 3. Curve 1 is to be compared with 4; 2 with 3.

Discussion and Summary

One of the advantages of the wave field transformation approach is that no preprocessing of the data is required. The complete data set is used in raw form, so the final image contains no arbitrary selection of data. For analysis of largescale refraction profiles, such as the Mojave Desert data, wave field transformation produces a solution in a matter of hours. For exploration (reflection) oriented processing, wave field transformation of refractions provides a method of extracting independent velocity information from a portion of the wave field that has previously been neglected by conventional analyses.

The method of refraction inversion by wave field transformation has been illustrated by application to three rather different data sets, one recorded on land in a common shot refraction geometry, and the other two recorded in shallow marine environments with standard acoustic exploration cables. In all three cases, the results obtained are compatible with those of conventional processing. Wave field transformation is seen to be robust, unbiased, and particularly suited to processing large volumes of data. These features, combined with the conceptual elegance involved in forming the solution...
from the data itself, encourage further development and application of the method.
