ABSTRACT

We present extensive photometric and spectroscopic observations of PTF1 J071912.13+485834.0, an outbursting AM CVn system discovered by the Palomar Transient Factory (PTF). AM CVn systems are stellar binaries with some of the smallest separations known and orbital periods ranging from 5 to 65 minutes. They are believed to be composed of a white dwarf accretor and a (semi-)degenerate He-rich donor and are considered to be the helium equivalents of Cataclysmic Variables. We have spectroscopically and photometrically identified an orbital period of 26.77 ± 0.02 minutes for PTF1 J071912.13+485834.0 and found a super-outburst recurrence time of greater than 65 days along with the presence of “normal” outbursts — rarely seen in AM CVn systems but well known in super-outbursting Cataclysmic Variables. We present a long-term light curve over two super-cycles as well as high cadence photometry of both outburst and quiescent stages, both of which show clear variability. We also compare both the outburst and quiescent spectra of PTF1 J071912.13+485834.0 to other known AM CVn systems, and use the quiescent phase-resolved spectroscopy to determine the origin of the photometric variability. Finally, we draw parallels between the different subclasses of SU UMa-type Cataclysmic Variables and outbursting AM CVn systems. We conclude by predicting that the Palomar Transient Factory may more than double the number of outbursting AM CVn systems known, which would greatly increase our understanding of AM CVn systems.

Subject headings: accretion, accretion disks — binaries: close — novae, cataclysmic variables — stars:

1. INTRODUCTION

AM CVn systems — ultra-compact semi-detached binaries — are stellar binaries with some of the smallest separations known. They have been found with orbital periods ranging from 5 to 65 minutes. The prototype, AM CVn, was initially identified as a possible binary star by Smak (1967) and was eventually theorized to be composed of a relatively massive white dwarf accretor and a much lower mass semi-degenerate or degenerate helium-transferring donor (Paczynski 1967; Faulkner et al. 1972). AM CVn systems are believed to be one of the strongest Galactic low-frequency gravitational wave sources (Nelemans et al. 2004; Roelofs et al. 2007a) and the source of the proposed “Ia” supernovae (Bildsten et al. 2007). We refer the reader to Nelemans (2003) and Solheim (2010) for reviews.

Short period systems — those with orbital periods below roughly 20 minutes — are in a constant state of high mass transfer from the secondary to the optically thick accretion disk. They are known as “high” state systems, and their spectra, dominated by the accretion disk, are characterized by broad, shallow helium absorption lines with few other features. High state systems have been observed to have superhumps — photometric variability of ~ 0.1 mag with a period slightly longer than the orbital period (e.g. Patterson et al. 1997) — similar to those found in SU UMa-type Cataclysmic Variables (Osaki 1990).

At the other end of the period range are the quiescent systems with orbital periods above roughly 40 minutes. They are believed to have low mass transfer rates and an optically thin disk. Instead of absorption lines, these systems have prominent helium emission lines in their spectra. Quiescent systems do not show prominent photometric variability.

Between these two period ranges are the so-called “outbursting” AM CVn systems, which feature outbursts similar to those found in dwarf novae-type Cataclysmic Variables. While in the “high” state, these systems exhibit the properties of short-period AM CVn systems, and while in the “quiescent” state, they exhibit properties of the long-period AM CVn systems (see e.g. Roelofs et al. 2007a). In outburst they are typically 3-5 magnitudes brighter than in quiescence and feature...
superhumps. These outbursts tend to last for a few weeks, and recur on a timescale (where known) between 46 days (e.g. Kato et al. 2000) and over a year (e.g. Copperwheat et al. 2011). Between the two states, some of these systems have been observed to have a “cycling” state wherein some experience magnitude changes of ~ 1 mag with a period of about a day (Patterson et al. 2000). One system, CR Boo, has also been found to have “normal” outbursts that last 1-2 days and recur every 4-8 days (Kato et al. 2000), as opposed to the longer “super-outbursts” described previously.

AM CVn systems have been extensively compared to Cataclysmic Variables (CVs). Of primary interest for this comparison are the SU UMa-type dwarf novae-type CVs, which exhibit both super-outbursts and normal outbursts, but with somewhat longer typical recurrence times than outbursting AM CVn systems. See Warnier (1995) for an extensive review. While the photometric behavior is similar between dwarf novae and AM CVn systems, the chemical composition, structure of the donor, and evolutionary pathways are very different.

Only 26 AM CVn systems have been reported in the literature. Being intrinsically rare and with colors similar to those of ordinary white dwarfs, they are difficult to discover and population estimates have proven to be difficult to calculate (e.g. Nelemans et al. 2001; Roelofs et al. 2007). Initially, AM CVn systems were serendipitous discoveries, typically as a result of their photometric variability or color. More recently, the population has almost doubled as a result of the Sloan Digital Sky Survey (SDSS). Seven systems were discovered from a search for spectra containing helium emission lines (Roelofs et al. 2002; Anderson et al. 2003, 2008) and five more from a follow-up color selection and spectroscopic survey (Roelofs et al. 2009; Rau et al. 2010).

However, the wide variety of photometric variability exhibited by AM CVn systems makes them an effective target for large-scale, synoptic surveys. The most recent published new AM CVn system, with an orbital period of 15.6 minutes, was discovered in Kepler satellite data from its superhump-induced photometric variability (Fontaine et al. 2011). Here, we present a new AM CVn system discovered in outburst by the Palomar Transient Factory — the first system discovered by a systematic, synoptic survey covering thousands of square degrees.

The Palomar Transient Factory (PTF) uses the Oschin 48-inch telescope (P48) at the Palomar Observatory to image 7.2 deg$^2$ with each exposure. In a typical night, up to ~ 2,000 deg$^2$ are observed to a depth of $R \sim 20.6$ (Law et al. 2009; Rau et al. 2009).

We begin by describing the discovery of PTF1J071912.13+485834.4 (hereafter PTF1J0719+4858) and summarizing our follow-up observations. In §3 we present photometric observations. We describe the features of both outburst and quiescent spectra in §4 as well as the determination of the spectroscopic period from phase-resolved spectroscopy. In §5 we compare PTF1J0719+4858 to other outbursting AM CVn systems, discuss the source of the quiescent photometric variability, and consider how many more such systems can be discovered by PTF. Finally, we summarize in §6.

2. DISCOVERY AND SUMMARY OF OBSERVATIONS

PTF1J0719+4858 was detected in outburst by the Palomar Transient Factory at $R = 15.8$ on 2009 December 01 and classified as a transient with the designation PTF09hpl. A graphical summary of the PTF photometry can be found in Figure 1. A classification spectrum was taken using Keck-I/LRIS (McCarthy et al. 1998) on 2010 January 14 and reduced using standard IRAF tasks. Noticing the lack of a redshift, the PTF extragalactic team classified the spectrum as a Cataclysmic Variable. In a subsequent inspection of the PTF spectral database, we noticed the presence of multiple distinct, double-peaked helium emission lines, some with a central peak (we refer the reader to §4.2 which contains a high signal-to-noise quiescence spectrum), and it was re-classified as an AM CVn system candidate.

We focused our follow-up efforts on both long-term monitoring and short time-scale variability studies, using the Palomar 60” telescope (P60) and two telescopes from the Las Cumbres Observatory Global Telescope Network (LCOGT; Shporer et al. 2010): the 2-m Faulkes Telescope North (FTN) and the 32” Byrne Observatory at Sedwick (BOS). Between October 2010 and March 2011, we obtained a total of 195 exposures in good weather for our long-term photometric monitoring campaign using P60 and FTN with a goal of obtaining at least one exposure per night. We present this light curve in §3.2. We also observed PTF1J0719+4858 at high cadence several times to characterize the photometric variability on the order of the orbital period, both in quiescence and in outburst. We discuss the periods identified from these

11 http://www.astro.caltech.edu/ptf
12 PTF refers to preliminary versions of the PTF catalog, as opposed to sources from the final catalog, which will use “PTF”. It is possible that a source in the PTF1 catalog will have slightly different coordinates in the PTF catalog.
observations in §3.3.

Besides photometric observations, we also obtained individual spectra of PTF1J0719+4858 on multiple nights, as well as phase-resolved spectroscopy. Individual spectra of PTF1J0719+4858 were obtained with Keck-I, the William Herschel Telescope, and the Palomar 200" Hale Telescope in October and November, 2010. To obtain the orbital period, we obtained roughly four hours of spectroscopic observations with Keck-I/LRIS using three minute exposures. These observations are presented in §4.2.

3. PHOTOMETRIC OBSERVATIONS AND RESULTS

3.1. Analysis and Reduction Process

Palomar 60" data was de-biased and flat-fielded using the P60 pipeline (Cenko et al. 2006). The FTN data was processed using the LCOGT pipeline. The BOS data was de-biased and flat-fielded using IRAF tasks, astrometrically calibrated using ASTROMETRY.NET (Lang et al. 2010) and cosmic rays were removed using the L.A. COSMIC algorithm (van Dokkum 2001). The SEXTRACTOR package (Bertin & Arnouts 1996) was used to identify sources in each exposure and their instrumental magnitudes were obtained using optimal point spread function photometry (Naylor 1998) as implemented by the STARLINK package AUTOPHOTOM.

Light curves were calculated using a matrix-based, least squares minimization, relative photometry algorithm. The primary goal of any such algorithm is to minimize noise, typically by assuming certain stars in the field are non-variable and identifying an optimal zero point for the exposure. We expanded on this to simultaneously solve for both the zero-point and additional de-trending terms that corrected for airmass and instrumental magnitudes were obtained using optimal point spread function photometry (Naylor 1998) as implemented by the STARLINK package AUTOPHOTOM.

To accomplish the de-trending, we modeled each observation as

\[ m_{i,j} = \bar{M}_j + Z_i + \alpha c_j A_i + \sum_{k=1}^{n_k} \beta_k c_j \]

where the needed data is:

- \( m_{i,j} \): the magnitude of source \( j \) on exposure \( i \).
- \( c_j \): a color for each source. The color is required to compensate for the stronger effects of airmass on blue stars, as well as the the differences in CCD efficiency over a range of wavelengths. For our light curves, we used \( c_j = g_j'−r_j' \), where \( g_j' \) and \( r_j' \) refer to the magnitudes of the \( j \)th source in the respective SDSS filters.
- \( A_i \): the airmass of each exposure.

and the terms to be fitted are:

- \( Z_i \): the optimal zero-point term of each exposure.
- \( \bar{M}_j \): the mean magnitude term of the source.

\[ \alpha, \beta_k \] are the airmass calibration coefficient for all exposures and sources

\[ \beta_k \] is the \( k \)th telescope/instrument calibration coefficient, for \( k = 1,2,\ldots,n_k \) where \( n_k \) is the number of telescopes. This term is introduced to take into account the different responses of each telescope/instrument. For light curves with data from only one instrument, these terms were not used.

It is important to ensure that all stars used for the solution (“calibration stars”) are themselves not variable. We restricted the stars used to those found in 80–100% of exposures, depending on the light curve, and iteratively removed any sources with high residuals. Since the solution is not unique unless reference magnitudes are provided, we used blue magnitudes from USNO-B 1.0.

This algorithm provided very good results — even light curves taken over months with different telescopes and conditions obtained a magnitude scatter (RMS) of \( \sim 0.035 \) mag for \( g' \approx 16 \) and \( \sim 0.055 \) mag for \( g' \approx 19.4 \), the quiescent magnitude of PTF1J0719+4858. The RMS errors provided with the figures in this paper are based on the median scatter of other stars with similar magnitude present in at least 50% of observations. Additionally, individual errors — the combination of the Poisson error and the fit errors — are provided for some of the light curves. These are typically very close to the magnitude scatter, except for those exposures obtained during bad weather.

For high cadence light curves, period analysis was performed with SIGSPEC (Reegen 2007). All default options were used, except as noted for individual cases, and weights for measurements were always provided. SIGSPEC produces a list of significant periods and corresponding “sig” values. A “sig” value of \( c \) means that the period has a chance of 1 in \( 10^c \) of being noise.

3.2. Long-term Photometric Behavior

The long term light curve of PTF1J0719+4858 from FTN and P60 is presented in Figure 2. We note the pattern of “high” states and “quiescent” states. Additionally, we note the presence of “normal” outbursts (as opposed to the “super-outbursts” more commonly associated with AM CVn systems). We observed the January 2011 super-outburst in its entirety and find a rise time from the last measurement in quiescence to the peak magnitude of 3.2 days with \( \Delta \text{mag} = 3.6 \). Immediately following this rise, we see a drop to a plateau that may be the cycling state seen in other AM CVn systems (e.g. Patterson et al. 2000). Finally, 22 days after the beginning of the super-outburst, PTF1J0719+4858 returned to quiescence.

The recurrence time was significantly different between the two super-cycles we observed. We approximate (assuming the behavior of the super-outburst itself is the same) that the recurrence time from the first super-outburst to the second was 65 days. However, the recurrence time from the second super-outburst to the third is greater than 78 days (this uncertainty is due to weather impacting our observations).

Between super-outbursts, we observed normal outbursts in PTF1J0719+4858, which have also been iden-
The light curve contains 41 exposures, with 14 from P60 (60 s), 15 from FTN (60 s), and 12 from BOS (300 s). 45 calibration stars were used. At $g' \approx 17$, RMS $\approx 0.02$ mag and at $g' \approx 19.5$, RMS $\approx 0.04$ mag.

### 3.3. High-Cadence Photometry

Short-term photometric variability was detected in several high cadence observations of PTF1J0719+4858 (see Table 1 and labels in Figure 2).

During the first super-outburst (labeled HC1), we de-

Fig. 4. — Superhumps of PTF1J0719+4858. The light curve was constructed using 12 calibration stars, and other sources at this magnitude had an RMS of ∼ 0.015 mag. The shape is consistent with superhumps in similar systems such as CR Boo (Patterson et al. 1997) and KL Dra (Wood et al. 2002). The quiescence spectrum features very broad, double-peaked emission lines, some with a possible central spike. The broadness of the lines makes their presence difficult to discern, albeit λ4200 is seen in the spectrum, as well as Fe II, Si, and Na II lines. The quiescent photometric period to determine a mass ratio (Patterson et al. 2003).

We also obtained a set of high-cadence observations (labeled HC2) obtained almost immediately after PTF1J0719+4858 returned to quiescence following the first observed super-outburst. Here, we see photometric variability of Δmag ≈ 0.2. We performed a StiGSpec analysis of the light curve for these two nights with the AntiAIC anti-aliasing feature enabled and found a period of 1606.3 ± 2.5 s with a “sig” of 13.7. Since we observed many periods of this variability, we present a phase-binned light curve in Figure 5. Additional observations that allow a more precise determination of the superhump period could be used along with the quiescent photometric period to determine a mass ratio (Patterson et al. 2003).

4. SPECTROSCOPIC OBSERVATIONS AND RESULTS

4.1. Follow-up Spectra

The identification spectra were reduced as part of the PTF spectroscopic program using standard IRAF tasks. We present a typical outburst spectrum — taken with WHT/ACAM (Bean et al. 2008) on 2010 November 6 and labeled as OS in Figure 2 — in Figure 6 with the prominent lines identified. The outburst spectra varied slightly, with absorption lines being more prominent on some than on others. However, He I λ4471 was always visible. The best spectrum in quiescence is the co-added spectrum of the phase-resolved observations, shown in Figure 7 again with lines identified.

The quiescence spectrum features very broad, double-peaked emission lines, some with a possible central spike. Shortward of 4000 Å, the spectrum shows an interplay of lines that is consistent with Ca II H & K emission interwoven with He I λ3888 (see Roelofs et al. 2006a), but the low resolution of the current observation and the broadness of the lines makes their presence difficult to establish. We can establish the presence of Fe II, Si, and N I emission lines in the rest of the spectrum. It is also possible that He II λ4200 is seen in the spectrum, albeit very weak. He II λ4200 has not been previously seen in an AM CVn system. In the outburst spectrum, we see weak absorption lines of He I and He II, as well as Fe II. Si is not seen, but we note the presence of N I λ8223, which has not been seen this strong in other high-state AM CVn systems.

Table 2 lists the equivalent widths of the most prominent emission lines. Based on the presence of the noted elements, we find that that the spectra of PTF1J0719+4858 are most similar to those of 2003aw (Roelofs et al. 2006a) and SDSSJ0804+1616 (Roelofs et al. 2009). Future work in identifying abundances may shed light on the chemical composition and evolutionary history of such systems (Nelemans et al. 2010).
Fig. 6.— Outburst spectrum of PTF110719+4858 taken with WHT/ACAM on 2010 November 6. Strong helium absorption lines are present throughout the spectrum, as well as a Fe II lines. We also highlight the N I λ8223 absorption line, which has not been seen before in an AM CVn system in the high state.

4.2. High Speed Spectroscopy in Quiescence

Here, we discuss the phase resolved spectroscopy undertaken at the Keck Observatory (see Table 3). The spectra were reduced using optimal extraction (Horne 1986) as implemented in the PAMELA code (Marsh 1989) as well as the STARLINK packages KAPPA, FIGARO, and CONVERT. For these exposures, wavelength calibration exposures were taken at the beginning, middle, and end of each set of observations using the Hg, Cd, and Zn lamps for the blue CCD and the Ne and Ar lamps for the red CCD. Wavelength calibration for individual spectra was interpolated between these calibration spectra. We present a co-added spectrum in Figure 7.

We use a technique similar to previous analyses of AM CVn system phase-resolved spectra, first developed by Nather et al. (1981), to establish the orbital period. Each spectrum was rebinned to the same wavelengths and the location of individual emission lines were identified. Because of the large number of cosmic rays on the red side despite processing with L.A. COSMIC (van Dokkum 2001), we concentrated on the blue side and used the helium lines at 4026 Å, 4387 Å, 4471 Å, 4686 Å, 4921 Å, and 5015 Å. The lines from each exposure were re-binned and co-added to produce a summed He emission line. We then subtracted the red 40% of the line from the blue 40% of the line, and divided by the continuum. This produced a time series of flux ratios, which we analyzed using SIGSPEC. We identified a period of $1606.2 \pm 0.9$ s with a “sig” of 3.1. The statistical significance spectrum is in Figure 8.

While not a very high confidence level, we believe the above period is, in fact, the orbital period, for two reasons. First, the period found is within the error bars of the previously discussed quiescent photometric period (see 8). Second, the movement of the disk’s hotspot can be identified by creating a phase-binned, trailed spectrum of the He emission line. The rotation of

* Spectral × Spatial
the disk produces an “S-wave” that has been observed previously in known systems (e.g. Roelofs et al. 2005, Rau et al. 2010). In the case of PTF1J0719+4858, this S-wave is very weak, but still discernible. We present the trailed spectrum in Figure 9. This is not the first system where the S-wave was difficult to detect. As reported in Roelofs et al. (2009), an S-wave in SDSSJ0804+1616 was not found in one of two sets of spectra. Further observations are required to establish whether PTF1J0719+4858 has similar variability in the strength of the S-wave or if it is simply a weak feature.

5. DISCUSSION

5.1. Comparison of long-term light curve with that of other AM CVn systems

We broadly group the known outbursting AM CVn systems into two categories: those having super-outbursts that occur at least every three months and those with less frequent super-outbursts. The latter group has either poorly determined or undetermined recurrence times. We summarize their properties in Table 4.
AM CVn systems have positive cate that these systems are more akin to the WZ Sge-of the longer period outbursting AM CVn systems indi-
treme case. On the other hand, the recurrence times
bursting systems appear to have fairly similar behavior,
able. However, given that all four of the frequently out-
hehelium equivalent of an ER UMa-type Cataclysmic V ari-
atives between 90 and 120 minutes (Osaki 1996), but have
rence times of several hundred days and orbital peri-
UMa-type systems typically have super-outburst recur-
ors between 90 and 120 minutes (Osaki 1996), but have
 recurrence times of decades and lower
days (Buat-Ménard & Hameury 2002), while WZ Sge-
type systems have recurrence times between 19 and 45
ods between 90 and 120 minutes (Osaki 1996), but have
rence times of several hundred days and orbital peri-
ponents also place a role (such as the mass of the
mass transfer with greater orbital periods. Additional
dcoveries of AM CVn systems, as well as better, more
 systematic observations of known systems, are necessary to
understand the reality of the difference in recurrence
times.

5.2. Origin of photometric variability in quiescence

The high-cadence photometric observations discussed in §3.3 and labeled as HC3 were coincident with the phase-resolved spectroscopy discussed in §4.2, providing us with an opportunity to determine the source of the observed photometric variability. We present a binned, phase-folded photometric light curve in Figure 10, together with the radial velocity of the hot spot. The binning provides an increase in the signal-to-noise and gives a roughly 5σ detection. We remind the reader that HC3 was observed in quiescence, during which time superhumps are not believed to occur in either AM CVn systems or CVs.

The increase in brightness immediately follows the blue-shifted portion of the radial velocity curve and is coincident with a lack of radial velocity. This indicates that the photometric variability in PTF1J0719+4858 is caused by the hot spot and the associated heated edge of the disk being closest to the observer (see drawings in Figure 10). We assume here that the S-wave is, in fact, caused by the hot spot.

AM CVn system variability in quiescence has been observed for other non-eclipsing systems such as CR Boo (Provencal et al. 1997) and KL Dra (Wood et al. 2002), but no study has been done of the origin. However, such studies for CVs have linked the hot spot to the observed photometric variability (e.g. Schoembs & Hartmann 1983).

The concern with this explanation is the lack of preci-
sion in the photometric data and the lack of time resolu-
tion as a result of the binning. This also makes it difficult to compare Figure 10 to observations of other AM CVn systems or CVs. However, we believe that there is sufficient data to link the quiescent variability to the location of the hotspot relative to the observer.

5.3. Potential for future discoveries with PTF

How many additional AM CVn systems might be dis-
covered by PTF? First, we estimate the fraction of all

* Reported as 46.3 d in Kato et al. (2000), but reported as variable in Kato et al. (2001) based on additional data
b Superhump period
c These systems have no published recurrence time, but it is believed to be significantly longer than 3 months

It appears that these sources can be cleanly divided by orbital period, with the break between 1606 s and 1699 s. For the first group, the recurrence times are fairly well determined and appear to correlate with the orbital period. The second group is more difficult to understand, primarily due to a lack of known recurrence times. The one published recurrence time, for SDSSJ0926, is very poorly determined (Copperwheat et al. 2011). However, there does appear to be a clear gap between the determined recurrence times of PTF1J0719+4858 and much more poorly determined recurrence time of SDSSJ0926+3624, and we question whether this difference in recurrence time is purely a result of the increased orbital period (and thus decreased mass transfer rates) or if different parameters also play a role (such as the mass of the primary and/or the entropy of the secondary).

We can draw parallels to the much more common Cataclysmic Variables (CVs). The class of CVs most like outbursting AM CVn systems are the SU UMa-type CVs, which also exhibit both normal outbursts and super-outbursts with superhumps (Warner 1995). SU UMa-type systems typically have super-outburst recurrence times of several hundred days and orbital periods between 90 and 120 minutes (Osaki 1996), but have been found to have two extreme cases. The ER UMa-type systems have recurrence times between 19 and 45 days (Buat-Ménard & Hameurs 2002), while WZ Sge-type systems have recurrence times of decades and lower orbital periods of 80–90 minutes. The long recurrence times of WZ Sge-type systems are explained by the lower mass transfer rates of WZ Sge-type systems, as a result of their more evolved state (CVs are believed to have negative $\dot{P}$, as opposed to AM CVn systems: Osaki 1996).

In Kato et al. (2000), CR Boo was proposed to be the helium equivalent of an ER UMa-type Cataclysmic Variable. However, given that all four of the frequently outbursting systems appear to have fairly similar behavior, we believe that this is typical behavior for AM CVn systems with these orbital periods, as opposed to an extreme case. On the other hand, the recurrence times of the longer period outbursting AM CVn systems indicate that these systems are more akin to the WZ Sge-type CVs. This is consistent with the assumption that AM CVn systems have positive $\dot{P}$ and thus have lower mass transfer with greater orbital periods. Additional discoveries of AM CVn systems, as well as better, more systematic observations of known systems, are necessary to understand the reality of the difference in recurrence times.
AM CVn systems that are outbursting. Consider a simple model of a single system’s evolution by assuming that gravitational wave radiation and angular momentum loss from mass transfer are solely responsible for the evolution of the orbital period (Paczyński 1967; Nelemans et al. 2001). Then, using typical mass values for an AM CVn system at its minimum period (0.6$M_\odot$ & 0.25$M_\odot$, although similar values do not significantly affect the results) we find that an AM CVn system spends $\sim 0.5\%$ of its life between orbital periods of 20 and 27 minutes (the frequent outbursters) and $\sim 3.3\%$ of its life between orbital periods of 27 and 40 minutes (the less frequent outbursters). We use these numbers as a simple estimate of the percentage of AM CVn systems that are outbursting.

We now estimate the number of systems PTF could discover. Given that AM CVn systems have outbursts with $\Delta$mag $\gtrsim 3$, we conservatively assume that any outbursting system with a quiescent magnitude of $\lesssim 23$ can be detected in outburst by PTF. We assume a scale height of 300 pc (Roelofs et al. 2007b) and a scale length of 2.5 kpc (Sackett 1997) in the Galaxy and an AM CVn system space density of $\rho_0 = 3.1 \times 10^{-6}$ pc$^{-3}$ (the observed space density based on pessimistic population models from Roelofs et al. 2007b). Given that the systems are in quiescence, we further assume that the accretor provides all of the system’s luminosity, and use eq. (5) from Roelofs et al. (2007b), which is a parametrization of Figure 2 in Bildsten et al. (2006), to calculate the absolute magnitudes of the AM CVn systems. This likely means that our estimate is conservative since the disk is known to provide part of the luminosity ($\sim 30\%$ for SDSSJ0926+3624; see Marsh et al. 2007) in quiescence. We find that there are approximately 1.3 systems$^{-1}$ per 100 deg$^{-2}$ with orbital periods between 20 and 40 minutes and at $20^\circ < |b| < 60^\circ$ (the galactic latitudes for most of PTF’s observations). Given PTF’s footprint of 10,000 deg$^2$, we estimate that PTF might detect up to 136 such systems. However, the uncertainty in the AM CVn system population density estimates likely means that this number is only accurate to within a factor of 10.

However, the apparent long outburst recurrence times of longer period systems will make these much more difficult to detect. If we consider only those systems with frequent outbursts and thus orbital periods between 20 and 27 minutes, we find that there are up to 18 such systems. Given the recurrence times of 45–80 days, the presence of normal outbursts in at least two systems, and the super-outburst duty cycle of 30–50%, it is very likely that all 18 systems can be detected as part of the PTF transient search.

We note that searches in lower galactic latitudes make detection much more likely. The population distribution of outbursting AM CVn systems almost doubles between $20^\circ < |b| < 25^\circ$ to $15^\circ < |b| < 20^\circ$. Although the analysis of lower-latitude data is more difficult due to the larger number of sources overall, it still presents the best opportunity to discover a large number of AM CVn sys-
tems. Despite the exciting possibilities of using synoptic surveys to search for outbursting systems with quiescent magnitudes up to $R \sim 23-25$ (and even deeper for future surveys), we caution that confirmation of these systems will be difficult. The established method for finding orbital periods is via phase-resolved spectroscopy, requiring large telescopes and short exposure times for even fairly bright objects. Even objects with a quiescent magnitude of $R \sim 23$ cannot be observed in such a fashion with today's telescopes. Instead, such systems can be observed in outburst. The hot spot has been observed in high state AM CVn systems (Roelofs et al. 2006) and it is likely that it can be seen in the high state of outbursting systems as well. Additionally, as demonstrated with PTF1J0719+4858 and other AM CVn systems, photometric periods can be obtained from both superhumps (and potentially) in quiescence, providing a good estimate of the orbital period.

6. SUMMARY

We have presented extensive photometric and spectroscopic observations of PTF1J071912.13+485834.0. We have observed the system in both quiescence and outburst, observing the strong emission lines and a weak photometric period in the former, and absorption lines and detectable superhumps in the latter. From the phase-resolved spectroscopy, we have identified a weak, albeit detectable, signal in the spectrum that indicates an orbital period of 1606.2 ± 0.9 s. This data has, in combination with the simultaneous high-cadence photometry, allowed us to determine the possible source of the quiescent photometric variability. We have also looked at the long-term light curve and found a variable super-outburst recurrence time, as well as regularly occurring normal outbursts. Based on the identified spectroscopic period, the double peaked emission lines in quiescence, and its photometric behavior, we classify PTF1J0719+4858 as an AM CVn system. PTF1J0719+4858 has the longest orbital period of known, frequently outbursting AM CVn systems. We have calculated that PTF has the capability to significantly increase the number of such systems and potentially find many more systems with less regular outbursts. Additional discoveries would expand our understanding of both the structure and evolution of AM CVn systems and their population density.

Observations obtained with the Samuel Oschin Telescope at the Palomar Observatory as part of the Palomar Transient Factory project, a scientific collaboration between the California Institute of Technology, Columbia University, Las Cumbres Observatory, the Lawrence Berkeley National Laboratory, the National Energy Research Scientific Computing Center, the University of Oxford, and the Weizmann Institute of Science. Some of the data presented herein were obtained at the W.M. Keck Observatory, which is operated as a scientific partnership among the California Institute of Technology, the University of California and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W.M. Keck Foundation. The William Herschel Telescope is operated on the island of La Palma by the Isaac Newton Group in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofisica de Canarias. This paper uses observations obtained with facilities of the Las Cumbres Observatory Global Telescope. The Byrne Observatory at Sedgwick (BOS) is operated by the Las Cumbres Observatory Global Telescope Network and is located at the Sedgwick Reserve, a part of the University of California Natural Reserve System.

S.B.C. wishes to acknowledge generous support from Gary and Cynthia Bengier, the Richard and Rhoda Goldman Fund, National Aeronautics and Space Administration (NASA)/Swift grant NNX10AI21G, NASA/Fermi grant NNX10A057G, and National Science Foundation (NSF) grant AST–0908886.
