The momentum spectrum of the alpha particles from the $\text{Be}^9(\alpha,\alpha)\text{Li}^4$ reaction has been measured in a magnetic spectrometer at $30^\circ$ with 10-MeV incident proton energy. The discrete alpha-particle groups observed correspond to states in $\text{Li}^4$ at 0, 2.19, 3.55, 4.40, and 5.32-MeV excitation energy. Higher excited states are obscured at all angles by observation of the continuous alpha spectrum from the breakup in flight of $\text{Be}^9$, $\text{Li}^4$, $\text{Be}^9$, and $\text{B}^9$.

INTRODUCTION

The energy spectrum of the alpha particles from the reaction $\text{Be}^9(\alpha,\alpha)\text{Li}^4$ provides a simple and direct method for investigating the excited states of $\text{Li}^4$. States with both isotopic spins, 0 and 1, are excited in this reaction, and stable targets are available in thin self-supporting foils of high purity. Earlier precision measurements of the alpha-particle spectrum by magnetic analysis revealed transitions only to the ground state and first two excited states. We have repeated this experiment at a higher bombarding energy, with observations at a number of laboratory angles, to search for transitions to other excited states in $\text{Li}^4$.

EXPERIMENTAL ARRANGEMENT

A 10-MeV proton beam was obtained from the ONR-CIT tandem accelerator. The magnetic analyzer for the beam energy was calibrated against the $\text{Al}^{27}(\alpha,\alpha)\text{Si}^{27}$ threshold at $5.800\pm0.008$ MeV. Entrance and exit slits of the beam-analyzing magnet were set to limit the momentum spread of the incident-proton beam to $P/\Delta P = 450$, where $\Delta P$ is the full width at

![Momentum spectrum of alpha particles from $\text{Be}^9(\alpha,\alpha)\text{Li}^4$ at 30° laboratory angle, 10-MeV incident proton energy. The momentum interval $\Delta P$ is $P/360$. The arrows indicate the location of alpha groups corresponding to the excited states of $\text{Li}^4$. The excitation energies in parentheses, for states not seen in this experiment, are taken from Ref. 5. The $\text{Be}^{9+}$ ions are from elastic scattering of H in the target.]

half-maximum of the momentum distribution. The proton beam of 0.3–1 μA passed through the thin self-supporting beryllium foil target and then into a cup which stopped the beam and permitted a measurement of the total charge of protons hitting the target. The foil thickness, determined from the energy loss of alpha particles passing through the foil, varied between 35 and 200 μg/cm² for the different targets used.

The 180°, double-focusing magnetic spectrometer of 61 cm radius measured the momentum of the alpha particles produced in the reaction. A 6.35-mm collector slit, providing a momentum resolution of \( P / \Delta P = 360 \), was used to survey the spectrum, and a finer resolution of 720 was used to determine the widths and positions of the discrete groups observed. The entrance aperture of the spectrometer was reduced so that the energy spread of the particles entering the spectrometer was equal to the energy interval defined by the collector slit. The spectrometer magnetometer, a nuclear magnetic resonance device, was calibrated with the ThC³alpha line at 8.7841±0.0028 MeV.

A surface barrier detector with pulse-height analyzer measured \( dE/dX \) of the particles passing through the collector slit to provide unambiguous identification of alpha particles in the presence of protons of the same energy. Triply charged Be²⁺ ions were also detected by this counter; they were recognized by their large energy loss in target and were clearly identified by their energy loss in a thin foil that could be placed in front of the counter.

RESULTS AND DISCUSSION

The momentum spectrum of alpha particles observed at a laboratory angle of 30° is shown in Fig. 1. The continuous spectrum extending up to 8 MeV comes from the breakup in flight of Li³⁺, Be²⁺, Be³⁺, and B⁺. Similar spectra were taken at 15°, 45°, 90°, and 150° in an effort to obtain better discrimination between the discrete alpha-particle groups and the continuous background, but, at all angles, the continuous spectrum was equally troublesome. Attempts to observe the recoil Li⁶ nucleus in a counter located in the target chamber, in coincidence with the alpha particle detected in the spectrometer, revealed only the transitions to the ground state and the 3.55-MeV state.

The location and widths of the excited states in Li⁶ corresponding to the discrete alpha groups are given in Table I. The parameters assigned to the 4.4- and 5.3-MeV states were determined from the energy spectrum shown in Fig. 2. Simple resonance shapes of adjustable width, resonant energy, and strength, were subtracted from the observed spectrum, and the resonant parameters were varied until the residual continuous spectrum was a smoothly varying function of alpha-particle energy. The dashed curves in Fig. 2 show the line shapes and continuous spectrum obtained. The locations of these states are relatively insensitive to any reasonable assumption as to the shape of the continuous spectrum, but the widths of these broad states can be determined only approximately in this experiment since they depend critically on the continuous spectrum that is assumed.

Our values for the positions and widths of the first four excited states of Li⁶ are in agreement with the values reported by Allen et al.⁴ from the alpha-particle spectrum from Li⁶(He³⁺,α)Li⁶. The excited states at 5.5, 6.6, 7.4, and 8.37 MeV are not seen in the present experiment, but the very strong continuous spectrum obscures the region where groups corresponding to these states would appear. The width of 0.35 MeV for the 4.4-MeV state is less than the value of ~0.6 MeV reported⁵ from the He⁴⁺-d scattering.

We are indebted to J. H. McNally for help in taking the data.
