Supporting Information

ABSTRACT: The catalytic asymmetric synthesis of alkyl fluorides, particularly α-fluorocarbonyl compounds, has been the focus of substantial effort in recent years. While significant progress has been described in the formation of enantioenriched secondary alkyl fluorides, advances in the generation of tertiary alkyl fluorides have been more limited. Here, we describe a method for the catalytic asymmetric coupling of aryl alkyl ketenes with commercially available N-fluorodibenzenesulfonimide (NFSI) and C₆F₅ONa to furnish tertiary α-fluoroesters. Mechanistic studies are consistent with the hypothesis that the addition of an external nucleophile (C₆F₅ONa) is critical for turnover, releasing the catalyst (PPY*) from an N-acylated intermediate. The available data can be explained by a reaction pathway wherein the enantioselectivity is determined in the turnover-limiting transfer of fluorine from NFSI to a chiral enolate derived from the addition of PPY* to the ketene. The structure and reactivity of the product of this proposed elementary step, an α-fluoro-N-acylpyridinium salt, have been examined.

Because of properties such as the high electronegativity and the small size of fluorine, as well as the relative stability of the C–F bond, the incorporation of fluorine into organic molecules, including stereoselective processes, has become a widely used method in medicinal chemistry for altering the bioactivity of drug candidates. The catalytic enantioselective α-fluorination of carbonyl compounds has been a subject of particular interest, and an array of versatile methods have been described for the generation of such secondary alkyl fluorides. In contrast, except in the case of doubly activated molecules, there has been limited progress in the development of effective processes that furnish tertiary α-fluorocarbonyl compounds, and we are not aware of any methods that directly afford esters, with the exception of kinetic resolutions. Here, we establish that a planar-chiral nucleophilic catalyst (PPY*) can achieve the coupling of a ketene, an electrophilic fluorine source, and an alkoxide, thereby providing such tertiary alkyl fluorides with high enantioselectivity (eq 1). We also present mechanistic studies that help to illuminate the reaction pathway.

In an earlier study, we reported that PPY* can catalyze the asymmetric chlorination of ketenes by 2,2,6,6-tetramethylcyclohexanone to produce tertiary α-chloroesters. When we attempted to extend this halogenation strategy to an analogous enantioselective fluorination of ketenes, building in part on the pioneering work of Lectka on the cinchona alkaloid/palladium/LiClO₄-catalyzed synthesis of secondary alkyl fluorides from acid chlorides and N-fluorodibenzenesulfonimide (NFSI; commercially available), we obtained discouraging results (eq 2).

We postulated that our failure to achieve the desired catalytic asymmetric fluorination might be due to the stability of a potential N-acylpyridinium intermediate (eq 3). Consequently, we decided to determine if the addition to the reaction mixture of a stoichiometric quantity of a more reactive nucleophile might be beneficial. We were, of course, cognizant of the possibility that the nucleophilic additive might react directly with the ketene to generate an achiral enolate and racemic product; fortunately, however, we were able to identify a nucleophile that allowed us to achieve our objective (Table 1).

Whereas the addition of MeOH or PhNH₂ did not result in a significant amount of the desired tertiary alkyl fluoride (Table 1, entries 1 and 2), the use of alkoxides led to a substantial quantity (entries 3–5). In the case of sodium tert-butoxide, the product...
was racemic (entry 3); on the other hand, sodium phenoxide furnished good enantioselectivity (entry 4), and a less nucleophilic phenoxide, sodium pentfluorophenoxide, provided excellent yield and ee (entry 5).14

Our optimized method is effective for the catalytic enantioselective synthesis of tertiary α-fluoroesters from an array of aryl alkyl ketenes (Table 2).15 The alkyl group of the ketene can vary in size from Me to cyclopentyl (entries 1–5; lower ee is observed with larger alkyl groups), and the aromatic substituent can be electron-poor, electron-rich, para-substituted, or meta-substituted (entries 6–9), as well as naphthyl or heteroaryl (entries 10 and 11). On a gram scale, the fluorination illustrated in entry 2 of Table 2 proceeded in 99% ee and 90% yield.

For the reaction conditions, see eq 1. All data are the averages of two experiments.16 Yield of purified product (contains ≤5% of the non-fluorinated ester).16 Catalyst loading: 10%.

Although our other chiral 4-((dimethylamino)pyridine (DMAP)-catalyzed reactions of ketenes have generally not been effective for dialkyl ketenes,16 in the case of this asymmetric fluorination process, we have observed a promising level of enantioselectivity (eq 3).

The enantioenriched α-fluoroesters that are generated in this catalytic asymmetric C–F bond-forming process can be transformed in good yield into a variety of other tertiary alkyl fluorides (Figure 1).

Two of the possible pathways for the PPY*-catalyzed enantioselective fluorination of ketenes to generate enantioenriched tertiary α-fluoroesters are illustrated in Figure 2. In one mechanism, a PPY*-derived chiral enolate (2) is a key intermediate (top), and in the other a PPY*-derived chiral fluorinating agent (4) is critical (bottom).17 To gain insight into the operative pathway, we determined the rate law for the reaction of phenyl ethyl ketene, which is first order in PPY* and in NFSI, and zeroth order in the ketene and in C6F5ONa.18 The rate of product formation does vary with the identity of the ketene, suggesting that the ketene is involved in the rate-determining step.

These observations are consistent with a “chiral enolate” pathway (top of Figure 2); but not with a “chiral fluorinating
agent” pathway (bottom of Figure 2) wherein nucleophilic addition of PPY* to the ketene affords enolate 2, this enolate is the resting state of the catalytic cycle, and, in the turnover-limiting step, enolate 2 is fluorinated by NFSI to provide enantioenriched N-acylpyridinium salt 3. Reaction with the phenoxide then furnishes the tertiary α-fluoroester and regenerates the catalyst, PPY*.

In view of our earlier inability to achieve PPY*-catalyzed asymmetric fluorination of ketenes with NFSI in the absence of an added nucleophile (eq 2), we hypothesized that N-acpyridinium salt 3 (Figure 2) might be isolable. Indeed, reaction of PPY*, phenyl benzyl ketene, and NFSI (1:1:1) provided α-fluorinated acylpyridinium salt 5 (eq 4). This ion pair is stable at room temperature under nitrogen for at least 6 months.

Although we were not able to obtain X-ray-quality crystals of the sulphonamide salt of the N-acpyridinium ion, anion exchange of N(SO₂Ph)₂ with Cs₂CB₁₁H₁₂ furnished a suitable crystal (Figure 3). The pyrrolidino group, the pyridine ring, and the carbonyl group are approximately coplanar, consistent with extended conjugation of the π system, which decreases the electrophilicity of the carbonyl group. With regard to the orientation around the N–C_carbonyl bond, the smaller group (carbonyl oxygen) is positioned on the side of the fused cyclopentadienyl ring, presumably to minimize unfavorable steric interactions. The stereochemistry of the fluorine-bearing carbon of the N-acpyridinium ion is the same as for the major enantiomer of the α-fluoroester that is generated by (+)-PPY* under our standard fluorination conditions.

We have confirmed that N-acpyridinium salt 5 is a chemically and kinetically competent potential intermediate in the proposed catalytic cycle that leads to the enantioenriched tertiary α-fluoroester (top of Figure 2). Thus, upon treatment of this salt with CsF·ONa in THF at −78 °C, the enantioenriched ester is formed with retention of stereochemistry (eq 5). It is interesting to note that this catalyst-regeneration issue from an N-acylated catalyst intermediate is not encountered in “related” processes such as the PPY*-catalyzed α-chlorination of ketenes or the cinchona alkaloid-catalyzed α-fluorination of acid chlorides (via monosubstituted ketenes) to afford secondary α-fluoroesters.

In conclusion, we have described a method for the catalytic enantioselective coupling of aryl alkyl ketenes (and a dialkyl ketene) with NFSI and Cs₂F·ONa to produce tertiary α-fluoroesters, a family of target molecules that have rarely been directly accessed via asymmetric catalysis. The addition of CsF·ONa was critical to the success of this effort, as it enables regeneration of the catalyst (PPY*) from a relatively stable N-acylated intermediate, which we have synthesized and investigated independently. Our mechanistic studies are consistent with a catalytic cycle wherein PPY* adds to the ketene and generates a chiral enolate which, in the stereochemistry- and rate-determining step, reacts with NFSI to furnish the enantioenriched N-acpyridinium salt.
