Cu$_2$SbSe$_4$-based compounds composed of earth-abundant elements have been found to exhibit good thermoelectric performance at medium temperatures. High $zT$ values were achieved in previous studies, but further insight into the transport mechanism as well as some key material parameters is still needed. In this work, we studied the electrical and thermal transport properties of Sn-doped Cu$_2$SbSe$_4$ between 300 K and 673 K. It was found that the single parabolic band model explains the electrical transport very well. Experimentally, we determined the band gap to be around 0.29 eV. The density-of-state effective mass was found to be about 1.5 $m_e$ for the doped samples. The transport properties suggested degeneracy splitting near the valence band maximum that was not captured by previous band structure calculations. The maximum $zT$ ~ 0.70 was obtained at 673 K, and the optimized carrier density was ~1.8 x 10$^{20}$ cm$^{-3}$, and the potential for further improvement of $zT$ via material engineering is briefly discussed.

Introduction

Thermoelectric materials, which can realize the direct conversion between heat and electricity in the solid state, are expected to play a significant role in the field of clean energy development and utilization. Developing thermoelectric materials with a high $zT$, such as superionic Cu$_2$Se$^-$ $^3$ with liquid-like phonon behaviour and layered oxyxenides BiCuSeO,$^6$ has been the main topic of research in thermoelectrics. Recently, copper chalcogenides have received increasing attention as promising thermoelectric materials with a high $zT$, such as superionic Cu$_2$Se$^-$ $^3$ with liquid-like phonon behaviour and layered oxyxenides BiCuSeO.$^6$ Other high-symmetry ternary or multinary copper chalcogenides composed of Cu-M (M is a chalcogen) tetrahedral bonds include chalcopyrite, tetrahedrite and famatinite, etc. Many of these compounds have also been found to be promising thermoelectrics, such as CuGaTe$_2$,$^{14,15}$ CuInTe$_2$,$^{16}$ Cu$_2$Zn$_{0.9}$SnS$_4$, $^{17}$ Cu$_2$ZnGeSe$_4$ $^{18}$ and Cu$_2$SbM$_4$ (M = Se, S), $^{19,20}$ even Cu$_{12}$Sb$_3$S$_{13}$ and Cu$_{12}$As$_4$S$_{13}$ right from their natural mineral form. $^{21,22}$ Among these compounds, Cu$_2$SbSe$_4$ is a p-type semiconductor with a small band gap. Previous investigations have been carried out focusing on adjusting the carrier density and forming solid solutions towards high $zT$. $^{23,24}$

In spite of the knowledge that has already been obtained for Cu$_2$SbSe$_4$, the insight into the transport mechanism as well as some key material parameters that are essential for further optimization towards higher $zT$ is still inadequate. In this work, we take a close look at the transport properties of p-type Cu$_2$SbSe$_4$. Our samples were prepared by mechanical alloying and spark plasma sintering. This simple method led to high quality samples with a homogeneous microstructure, nearly ideal doping efficiency and well behaved transport properties. This compound was found to be a semiconductor with a large effective mass of about 1.5 $m_e$ (when doped) and a small band gap of ~0.29 eV. The transport data also suggest a split of valence bands that was not revealed by previous calculations. These findings provide an in-depth understanding of the promising $zT$ and the possible strategies for further material engineering.

Experimental

Samples with nominal compositions of Cu$_{2.95}$Sb$_{1-x}$Sn$_x$Se$_4$ ($x$ = 0, 0.01, 0.02, 0.03, 0.04) were fabricated via mechanical alloying (MA) and spark plasma sintering (SPS). A Cu deficiency is chosen to compensate for Se volatilization and achieve the best performance, which was discussed in detail in a previous report. $^9$ A mixture of Cu, Sb, Sn and Se powders of high purity were milled in a stainless steel vessel on a planetary ball mill at 425 rpm for 10 hours protected by a mixed atmosphere of 95 vol% Ar and 5 vol% H$_2$ gases and were then milled in an
alcohol solution. The as-synthesized powders were sintered by SPS at 703 K for 5 min under a uniaxial pressure of 50 MPa into disk-shaped samples about 3 mm in thickness and about 93% or higher in relative density.

The phase structures were investigated by X-ray diffraction (XRD) with a D/max-RB diffractometer (Rigaku, Japan) using Cu Kα radiation. Scanning electron microscopy (SEM) images of the bulk materials were taken in the secondary electron detector (SE2) mode and the backscattering electron (BSE) mode by field emission scanning electron microscopy (FE-SEM, JSM-7001, JEOL, Japan). Electronic probe microscopic analysis (EPMA, JXA-8230, JEOL, Japan) was used to analyze the ratio and distribution of the elements on polished surface of bulk samples. Bar-shaped specimens were cut along the radial direction of a disk sample for measurements of the Seebeck coefficient (S) and the electrical resistivity (ρ) as a function of temperature using a Seebeck coefficient/electric resistance measuring system (ZEM-2, Ulvac-Riko, Japan). The Hall coefficient (RH) at and above 300 K was measured under a reversible magnetic field by the van der Pauw technique using a Hall measurement system (8340DC, Toyo, Japan). The Hall carrier density (n_H) was calculated via n_H = 1/(εRH), and the Hall carrier mobility (μ_H) was obtained using the relationship, μ_H = RH/ρ. The thermal diffusivity (D) was measured in the thickness direction of a disk-shaped sample of φ 10 mm and about 1.5 mm in thickness using a laser flash diffusivity method (TC9000, Ulvac-Riko, Japan). The specific heat capacity (C_p) was measured using the Quantum Design physical property measurement system (PPMS) as well as the Netsch LFA 457 laser flash thermoanalysis system. The thermal conductivity (κ) was calculated by κ = DCP/ρ, where d is the density measured by the Archimedes method. Optical absorption edge measurements were carried out on the undoped sample using a Nicolet 6700 FTIR Spectrophotometer equipped with a Praying Mantis Diffuse Reflectance attachment (Harrick Scientific Instruments) at room temperature and up to 573 K. The scans were referenced to KBr standard samples. The optical gaps were obtained by extrapolating \( α \), the absorption coefficient, to 0 as a function of \( (hν)^n \), where \( hν \) is the photon energy, and \( n \) is equal to 2 for direct gaps, 0.5 for indirect gaps.

Results and discussion

The XRD patterns of the samples subjected to SPS are shown in Fig. 1, which suggest single phase Cu_{3}SbSe_{4} (PDF #85-0003) regardless of the Sn content. No peak shift due to Sn doping can be seen. There has been debate on the specific valence number of Sb in Cu_{3}SbSe_{4}, both 5+ and 3+ have been suggested. Nonetheless, with a simple argument that Sn has one less valence electron than Sb and is tetrahedrally bonded just as Sb in the structure, each Sn is expected to donate one free hole. This trend is well followed for the samples in the present study, as shown in Fig. 3: the measured Hall carrier density at room temperature follows exactly the calculated result (solid line) based on the density of substitutional Sn atoms assuming each of them contribute one free hole, using the single parabolic band (SPB) model (which determines the Hall factor \( r_H \) that links \( n_H \) with the chemical carrier density via \( n_H = n/r_H \)).

Fig. 4 shows the electrical resistivity (ρ) and Seebeck coefficient (S) as functions of temperature. All the samples showed p-type character. The undoped sample exhibited a nondegenerate direct gap of \( 0.6 \) eV, while the Sn-doped samples showed a direct gap of \( 0.5 \) eV for indirect gaps, \( 0.5 \) for indirect gaps.

Undoped Cu_{3}SbSe_{4} is an intrinsic semiconductor with a carrier density in the order of \( 10^{18} \) cm\(^{-3} \). Substituting Sn for Sb continuously increases the carrier density up to \( 2 \times 10^{20} \) cm\(^{-3} \). The morphology of the fractured and polished surfaces of a representative sample of Cu_{2.95}Sb_{1-x}Sn_{x}Se_{4} is shown in Fig. 2. The fractured surface exhibits well crystallized grains with an average grain size of \( \sim 2 \) μm. The backscattering electron (BSE) image and EPMA mapping confirmed a homogeneous distribution of elements without the segregation of secondary phases.

behaviour with a relatively large and decreasing Seebeck coefficient and resistivity with increasing temperature. From $S$ of the undoped sample, the band gap $E_g$ was estimated to be about 0.29 eV via 

$$E_g = 2eS_{\text{max}}T_{S_{\text{max}}}. \quad (1)$$

This estimate is consistent with the band gap measured by the optical absorption spectrum, which indicates a clear direct transition at 0.29 eV, as shown in Fig. 5. Previously, a similar band gap was reported by Berger et al. using the optical method. We have also noticed that a much smaller gap of 0.13 eV was suggested by Nakanishi et al. by analyzing the temperature dependence of electrical resistivity and Hall coefficient, and 0.11 eV via the infrared transmission spectra. A similar value was also obtained by Li et al. by fitting the electrical resistivity against temperature. In fact, we found a similar activation energy of $\Delta E \sim 0.13$ eV in this study by fitting the linear relation, $\ln \rho^{-1/2}$, from the undoped sample. Further, our optical absorption measurements showed a very weak absorption above 0.12 eV, possibly corresponding to an indirect transition. However, we conclude that the activation energy of 0.12 eV is unlikely to be the primary band gap, because the large $S$ values in undoped samples would not be achievable. In order to maintain a high Seebeck coefficient ($\sim 400 \mu V K^{-1}$ at $\sim 300 K$), the chemical potential needs to be deep in the gap, while a small gap of 0.12 eV would inevitably induce significant minority carriers that compensate for the Seebeck value. As a result, the band gap is believed to be 0.29 eV corresponding to a direct transition, which is several orders of magnitude stronger than the supposed indirect transition. The activation energy of 0.12 eV is then speculated to be due to defect levels inside the band gap. Nakanishi et al. were not able to observe the much stronger direct transition because they used the optical transmission, which had already been saturated to zero throughput after the first indirect transition at 0.12 eV. A band gap around 0.3 eV is comparable with other good thermoelectrics, such as PbTe\textsuperscript{34–36} or PbSe,\textsuperscript{37–39} Mg$_2$Si$_{1-x}$Sn$_x$ (ref. 40) and ZrNiSn.\textsuperscript{41} In addition, small band gaps usually mean less ionic character, making it easier for delocalized charge carriers that lead to high mobilities desirable for thermoelectrics. However, the disadvantage of a small band gap is the tendency of the excitation of minority carriers.

The measured Hall mobility, $\mu_{H}$, of all samples decreased with increasing temperature [Fig. 6(a)]. Near room temperature, the $T^{-1/2}$ law is roughly obeyed by all samples, indicating the dominance of acoustic phonon scattering of carriers. Fig. 6(b) shows the measured $n_{H}$ at different temperatures. For each doped sample, $n_{H}$ remains constant near room temperature and
above 500 K, it slowly increases with temperature. Considering a small and temperature-independent $E_g = 0.29$ eV in Cu$_3$SbSe$_4$, the apparent increase in $n_s$ is likely due to bipolar excitation.

Fig. 7 shows the carrier density dependence of the Seebeck coefficient and Hall mobility at room temperature, together with the data previously reported for this system.$^{23,33,42}$ We found that the SPB model with acoustic phonon scattering assumption could well explain both properties. From the carrier density dependence of the Seebeck coefficient (the Pisarenko relation), it seems that all the measured $S$ are consistent with a constant density-of-state (DOS) effective mass, $m^* = 1.5 \, m_e$. However, a range of $m^*$ values from 1.1 $m_e$ to 1.7 $m_e$ are acceptable. In fact, by calculating $m^*$ for each individual sample, we found a clear increase when going from undoped to doped samples [inset of Fig. 7(a)], error bars are estimated assuming 5% uncertainty in $S$ measurement that is normally seen]. A large effective mass usually means less mobile carriers and a lower thermoelectric quality factor defined as:

\[
B = \frac{2k_B^2 \hbar}{3\pi m^* \Omega_d} \frac{N_v}{m^* \Omega_d^{3/2}} T
\]

where $\nu$ is the longitudinal speed of sound, $d$ is the density, $N_v$ is the degeneracy of band, $m^*$ is the inertial effective mass, $\Omega_d$ is the lattice thermal conductivity, and $\Omega$ is the deformation potential coefficient.$^{44}$ However, in the case of Cu$_3$SbSe$_4$, the large $m^*$ comes from three bands that are degenerate (suggested by calculation$^{29}$) at the valence band maximum. As known in lead chalcogenides, a large effective mass from highly degenerate bands is favourable for high thermoelectric performance.$^{45}$

The changing $m^*$ with doping level is also indicated by the carrier density dependence of the Hall mobility $\mu_H$. In the SPB model, $\mu_H$ of a system with a reduced chemical potential $\eta$ can be expressed as:

\[
\mu_H = \frac{3\sqrt{\pi}}{8} \mu_0 \frac{F_{-1/2}(\eta)}{F_0(\eta)} = \frac{\pi e \hbar^2 \nu^2 N_v^{5/3}}{2 \sqrt{2m^* (k_B T)^{3/2} \Omega_d^{3/2}}} \frac{F_{-1/2}(\eta)}{F_0(\eta)}
\]

\[
F_0(\eta) = \int_0^\infty \frac{x^\eta dx}{1 + \exp(x - \eta)}
\]

where $\mu_0$ is the nondegenerate limit of mobility governed by the acoustic phonon scattering process. We found that for doped samples, the SPB model provides a good fit with $\mu_0$ determined to be 49 cm$^2$ V$^{-1}$ s$^{-1}$. The measured mobility of the undoped sample on the other hand, is about twice as high as this value. We notice that all available reports$^{23,33,42}$ on undoped samples agree with our findings. Furthermore, for the sample studied in this work, this result is repeatable in at least two measurements from room temperature to 673 K. So the high mobilities are unlikely to be due to measurement error or non-equilibrium conditions. Using the SPB model, the difference can be well explained by the variation in effective mass considering $m^*$ is 1.1 $m_e$ for the undoped sample and 1.5 $m_e$ for doped ones, as suggested in the inset of Fig. 7(a).
Previous band structure calculations for Cu$_3$SbSe$_4$ suggested a maximum of the valence band at the $I$ point where three bands with different effective masses are degenerate. The observed Pisarenko relation at 300 K, however, clearly implies a changing effective mass that cannot be explained by multiple degenerate bands. The observed transport properties instead suggest a split of at least two of these three bands near the maximum, possibly due to spin-orbit coupling, which was not considered in the reported calculation. Consequently, as the chemical potential moves deep into the valence bands with increasing carrier density, the secondary bands begin to play a more noticeable role in transport, leading to a larger $m^*$ when the system is characterized with the SPB model.

While the observed Pisarenko relation and changing effective mass with increased doping level can be simply explained by the split of bands near the valence band maximum, the carrier density dependence of the mobility [seen in Fig. 7(b)] requires more complicated physics to completely understand it. Even with the band configuration, one would not expect the trend in Fig. 7(b) without allowing for inter-band scattering or additional scattering mechanisms associated with the increased density of dopants. Nonetheless, for the doped samples, which are of most interest to thermoelectrics, the SPB model with acoustic phonon scattering assumption still provides an effective way to understand the transport properties. With the reported $v_t$ of 3643 m s$^{-1}$, and assuming $N_v = 3$, the deformation potential coefficient $\Xi$, was found to be $15 \pm 0.5$ eV at 300 K. This value is smaller than those found in systems with a smaller effective mass, such as lead chalcogenides and Bi$_2$Te$_3$, whereas it is noticeably larger when compared with systems with a larger effective mass (>1 $m_e$ for a single valley), such as La$_3$Te$_4$ (ref. 47), Yb$_{14}$MnSb$_{11}$ (ref. 48) and ZrNiSn.

To determine the thermal conductivity of the samples, $C_p$ was measured between 300 K and 673 K, and the values are shown in Fig. 8. We notice that the measured results from two different instruments, while consistent with each other, are considerably higher than the Dulong–Petit $C_V$. Above the Debye temperature [131 K by Berger et al. 60–80 K by Zhang et al.], and 65 K by Skoug et al.], the $C_p$ for solids is generally larger than $C_V$ due to lattice expansion. While this qualitatively explains the linear increase in $C_p$ with temperature, the difference at room temperature (20%) is much larger than one would expect. The difficulty in an accurate determination of $C_p$ experimentally and thus the different values used by different studies is partially responsible for the difference in the reported $\zeta T$ values.

Fig. 9 shows the total thermal conductivity and the lattice thermal conductivity as functions of temperature. The electronic thermal conductivity $\kappa_e$ was calculated by $\kappa_e = L T/\rho_s$, where the Lorenz number $L$, was calculated with the SPB model. The lattice thermal conductivity $\kappa_L$ decreased with temperature following $T^{-1}$ (dashed line), which indicates the dominance of phonon–phonon Umklapp scattering in phonon transport. Even in the undoped sample, $\kappa_L$ decreased with $T$ over the whole measurement range, and no obvious bipolar contribution was observed. Owing to the low percentage of Sn substitution and the small size difference between Sb and Sn, no difference in $\kappa_L$ between doped and undoped samples was observed. The minimum lattice thermal conductivity for Cu$_3$SbSe$_4$, $\kappa_{\text{min}}$ was estimated using Cahiill’s formula and was found be around 0.47 W m$^{-1}$ K$^{-1}$ from 275 K to 700 K. Experimentally, $\kappa_L$ at 673 K was around 1.1 W m$^{-1}$ K$^{-1}$, so a further reduction of $\kappa_L$ is possible.

The figure of merit, $\zeta T$, is shown as a function of temperature in Fig. 10(a). The maximum value $\sim 0.70$ was reached at 673 K in the sample with 2% Sn doping, and the corresponding Hall carrier density was $\sim 1.8 \times 10^{20}$ cm$^{-3}$. We further calculated $\zeta T$...
as a function of $n_H$ from the SPB model using the parameters for doped samples determined at 300 K. The result is shown in Fig. 10(b). The optimal carrier density corresponding to the highest $zT$ increased from $\sim 4-5 \times 10^{20} \text{cm}^{-3}$ at 300 K to $\sim 1-2 \times 10^{20} \text{cm}^{-3}$ at 673 K, as demonstrated experimentally and theoretically. According to the modeling, $zT$ significantly higher than 0.7 is unlikely for Cu$_3$SbSe$_4$ just by tuning the carrier density. Two possible routes to a higher $zT$ via material engineering are: first by tuning the position of individual valence bands, so they are better aligned at the maximum, and second by forming solid solutions which reduce $\kappa_L$. It should be noted that at high temperatures, Cu$_3$SbSe$_4$ has an inherent $\kappa_L$ only twice as high as the theoretical minimum (comparable to the case of PbTe or PbSe where $\kappa_L$ is around 0.7 W m$^{-1}$ K$^{-1}$ and $\kappa_{min}$ is around 0.4 W m$^{-1}$ K$^{-1}$) and that forming a solid solution will also decrease the carrier mobility. Therefore, forming solid solutions would likely increase $zT$ but not significantly. Actually the $zT$ value reported for Cu$_3$SbSe$_4$ is 0.89: about a 20% increase over that of Cu$_3$SbSe$_4$ reported by the same group.$^{20,23}$

**Conclusions**

Polycrystalline Cu$_3$SbSe$_4$ doped with Sn were fabricated with high phase purity and a precisely controlled carrier density by mechanical alloying and spark plasma sintering. The transport behaviour of this compound was explained by the single parabolic band (SPB) model. The Seebeck coefficients and mobilities at 300 K of the samples with different doping levels suggested a split of the bands at the valence band maximum, which according to previous calculations are triply degenerate. The transport data and optical band gap measurements suggested a direct band gap of $\sim 0.29$ eV, which is temperature independent. The thermal conductivity was governed by Umklapp phonon scattering, and a $T^{-1}$ dependence was observed for all samples. The maximum $zT$ value of $\sim 0.70$ was obtained at 673 K with 2% Sn (Hall carrier density $1.8 \times 10^{20} \text{cm}^{-3})$. The analyses and findings in this study would potentially help the understanding of transport properties in similar Cu-based ternary or multinary thermoelectric materials.
