In this paper, spatial temperature profiles are examined in the nonequilibrium relaxation region behind a stationary shock wave in a hypervelocity air Mach 7.42 freestream. The normal shock wave is established through a Mach reflection from an opposing wedge arrangement in an expansion tube facility. Schlieren images confirm that the shock configuration is steady and the location is repeatable. Emission spectroscopy is used to identify dissociated species and to make vibrational temperature measurements using both the nitric oxide and the hydroxyl radical A-X band sequences. Temperature measurements are presented at selected locations behind the normal shock. LIFBASE is used as the simulation spectrum software for OH temperature-fitting; however, the need to access higher vibrational and rotational levels for NO leads to the use of an in-house developed algorithm. For NO, results demonstrate the contribution of higher vibrational and rotational levels to the spectra at the conditions of this study. Very good agreement is achieved between the experimentally measured NO vibrational temperatures and calculations performed using an existing state-resolved, three-dimensional forced-harmonic oscillator thermochemical model. The measured NO vibrational temperatures are significantly higher than the OH temperatures.

I. Introduction

At hypersonic conditions encountered during atmospheric planetary entry, molecular real gas processes become significant. Thermal transitions and chemical reactions are known to affect flight aerodynamics, for example increased energy absorption by chemical reactions leads to a decreased shock standoff distance for a given test configuration [1]. Behind a strong shock, high temperatures and large radiative heating rates occur. The extent and profile of the postshock relaxation region must be predicted to infer aerothermodynamic loads on the vehicle body. The complexity of a thermochromically active, hypersonic flow tests the current limits of computational modeling [2]. Experimental data, particularly obtained using nonintrusive techniques, are therefore valuable, but conditions are typically challenging for measurement diagnostics.

The goal of this study is to investigate the nonequilibrium relaxation region behind a normal shock using spectroscopic radiation measurements. By doing so, we aim to demonstrate the applicability of emission spectroscopy as a diagnostic for hypervelocity flows. The normal shock is created via a Mach reflection (MR) using an opposing wedge arrangement. The choice of a normal shock eliminates flowfield complexities associated with a curved bow shock, such as mixed subsonic–supersonic regions, entropy gradients due to flow curvature, and three-dimensionality. Nitric oxide A-X (also referred to as the gamma, or $\gamma$ band) and hydroxyl radical A-X band transitions are used to measure postshock vibrational temperature profiles in a high-enthalpy, nominal Mach 7.4 air flow.

NO and OH spectral data have previously been the focus of a series of sounding rocket flight experiments measuring ultraviolet emission behind a bow shock which were carried out in an effort to validate aerodynamic and radiative transfer models at reentry conditions [3]. Single scans at 89.7 to 76.4 km were dominated by nitric oxide (A-X) gamma band emissions. In contrast, the summed spectra at 100 km was dominated by hydroxyl (A-X) bands, primarily (1,0) and (0,0). Significant computational and theoretical analyses have been completed upon these data. Initially, the primary aim was to compare radiation model predictions with data based upon spectral emission obtained from four NO electronic bands [4–6]. With only A-X band radiation being observed for the OH molecule, focus then shifted to developing OH specific radiation models for comparison with the experimental data. Numerical investigations have been completed based upon these models including work completed by Levin et al. [7–10], Gimselschein et al. [11], Kossi and Boyd [12], and Levin et al. [13]. In certain cases, significant differences were found between OH A-system vibrational temperature and those of the bulk flow. With outstanding issues arising from the flight experiments, one aim of this study is to provide additional temperature data behind hypersonic shock fronts with strong OH A-X emission at elevated temperatures.

In a partially dissociated and vibrationally excited freestream, Nerem et al. have measured relaxation times of dissociated air behind a normal shock for shock speeds between 4.9 to 6.8 km/s by examining the radiative emission time-history [14]. Vibrational temperatures and relaxation times behind normal shock waves, with shocked temperatures between 1400–3200 K, were measured by Russo for CO test gas mixtures [15]. Time-resolved vibrational temperature measurements of CO were made using the emission band-reversal method and the line-reversal method for seeded sodium by assuming equilibrium between CO vibrational and sodium electronic temperatures. In the Mach range of 3.5–5.7, Moser and Hindelang measured nitric oxide vibrational relaxation times behind incident normal shock waves [16,17]. Moser and Hindelang employed infrared diode laser absorption spectroscopy tuned to specific ro-vibrational transitions for a NO–Ar gas mixture. At shock velocities of 6.2 km/s, Sharma and Gillespie conducted rotational and vibrational temperature measurements behind a normal shock [18], which sought to advance previous nonequilibrium relaxation...
region measurements by Allen et al. [19–21]. In each of these cases, nitrogen was the test gas. Sharma and Gillespie [18] completed their measurements using photomultiplier tube radiometers and the second positive system of N2. Using the Marseille free-piston shock tube and a shock velocity of 5.8 km/s, Labracherie et al. studied the nonequilibrium region downstream of a normal shock wave [22]. Labracherie et al. presented the temporal evolution of vibrational and rotational temperatures and did not specifically investigate spatial temperature gradients. Temperature measurements were made for a methane–nitrogen–argon mixture using the CN B-X electronic transition. Using the spontaneous emission of the \( \Delta v = 0 \) band of CN, Ramjuan et al. spatially measured the relaxation region behind a normal shock with a velocity of 5.6 km/s [23]. Recently, Rond et al. used the CN violet system to show time-resolved postshock intensity profiles and to measure postshock vibrational temperatures using emission spectroscopy [24].

These previous studies demonstrate that emission spectroscopy is a viable technique for determining internal energy mode temperatures within a nonequilibrium flowfield. CO2 flowfields were the focus of many of the experimental studies that utilized emission spectroscopy as the diagnostic technique, and CN was the species of interest. In the current study, we examine air flows with NO and OH as the emitter species. Experimental results from Calspan University of Buffalo Research Center, for shock velocities between 3–4 km/s, used emission spectroscopy to identify the NO A-X band as the dominant radiator behind strong shocks for a O2–N2 gas mixture [25]. A follow-up experimental study used the region behind the shock wave to determine the squared transition moment value of the NO gamma band and to obtain time-dependent NO gamma radiative signals [26]. The calculation of internal energy mode temperatures using radiation signals from NO band systems via comparison with numerical spectra simulation has been successfully demonstrated on numerous occasions in air plasma experiments. In the NASA Ames 20 MW arcjet wind tunnel, vibrational temperatures have been measured by using the emission spectra of the NO \( \gamma (A-X) \) and \( \delta (C-X) \) bands [27,28]. In the same facility, rotational temperatures have also determined using the NO \( \delta(0,4), \gamma(0,0), \gamma(0,1), \gamma(0,2), \) and \( \gamma(0,3) \) bands [29]. Using strong \( \gamma \) and weaker \( \beta (B-X), \delta, \) and \( \epsilon (D-X) \) band transitions, all internal energy mode temperatures were measured for plasma discharges in air [30].

In the previous shock wave studies, measurements have been made behind propagating waves. In the present experiments, we instead establish a stationary shock using an opposing double wedge model geometry. The flowfield is first visualized using the schlieren technique. Shock angles are measured, and since the free stream inflow conditions are known, the frozen postshock state is well-characterized.

The shock tube was almost exclusively the only type of impulse facility used in the previous experimental studies discussed above. In reflected-shock tunnels, chemical freezing within the nozzle and freestream nonequilibrium effects can alter the test gas [31–33]. An expansion tube is an alternate means of achieving high-enthalpy conditions. Therefore, this work also serves as a test bed for demonstrating the applicability of emission spectroscopic techniques for temperature measurement within an expansion tube. Emission spectroscopy can provide useful data for facility characterization. At the TCM2 free-piston shock tunnel in France, emission spectra have been used to calculate useful test times and demonstrate test-time homogeneity for different operating conditions [34,35]. Test-time determination and species identification in the JX1 expansion tube facility using emission spectroscopy was performed by Ramjuan et al. [36]. Expansion tubes typically exhibit shorter test times than those exhibited in shock-tube and arcjet wind tunnel facilities, which reduces the emission signal strength. To the knowledge of the authors, this is the first study to conduct vibrational temperature measurements using optical emission spectroscopy in an expansion tube.

## II. Experimental Setup

### A. Hypervelocity Expansion Tube Facility

The hypervelocity expansion tube (HET) is a 9.14 m long facility consisting of three sections (driver, driven, and accelerator) all with 150 mm inner bore diameter, initially separated by primary and secondary diaphragms. The initial gas pressure and composition can be varied to achieve nominal Mach number operating conditions between 3.0 to 8.5 and stagnation enthalpies of 4.5 to 8.0 MJ/kg. In the present study, an air test gas, helium driver, and accelerator gas run condition (labeled Air-5) with Mach number 7.42 is selected. Calculated test gas properties are shown in Table 1.

The facility is initially evacuated, then each section filled to the desired initial pressure. Both dry (bottled) and moist (room) air were used as the test gas. The primary diaphragm burst pressure (driver pressure) is measured using a Setra 206 pressure gauge. Driven and accelerator initial fill pressures are monitored using MKS Piezo + A900-02 transducers. Vacuum pressures (below 2000 mtorr) in the accelerator section are measured using a MKS Baratron 626A transducer with 2 torr full scale, rated to 0.25% of the reading. This model was deliberately selected as the capacitance manometer pressure-measurement mechanism is invariant to the gas composition. Initial pressures in the accelerator section are typically on the order of 300 mtorr, and the influence of air-leakage into the acceleration section is mitigated by initially evacuating the section down to 200 mtorr, flushing with helium up to 12 kPa, and then performing the final evacuation down to the desired pressure. Within the facility, the acceleration section leak-rate was measured to be 0.3–0.4 m torr/min, and the subsequent partial pressure of air based upon these leak-rate measurements is low enough such that the effect is negligible based on perfect-gas dynamic calculations. Characterization of the out-gassing phenomena for these set of experiments, yielded a maximum 7 mtorr increase after the final accelerator evacuation. Pressure data were recorded using a National Instruments data acquisition system, consisting of a PXI-1031 chassis, a BNC-2100 eight-channel connector block, and a 14-bit PXI-6133 3 MS/s simultaneous sampling multifunction data acquisition module. A full description of the facility, measurement capabilities, and facility operation can be found in Dufrene et al. [37]. Facility operation has been previously characterized experimentally and numerically [37,38].

In an expansion tube, imperfect secondary diaphragm rupture, shorter test times, and core flow reduction due to acceleration section viscous effects result in a challenging measurement environment. However, the advantages of minimized freestream dissociation and no nonequilibrium processes during a nozzle expansion, make the expansion tube an attractive alternative means for creating hypervelocity flows.

### B. Imaging System and Spectroscopic Setup

MR configurations were visualized using a schlieren system consisting of a Xenon nanopulsers (10 ns duration) white light source and pco.1660 (Cooke Corporation) charge-coupled device (CCD) camera. The system is triggered via the transmitted shock arrival at a 1 MHz response pitot pressure transducer (PCB 113A26)

*Theoretical calculations assuming one-dimensional, perfect-gas dynamics are compared with experimental measurements. Subscript 7 denotes the test gas. \( M_\gamma \) is the Mach number, \( T_\gamma \) is the static temperature, and \( h_{\gamma} \) is the stagnation enthalpy.*
sting-mounted in the test section 31.75 mm below the model centerline. Schlieren images and pitot pressure traces from previous experiments [37] and simulations [39] ensure a repeatable and steady MR during the test time.

For the spectroscopic measurements, the broadband emission light is collected and collimated at 90 deg to the vertical axis plane of the test section with a 200 mm focal length, 50.8 mm diameter (f/4) UV coated lens (Figs. 1a and 1b). The collimated light is then focused for an imaging spectrograph. Two spectrographs were used in this study: a f/2 CP140 Jobin Yvon spectrograph for measurements which will be referred to as coarse, and a f/4 270M SPEX spectrograph for measurements which will be referred to as fine. Spectral lines were visualized using a Princeton Instruments PI-MAX MG:512SB intensified CCD camera system and a ST-133 camera controller. For each run, the camera exposure was set to 80 μs in order to capture as large a portion of the test gas as possible without accelerometer or driver gas contamination. For the f/4 270M SPEX spectrograph measurements, a slit size of 43 μm was selected as a compromise between signal strength and resolution. At the focal plane of the spectrometer for the fine measurements, the dispersion across the chip was 0.07 nm/pixel, corresponding to a wavelength range of 35.71 nm. The measured resolution is 1.4 Å.

The experimental values presented are ensemble averaged across a total of 28 separate events, one-dimensional, perfect-gas calculations. The experimental values comparison between experimentally measured values and inviscid, one-dimensional, perfect-gas calculations. The experimental values presented are ensemble averaged across a total of 28 separate events, consisting of 20 experiments for NO spectra acquisition and 8 experiments for OH spectra acquisition. Across most of the test condition parameters the agreement between theoretical expectation and measurement is very good. The largest discrepancy is seen in the calculated and measured values of the transmitted shock velocity, u.

However, two-dimensional Navier–Stokes simulations of a very similar run condition (Air-1) have shown that the transmitted shock is considerably attenuated due to viscous effects through the acceleration section [38]. Good agreement was obtained between the numerically predicted and the experimentally measured velocity.

The previous run condition, Air-1, differs from Air-5 (condition used in the current study, see Sec. II.A) only by the primary diaphragm burst pressure. Perfect-gas predictions indicate that the transmitted shock velocity differs by only 1% for the change in burst pressure. Therefore, u is assumed to be invariant with burst pressure and the calculated u over-prediction results from the inviscid, one-dimensional assumption. The experimental test gas Mach number is calculated from the measured pitot pressure, p_{pitot}, using the

### III. Thermochemical Calculations

The experimental results are compared with calculations using an existing thermochemical model [40], based on the semiclassical, forced-harmonic oscillator model with free-rotating molecule paths by Adamovich and Rich [41], Macheret and Adamovich [42], and Adamovich [43]. The molecule–molecule rates of Adamovich [43] are extended to higher collisional energies by a curve fit function obtained by minimizing the deviation from the numerical integration of the transition probability over all possible \( O_2, N_2, \) and NO transfers. The three-dimensional collisional model of Adamovich and Rich [41] and [42] is used for the molecule–atom rates. State-resolved chemical reaction rates are taken from Bose and Candler [44,45]. Boltzmann distributions are assumed for NO produced by the first Zeldovich reaction. However, non-Boltzmann distributions are modeled for NO produced by the second Zeldovich reaction [45]. Using the master equation approach of Park [33], a total of 37, 48, and 40 vibrational levels for \( O_2, N_2, \) and NO, respectively, are obtained in addition to monatomic O, N, and Ar, resulting in a 128-species mixture. The extended thermochemical model has been previously validated by comparison with experimentally obtained data for rate constants [46,47], vibrational relaxation times [48,49], dissociation rates [50,51], and vibration–vibration transfer probabilities [52]. Initial inflow conditions for the calculations (static pressure, static temperature, and test gas Mach number) are obtained from inviscid, perfect-gas calculations of expansion tube operation.

### IV. Results

#### A. Test Gas Freestream Condition

Table 1 summarizes the test gas freestream condition with a comparison between experimentally measured values and inviscid, one-dimensional, perfect-gas calculations. The experimental values presented are ensemble averaged across a total of 28 separate events, consisting of 20 experiments for NO spectra acquisition and 8 experiments for OH spectra acquisition. Across most of the test condition parameters the agreement between theoretical expectation and measurement is very good. The largest discrepancy is seen in the calculated and measured values of the transmitted shock velocity, u.

However, two-dimensional Navier–Stokes simulations of a very similar run condition (Air-1) have shown that the transmitted shock is considerably attenuated due to viscous effects through the acceleration section [38]. Good agreement was obtained between the numerically predicted and the experimentally measured velocity.

The previous run condition, Air-1, differs from Air-5 (condition used in the current study, see Sec. II.A) only by the primary diaphragm burst pressure. Perfect-gas predictions indicate that the transmitted shock velocity differs by only 1% for the change in burst pressure. Therefore, u is assumed to be invariant with burst pressure and the calculated u over-prediction results from the inviscid, one-dimensional assumption. The experimental test gas Mach number is calculated from the measured pitot pressure, p_{pitot}, using the
theoretical prediction of the static test gas pressure, \( p_f \). Very low signal-to-noise ratios prevent experimental measurement of \( p_f \) for the current run condition. Despite a lower than theoretically predicted test-time, a sufficient slug of test gas exists in which to make spectroscopic measurements.

B. Asymmetric Mach Reflection

A MR is created by an asymmetric wedge configuration as shown in the schlieren image of Fig. 2a, which displays the Mach stem bridging two triple points from which free shear layers emanate. Twenty-five- and thirty-five-degree half-angle wedges are used with a tip-to-tip separation of 25.4 mm. In order to avoid three-dimensional effects, inlet aspect ratios of 1.25 and wedge aspect ratios of 5 were used [53].

The MR has been extensively studied throughout the literature as an example of a shock–shock interaction which occurs extensively in aerodynamic applications. With significant thermochemical effects present in the current study, it is important to characterize their anticipated influence upon the MR configuration. Numerous previous studies have confirmed that the overall MR configuration is displaced forward and the Mach stem height is decreased in the presence of nonequilibrium effects [54–57]. The Mach stem height reduction increases the experimental difficulty as the postshock measurement area is also decreased. Numerical simulations of the current asymmetric wedge arrangement indicate that the flowfield is significantly dependent upon the thermochemical model [39]. Frozen, finite-rate and equilibrium models were examined, for which the finite-rate simulation provided the best agreement with experiment. However, the simulation predicted a slightly further recessed and longer Mach stem than experimentally observed. The simulations also indicated that the Mach stem position is stationary 20 \( \mu s \) after the passing of the contact surface. For a test gas duration of approximately 120 \( \mu s \) this, combined with a consistent triggering event, confirms that a steady MR exists during data collection.

The MR configuration geometry has been verified via measurement of shock angles from the schlieren images. The results are presented in Table 2 and compared against perfect-gas predictions. The subscripts refer to the MR schematic depicted in Fig. 2b. The theoretical reflected-shock angles were determined from shock-polar calculations. Comparisons yield very good agreement between incident shock angles. The differences observed for the lower triple point reflected-shock and slipstream angles are more pronounced, especially so for the slipstream angle. While the static test gas temperature has not been directly measured, the agreement between test gas pitot pressure, test gas Mach number, primary and transmitted shock speeds, and incident shock angles suggests that freestream conditions are well-predicted by perfect-gas theory.

From schlieren images, the Mach stem is measured to be 3.9 mm high, almost perpendicular, located 12.7 mm downstream of the wedge tip plane and its centerline located 2 mm below the tube axial centerline. As Fig. 2a shows, the uniform region behind the Mach stem which is not influenced by the converging shear-layer slipstreams is very small (approximately 5 mm). It is therefore imperative that the spatial locations of the spectra collection points are known very precisely with respect to the wedge tip plane. This involves determining the repeatability of the Mach stem location and potential shift from experiment to experiment. The deviation on both height and location measurements was found to be \( \pm 0.5 \) mm. With an uncertainty of \( \pm 0.25 \) mm in the imaging location (see Sec. IIIB) this results in a combined spatial uncertainty of \( \pm 0.75 \) mm. Repeat experiments show the movement of the Mach stem is small enough with respect to the uniform region length and the Mach stem height such that the calibration imaging point (acquired before the experiment) corresponds to the same location within the flowfield during the experiment. Measurements were made along the Mach stem centerline at \( -1, 0, 1, 2, 3, 4, \) and 5 mm downstream of the Mach stem, locations indicated by the symbols in Fig. 2a.

Calculations of the expected species concentrations and temperatures in the postshock relaxation region were carried out using the thermochemical model discussed in Sec. III, and are presented in Figs. 3 and 4. These figures demonstrate the chemical and thermal nonequilibrium nature of the flowfield. The mole fraction profiles up to 5 mm downstream of the Mach stem for the five major species considered in the model, NO, O\(_2\), N\(_2\), O, and N, are shown in Fig. 3. The results predict dissociation behind the normal shock with the presence of NO, O, and N. Figure 4 displays the translational temperature, and the equivalent [40] and A-state vibrational temperatures for NO, N\(_2\), and O\(_2\) calculated along the centerline of the Mach stem up to 5 mm downstream of the Mach stem. The frozen and equilibrium temperatures are calculated to be 7332 and 3872 K, respectively. The A-state vibrational temperature (described as the first vibrational temperature in the Massa and Austin paper) is calculated according to

\[
\epsilon_1 - \epsilon_0 = k \log \left( \frac{[N_2]}{[N]} \right)
\]

where \( N \) and \( e \) denote the mole numbers and energies for the subscripted levels, respectively, and \( k \) is the Boltzmann constant [40]. The NO temperatures initially overshoot the frozen temperature.

The emission from the OH radical has the strongest signal with temperature-intensity levels (a drop in intensity is observed for the A-state vibrational temperatures. The upper and lower dashed (thick) lines show the frozen (7332 K) and equilibrium (3872 K) temperatures, respectively.

This behavior is associated with the formation of NO in a non-Boltzmann distribution via the second Zeldovich reaction [44,45]. NO also exhibits the largest difference between the equivalent and Boltzmann distribution via the second Zeldovich reaction [44,45].

C. Species Identification

A spectrum obtained 10 mm downstream of the Mach stem over the wavelength regime of 200–400 nm using the f/2 CP140 Jobin Yvon spectrograph is shown in Fig. 5. Coarse resolution acquisition was initially undertaken as a means of identifying potential temperature-measurement appropriate species. Only the 50 μm results are presented since this resolution provided the largest intensity levels (a 25 μm slit was also used). The identified emitters with temperature-fitting potential in this wavelength regime are NO, OH, and N2. Emission from the OH radical has the strongest signal and dominates the entire spectrum. Certain portions of the spectrum are magnified in order to show the presence of N2 and NO. Based on these results, the decision was made to concentrate efforts for temperature measurements upon the ultraviolet portion of the spectrum using OH and NO. Additional measurements also detected no noticeable signatures in the visible region.

The presence of water vapor or associated radical species had no measurable effect on the temperature measurements, experiments were carried out with both dry (bottled) and moist (room) air.

D. OH Results

Because of the strong signal strength, initial measurements were conducted using the emission spectra of OH. The OH A-X band calibration setup was also easier to implement than the NO A-X band as a traditional blackbody radiation source with analytical solution could be used. The location of data collection with respect to the MR are shown in Fig. 2a. No signal was observed at the ∼1 mm location upstream of the Mach stem.

Fine-scale spectra were collected and temperature fits constructed for the A^2Σ^+ \rightarrow X^2Π electronic transition in the 307–320 region. An example of an emission spectrum for the OH A-X band obtained 4 mm downstream of the Mach stem is shown in Fig. 6. Simulated and experimentally observed spectra are compared. At each axial location, LIFBASE [58] was used to generate simulated spectra across a broad temperature range at coarse temperature increments of 100 K using Lorentzian profiles and a resolution of 0.14 nm. Wavelengths were interpolated so that the LIFBASE data points matched up with the experimental points and at each temperature increment a scaling factor was computed which reduces the residual, a value defined to be the sum of the differences between experimental and predicted intensity peak values across the entire spectral range. The smallest residual of the entire temperature range provided the fit vibrational temperature. The rotational and translational energy modes are assumed to be in equilibrium. Once the coarse temperature was determined, further optimization was performed such that the final temperature increment was 20 K. This final simulation uncertainty of 20 K is deemed appropriate as it is small compared with typical temperature uncertainty values arising from the major sources of experimental error (see Sec. IV.F), independent of the spatial location of the measurement. As shown by Fig. 6, the results indicate that the intensities across the entire spectrum match up very well and that reasonable temperature fits have been achieved. Spectra collected at 1 mm upstream of the Mach stem yielded no signal, confirming the spatial precision of the imaging location technique and lack of freestream dissociation in the facility.

E. NO Results

Experiments were undertaken in order to investigate the NO γ band. Since this is a nonequilibrium flowfield, it should be noted that there are multiple vibrational temperatures associated with the different electronic states of the nitric oxide molecule. Figure 7 is an example of three NO spectra at three different streamwise locations of 2, 3, and 4 mm downstream from the Mach stem. The signal strength is observed to attenuate markedly with increasing axial distance.
Fig. 7 NO $\gamma$ band spectra obtained at three different locations (2, 3, and 4 mm) downstream of the Mach stem.

Spectral fitting to the NO data using LIFBASE yielded very high temperatures, possibly due to the LIFBASE rotational and vibrational quantum number limits of 80 and 5, respectively. Calculations across an appropriate temperature range revealed that nonnegligible Boltzmann rotational and vibrational populations exist for NO above these limits. Hence, an in-house algorithm developed by Glumac with user-defined maximum limits was used to generate simulated spectra. Vibrational and rotational energies are determined to the third- and second-order, respectively, via Dunham-type potential expansions. For consistency, the spectroscopic constants used in these expansions are taken as those from LIFBASE [58] and are summarized in Appendix A. For the doublet ground state, the lower and upper configuration energies are calculated using the analytical expressions of Kovacs [59]. The dependence of the spin-orbit parameter, $A$, upon the vibrational quantum number is taken from Amiot [60]. Line strengths were calculated via multiplication of the Franck–Condon factors and the Hönl–London factors. The Hönl–London factors for the doublet transitions were determined following the expressions of Kovacs [59] and the Franck–Condon factors were taken from Ory et al. [61]. Conversion from vacuum to air wavelengths is achieved via the Edlen formula. The LIFBASE simulation formulates emission intensity as a function of molecule lifetime, emission coefficients, and predissociation rates. LIFBASE calculates the emission coefficients by incorporating the Hönl–London factors and the transition probabilities that are calculated using the Rydberg–Klein–Ress method. The predissociation phenomena has been observed for the NO $\gamma$ band and has been experimentally [62], theoretically [63], and numerically [64] shown to be dependent upon both vibrational and rotational quantum numbers. Vibrational levels of $v' = 4$ and $v' = 5$ can predissociate and for $v' = 3$, rotational levels above $N' = 25$ can predissociate [62]. However, for the most part transitions from these levels result in energies outside the current wavelength regime. As identified by Fig. 8, the dominant vibrational transitions which weigh heavily upon the temperature-fitting procedure will not predissociate as explained above. Furthermore, LIFBASE simulations for 220–255 nm show no difference between spectra with and without predissociation broadening. Therefore, predissociation is not considered to be a phenomena which needs to be considered for the wavelength range of interest. Spectroscopic constants and expressions used within the inhouse simulation are outlined in Table A1.

Figure 8 shows a comparison between LIFBASE and an in-house simulation for a temperature of 6200 K for limits of $v_{\text{max}} = 5$ and $J_{\text{max}} = 80$ (limits inherent to LIFBASE). The major vibrational band transitions are also indicated. The spectra are normalized by the maximum intensity in each case, which corresponds to the (0,1) peak value. The agreement between the two simulations is very good and within the experimental spectral resolution. Figure 9 shows a comparison between the two in-house simulations, one with the lower limits of $v_{\text{max}} = 5$ and $J_{\text{max}} = 80$ and the other with the extended limits of $v_{\text{max}} = 20$ and $J_{\text{max}} = 250$. As evident in the figure, the use of the extended limits alters the intensity distribution across major portions of the spectrum. The extended vibrational limits (and hence larger $\Delta v$ values) will not influence the simulated spectrum, however, the modeling of extra rotational levels will alter the spectrum within the 220–255 nm range. Since the intensity distribution is the optimization parameter for the temperature-fitting procedure, the inclusion of additional limits via the in-house simulations is justified.

Fine-scale spectra were collected and temperature fits constructed for the NO $A^3\Sigma^+ \rightarrow X^1\Pi$ electronic transition in the 220–255 nm region using the extended limits. The temperature-fitting procedure was the same as described for the OH $A-X$ transition. NO spectra

Fig. 8 Comparison between simulated spectra using an in-house developed algorithm and LIFBASE for an A-state vibrational temperature of 6200 K. $v_{\text{max}} = 5$ and $J_{\text{max}} = 80$. The major vibrational band transitions are indicated.

Fig. 9 Comparison between the results of two simulated spectra using an in-house developed algorithm, one with $v_{\text{max}} = 5$ and $J_{\text{max}} = 80$ (limits inherent in LIFBASE), and the other with the extended limits of $v_{\text{max}} = 20$ and $J_{\text{max}} = 250$.

Fig. 10 Simulated and experimental NO spectra obtained 2 mm downstream of the Mach stem for an A-state vibrational temperature of 6900 K.
were collected at 1, 2, 3, and 4 mm downstream of the Mach stem. Further downstream spectral acquisition of the relaxation region was restricted by the influence of converging shear layers bounding the measurement region, as shown in Fig. 2a. A sample spectrum, collected at 2 mm behind the Mach stem, is shown in Fig. 10 along with the simulated comparison. The vibrational temperature in this case was determined to be 6900 K. Using the LIFBASE limits, the calculated vibrational temperature was 7600 K. As exhibited for all imaging locations, the NO spectra are somewhat noisy and the visual fit fidelity is not as pronounced as in the OH spectra. As shown in Fig. 10, the major vibrational band transition intensities are all accurately matched.

The potential of contaminant emission within the 220–255 nm range was further investigated. Previous spectroscopic measurements at the TCM2 hypersonic facility have highlighted the importance of reducing test gas contamination. Pilverdier et al. noticed that a Mylar secondary diaphragm displayed significantly less emissive intensity than one made from copper [34]. The HET facility operates with a Mylar diaphragm. Ramjuaan et al. also emphasized the importance of cleaning the facility [36]. As a result, before each shot both the driven and accelerator section were cleaned. No differences in the nitric oxide spectra were observed.

Dry air was also used as the test gas in order to see if the trace quantities of water vapor were affecting the results. The test location 2 mm behind the Mach stem was used to determine the influence of the moisture within the air. At this location five room air shots and six dry air shots were conducted and the temperatures determined. The standard deviation of these determined temperatures was 320 and 2 mm behind the Mach stem was used to determine the influence of the moisture within the air. At this location five room air shots and six dry air shots were conducted and the temperatures determined. The standard deviation of these determined temperatures was 320 and 2 mm behind the Mach stem was used to determine the influence of the moisture within the air. Values are given as percentages of the total uncertainty.
temperature increment selection of the fit to simulated spectra. The first two sources are dependent upon the relaxation region temperature gradient, which was determined from numerical calculations. As described in Secs. II.B and IV.B, the uncertainties in the imaging location and MR movement are 0.25 and 0.5 mm, respectively. The freestream static temperature was used as the parameter to gauge test condition variability. For the purpose of the uncertainty analysis, the freestream static temperature is taken to be only dependent upon the HET initial pressures. Theoretically, the freestream static temperature would also be dependent upon the section gas compositions. As discussed above in Sec. II.A, the air leak-rate into the helium filled expansion section is negligible and hence will not influence the gas dynamic prediction. Moisture within the air is expected to have a negligible influence upon the air test gas and is also not considered. Driver pressures are so large (roughly 25 atm) that any residual air within the helium gas is completely negligible. Therefore, freestream static temperatures are taken to be dependent only upon the initial HET pressures. The temperature-measurement error bars at each imaging location, $\Delta T$, based upon the five uncertainty parameters described above is calculated using the following equation:

$$\Delta T = \sqrt{\sum_{i=0}^{5} \left( \frac{\partial T}{\partial x_i} \right)^2}$$  \hspace{1cm} (2)

where $\omega_i$ denotes the uncertainty in the measurement of a certain parameter, $x_i$. Values are presented as percentages of the total uncertainty. The largest contribution to the total uncertainty is due to the MR movement from shot-to-shot. Combined with the imaging location uncertainty, these two factors account for more than 70% of the total uncertainty at each spatial location.

V. Conclusions

Emission spectroscopy is used to measure nitric oxide and hydroxyl radical vibrational temperatures behind a strong normal shock. The stationary normal shock is created via a MR using an opposing wedge model in a high-enthalpy Mach 7.42 air freestream in an expansion tube facility. The inflow conditions for the normal shock have been experimentally defined by pressure, velocity, and shock angle measurements. Experimental spectral data from the NO and OH A-X band sequences were collected at selected locations, 1 mm apart, behind the Mach stem. OH temperature fits were conducted using simulated spectra generated by MATBASE, whereas the NO fits required higher vibrational and rotational levels and the use of an in-house spectral simulation algorithm. A state-resolved thermochemical model was used to calculate the NO A-state temperature profile up to 5 mm downstream of the Mach stem. Very good agreement is obtained between NO vibrational measurements and computations. As has been reported for previous studies of flight data, the temperatures calculated from OH emission differ significantly from those of other species in these nonequilibrium flows. These results extend previous studies applying emission spectroscopy for test gas identification in impulse facilities and demonstrate the measurement of species vibrational temperatures in an expansion tube.

Appendix: Spectroscopic Calculations

The expressions used for the vibrational energy, $G(v)$, and rotational energy, $F_v(J)$, are

$$F_v(J) = B_v J(J + 1)$$ \hspace{1cm} (A1)

$$G(v) = \omega_v(v + 1/2) - \omega_v x_1(v + 1/2)^2 + \omega_v y_1(v + 1/2)^3$$ \hspace{1cm} (A2)

$$B_v = B_x - \alpha_v(v + 1/2)$$ \hspace{1cm} (A3)
