We measure the direct CP violation asymmetry, $A_{CP}$, in $B \rightarrow X_s\gamma$ and the isospin difference of the asymmetry, $\Delta A_{CP}$, using 429 fb$^{-1}$ of data collected at $\Upsilon(4S)$ resonance with the BABAR detector at the PEP-II asymmetric-energy $e^+e^-$ storage rings operating at the SLAC National Accelerator Laboratory. $B$ mesons are reconstructed from ten charged $B$ final states and six neutral $B$ final states. We find $A_{CP} = +(1.7 \pm 1.9 \pm 1.0)\%$, which is in agreement with the Standard Model prediction and provides an improvement on the world average. Moreover, we report the first measurement of the difference between $A_{CP}$ for charged and neutral decay modes, $\Delta A_{CP} = +(5.0 \pm 3.9 \pm 1.5)\%$. Using the value of $\Delta A_{CP}$, we also provide 68% and 90% confidence intervals on the imaginary part of the ratio of the Wilson coefficients corresponding to the chromomagnetic dipole and the electromagnetic dipole transitions.

I. INTRODUCTION

The flavor-changing neutral current decay $B \rightarrow X_s\gamma$, where $X_s$ represents any hadronic system with one unit of strangeness, is highly suppressed in the standard model (SM), as is the direct CP asymmetry,

$$A_{CP} = \frac{\Gamma_{B^0 \rightarrow X_s\gamma} - \Gamma_{\bar{B}^0 \rightarrow X_s\gamma}}{\Gamma_{B^0 \rightarrow X_s\gamma} + \Gamma_{\bar{B}^0 \rightarrow X_s\gamma}},$$

(1)

due to the combination of CKM and GIM suppressions [1]. New physics effects could enhance the asymmetry to a level as large as 15% [2–4]. The current world average of
$A_{CP}$ based on the results from BABAR [5], Belle [6] and CLEO [7] is $-0.8 \pm 2.9\%$ [8]. The SM prediction for the asymmetry was found in a recent study to be long distance dominated [9] and to be in the range $-0.6% < A_{CP} < 2.8\%$.

Benzke et al. [9] predict a difference in direct CP asymmetry for charged and neutral $B$ mesons,

$$\Delta X_{\gamma} = A_{B^\pm \rightarrow X_{\gamma}} - A_{B^\pm \rightarrow B^\pm \rightarrow X_{\gamma}},$$

which suggests a new test of the SM. The difference, $\Delta X_{\gamma}$, arises from an interference term in $A_{CP}$ that depends on the charge of the spectator quark. The magnitude of $\Delta X_{\gamma}$ is proportional to Im$(C_{8g}/C_{7g})$ where $C_{7g}$ and $C_{8g}$ are Wilson coefficients corresponding to the electromagnetic dipole and the chromomagnetic dipole transitions, respectively. The two coefficients are real in the SM; therefore, $\Delta X_{\gamma} = 0$. New physics contributions from the enhancement of the CP-violating phase or of the magnitude of the two Wilson coefficients [11,10], or the introduction of new operators [11], could enhance $\Delta X_{\gamma}$ to be as large as 10% [9]. Unlike $C_{7g}$, $C_{8g}$ currently does not have a strong experimental constraint [12]. Thus a measurement of $\Delta X_{\gamma}$ together with the existing constraints on $C_{7g}$ can provide a constraint on $C_{8g}$.

Experimental studies of $B \rightarrow X_{\gamma}$ are approached in one of two ways. The inclusive approach relies entirely on observation of the high-energy photon from these decays without reconstruction of the hadronic system $X_{\gamma}$. By ignoring the $X_{\gamma}$ system, this approach is sensitive to the full $b \rightarrow s\gamma$ decay rate and is robust against final state fragmentation effects. The semi-inclusive approach reconstructs the $X_{\gamma}$ system in as many specific final state configurations as practical. This approach provides additional information, but since not all $X_{\gamma}$ final states can be reconstructed without excessive background, fragmentation model-dependence is introduced if semi-inclusive measurements are extrapolated to the complete ensemble of $B \rightarrow X_{\gamma}$ decays. BABAR has recently published results on the $B \rightarrow X_{\gamma}$ branching fraction and photon spectrum for both approaches [13,14]. The inclusive approach has also been used to search for direct CP violation, but since the inclusive method does not distinguish hadronic final states, decays due to $b \rightarrow d\gamma$ transitions are included.

We report herein a measurement of $A_{CP}$ and the first measurement of $\Delta X_{\gamma}$ using the semi-inclusive approach with the full BABAR data set. We reconstruct 38 exclusive $B$-decay modes, listed in Table I, but for use in this analysis a subset of 16 modes (marked with an asterisk in Table I) is chosen for which high statistical significance is achieved. Also, for this analysis, modes must be flavor self-tagging (i.e., the bottomness can be determined from the reconstructed final state). The 16 modes include ten charged $B$ and six neutral $B$ decays. After all event selection criteria are applied, the mass of the hadronic $X_{\gamma}$ system ($m_{X_{\gamma}}$) in this measurement covers the range of about 0.6 to 2.0 GeV/$c^2$. The upper edge of this range approximately corresponds to a minimum photon energy in the $B$ rest frame of 2.3 GeV. For $B \rightarrow X_{\gamma}$ decays with $0.6 < m_{X_{\gamma}} < 2.0$ GeV/$c^2$, the ten charged $B$ modes used account for about 52% of all $B^+ \rightarrow X_{\gamma}$ decays and the six neutral modes account for about 34% of all neutral $B^0 \rightarrow X_{\gamma}$ decays. In this analysis it is assumed that $A_{CP}$ and $\Delta X_{\gamma}$ are independent of final state fragmentation. That is, it is assumed that $A_{CP}$ and $\Delta X_{\gamma}$ are independent of the specific $X_{\gamma}$ final states used for this analysis and independent of the $m_{X_{\gamma}}$ distribution of the selected events.

II. ANALYSIS OVERVIEW

With data from the BABAR detector (Sec. III), we reconstructed $B$ candidates from various final states (Sec. IV). We then trained two multivariate classifiers (Sec. V): one to separate correctly reconstructed $B$ decays from misreconstructed events and the other to reject the continuum background, $e^-e^- \rightarrow q\bar{q}$, where $q = u, d, s, c$. The output of the first classifier is used to select the best $B$ candidate for each event. Then, the outputs from both classifiers are used to reject backgrounds. We use the remaining events to determine the asymmetries.

We use identical procedures to extract three asymmetries: the asymmetries of charged and neutral $B$ mesons, and of the combined sample, and the difference, $\Delta A_{X_{\gamma}}$. The bottomness of the $B$ meson is determined by the charge of the kaon for $B^0$ and $\bar{B}^0$, and by the total charge of the reconstructed $B$ meson for $B^+$ and $B^-$. We can decompose $A_{CP}$ into three components:

$$A_{CP} = A_{\text{peak}} - A_{\text{det}} + D,$$

where $A_{\text{peak}}$ is the fitted asymmetry of the events in the peak of the $m_{X_{\gamma}}$ distribution (Sec. VI), $A_{\text{det}}$ is the detector asymmetry due to the difference in $K^+$ and $K^-$ efficiency (Sec. VII), and $D$ is the bias due to peaking background contamination (Sec. VIII). In this analysis we establish upper bounds on the magnitude of $D$, and then treat those as systematic errors.

III. DETECTOR AND DATA

We use a data sample of 429 fb$^{-1}$ [15] collected at the $\Upsilon(4S)$ resonance, $\sqrt{s} = 10.58$ GeV/$c^2$, with the BABAR detector at the PEP-II asymmetric-energy $B$ factory at the SLAC National Accelerator Laboratory. The data correspond to $471 \times 10^6$ produced $BB$ pairs.

The BABAR detector and its operation are described in detail elsewhere [16,17]. The charges and momenta of charged particles are measured by a five-layer double-sided
silicon strip detector (SVT) and a 40-layer drift chamber (DCH) operated in a 1.5 T solenoidal field. Charged $K/\pi$ separation is achieved using $dE/dx$ information from the trackers and by a detector of internally reflected Cherenkov light (DIRC), which measures the angle of the Cherenkov radiation cone. An electromagnetic calorimeter (EMC) consisting of an array of CsI(Tl) crystals measures the energy of photons and electrons.

We use a Monte Carlo (MC) simulation based on EVTGEN [18] to optimize the event selection criteria. We model the background as $e^+e^- \rightarrow q\bar{q}$, $e^+e^- \rightarrow \tau^+\tau^-$ and $BB$. We generate signal $B \rightarrow X_{s}\gamma$ with a uniform photon spectrum and then weight signal MC events so that the photon spectrum matches the kinematic-scheme model [19] with parameter values consistent with the previous BABAR $B \rightarrow X_{s}\gamma$ photon spectrum analysis ($m_B = 4.65$ GeV/$c^2$ and $\mu_B^2 = 0.20$ GeV$^2$) [20]. We use JETSET [21] as the fragmentation model and GEANT4 [22] to simulate the detector response.

IV. $B$ RECONSTRUCTION

We reconstructed $B$ meson candidates from 38 final states listed in Table I. The 16 modes marked with an asterisk (*) in Table I are used in the $CP$ measurement. The other final states are either not flavor-specific final states or are low in yield. We reconstruct the unused modes in order to veto them after selecting the best candidate. In total, we use ten charged $B$ final states and 6 neutral $B$ final states in the $A_{CP}$ measurement. These final states are the same as those used in a previous BABAR analysis [5].

Charged kaons and pions are selected from tracks classified with an error-correcting output code algorithm [17,23]. The classification uses SVT, DIRC, DCH, and EMC information. The kaon particle identification (PID) algorithm has approximately 90% efficiency and a pion-as-kaon misidentification rate of about 1%. Pion identification is roughly 99% efficient with a 15% kaon-as-pion misidentification rate.

Neutral kaons are reconstructed from the decay $K_S^0 \rightarrow \pi^+\pi^-$. The invariant mass of the two oppositely charged tracks is required to be between 489 and 507 MeV. The flight distance of the $K_S^0$ must be greater than 0.2 cm from the interaction point. The flight significance (defined as the flight distance divided by the uncertainty in the flight distance) of the $K_S^0$ must be greater than three. $K_L^0$ and $K_S^0 \rightarrow \pi^0\pi^0$ decays are not reconstructed for this analysis.

The neutral $\pi^0$ and $\eta$ mesons are reconstructed from two photons. We require each photon to have energy of at least 30 MeV for $\pi^0$ and at least 50 MeV for $\eta$. The invariant mass of the two photons must be in the range of [115,150] MeV for $\pi^0$ candidates and in the range of [470,620] MeV for $\eta$ candidates. Only $\pi^0$ and $\eta$ candidates with momentum greater than 200 MeV/$c$ are used. We do not reconstruct $\eta \rightarrow \pi^+\pi^-\pi^0$ decays explicitly, but some are included in final states that contain $\pi^+\pi^-\pi^0$.

Each event is required to have at least one photon with energy $1.6 < E_{\gamma} < 3.0$ GeV, where the asterisk denotes variables measured in the $\Upsilon(4S)$ center-of-mass (CM) frame. These photons are used as the primary photon in reconstructing $B$ mesons. Such a photon must have a lateral moment $^2$ less than 0.8 and the nearest EMC cluster must be at least 15 cm away. The angle of the photon momentum with respect to the beam axis must satisfy $-0.74 < \cos \theta < 0.93$.

We make some further preliminary requirements to reduce the data before giving events to the multivariate classifiers for final selection. The invariant mass of $X_s$ (all daughters of the $B$ candidate excluding the primary photon) must satisfy $0.6 < m_{X_s} < 3.2$ GeV/$c^2$. The $X_s$ candidate is then combined with the primary photon to form a $B$ candidate, which is required to have an energy-substituted mass $m_{ES} = \sqrt{s/4 - p_B^2}$, where $p_B$ is the momentum of $B$ in the CM frame, greater than 5.24 GeV/$c^2$. We also require the difference between half of the beam total energy and the energy of the reconstructed $B$ in the CM frame, $|\Delta E| = |E_{\text{beam}}/2 - E_B|$, to be less than 0.15 GeV. The angle between the thrust axis of the rest of the event(ROE) and the primary photon must satisfy $|\cos \theta_{\text{TR}}| < 0.85$.

$^2$The lateral moment is the ratio for the sum of energies of all but the two most energetic crystals in the cluster weighted by the squares of distances to the cluster center and the sum of energies of all crystals weighted by the square of distance to the cluster center.

TABLE I. The 38 final states we reconstruct in this analysis. Charge conjugation is implied. The 16 final states used in the $CP$ measurement are marked with an asterisk.
V. EVENT AND CANDIDATE SELECTION

There are three main sources of background. The dominant source is continuum background, \( e^+ e^- \rightarrow q \bar{q} \). These events are more jet-like than the \( e^+ e^- \rightarrow \Upsilon(4S) \rightarrow B \bar{B} \). Thus, event shape variables provide discrimination. The continuum \( m_{ES} \) distribution does not peak at the \( B \) meson mass. The second background source is \( B \bar{B} \) decays to final states other than \( X_s \); hereafter we refer to these as generic \( B \bar{B} \) decays. The third source is a cross-feed background which comes from actual \( B \rightarrow X_s \gamma \) decays in which we fail to reconstruct the \( B \) in the correct final state. The \( e^+ e^- \rightarrow \tau^+ \tau^- \) contribution is negligibly small.

We first place a preliminary selection on the ratio of angular moments\(^3\)\(^4\) [24], \( L_{12}/L_{10} < 0.46 \) to reduce the number of the continuum background events. This ratio measures the jetiness of the event. Since the mass of the \( B \) meson is close to half the mass of the \( \Upsilon(4S) \), the kinetic energy that the \( B \) meson can have is less than that available to \( e^+ e^- \rightarrow \) light quark pairs. Therefore, the signal peaks at a lower value of \( L_{12}/L_{10} \) than does the continuum background.

The \( B \) meson reconstruction typically yields multiple \( B \) candidates per event (~10 on the average). To select the best candidate, we train a random forest classifier [25] based on \( \Delta E/\sigma_E \), where \( \sigma_E \) is the uncertainty on the \( B \) candidate energy, the thrust of the reconstructed \( B \) candidate,\(^4\) \( \Delta \theta \) momentum, the invariant mass of the \( X_s \) system, and the zeroth and fifth Fox-Wolfram moments [26]. This signal selecting classifier (SSC) is trained on a large MC event sample to separate correctly reconstructed \( B \rightarrow X_s \gamma \) decays from misreconstructed ones. For each event, the candidate with the maximum classifier output is chosen as the best candidate. This is the main difference from a previous \( BABAR \) analysis [5] which chose the event with the smallest \( \Delta E \) as the best candidate. This method increases the efficiency by a factor of approximately two for the same misidentification rate. For example, selecting events with \( m_{ES} > 5.27 \) GeV/\( c^2 \), at a fake rate of 25\%, the signal rate is 16\% for the \( \{\Delta E\} \) selection and 33\% for the SSC.

It should be emphasized that the best candidate selection procedure also selects final states in which the bottomness of the \( B \) cannot be deduced from the final decay products (flavor-ambiguous final states). After selecting the best candidate, we keep only events in which the best candidate is reconstructed with the final states marked with an asterisk in Table I. This removes events which are flavor-ambiguous final states from the \( A_{CP} \) measurement. Furthermore, because of the way the SSC was trained to discriminate against misreconstructed \( B \) candidates, SSC also provides good discriminating power against the generic \( B \bar{B} \) background.

To further reduce the continuum background we build another random forest classifier, the background rejecting classifier (BRC), using the following variables:

(i) \( \pi^0 \) score: the output from a random forest classifier using the invariant mass of the primary photon with all other photons in the event and the energy of the other photons, which is trained to reject high-energy photons that come from the \( \pi^0 \rightarrow \gamma \gamma \) decays.

(ii) Momentum flow\(^5\) in \( 10^5 \) increments about the reconstructed \( B \) direction.

(iii) Zeroth-, first- and second-order angular moments along the primary photon axis computed in the CM frame of the ROE.

(iv) The ratio of the second and the zeroth angular moments described above.

(v) \( \cos \theta_B^\gamma \): the cosine of the angle between the \( B \) flight direction and the beam axis in the CM frame.

(vi) \( \cos \theta_B^\tau \): the cosine of the angle between the thrust axis of the \( B \) candidate and the thrust axis of the ROE in the CM frame.

(vii) \( \cos \theta_B^\gamma \): the cosine of the angle between the primary photon momentum and the thrust axis of the ROE in the CM frame.

To obtain the best sensitivity, we simultaneously optimize, using MC samples, the SSC and BRC selections in four \( X_s \) mass ranges ([0.6–1.1], [1.1–2.0], [2.0–2.4], and [2.4–2.8] GeV/\( c^2 \)), maximizing \( S/\sqrt{S + B} \), where \( S \) is the number of expected signal events and \( B \) is the number of expected background events with \( m_{ES} > 5.27 \) GeV/\( c^2 \). The optimized selection values are the same for both \( B \) and \( \bar{B} \).

VI. FITTED ASYMMETRY

For each \( B \) flavor, we describe the \( m_{ES} \) distribution with a sum of an ARGUS distribution [27]\(^6\) and a two-piece normal distribution (\( G \)):\(^6\)

\[ \text{ARGUS}(x; c, \chi, p) = \frac{2^{-p} p^{2(p+1)}}{\Gamma(p+1) - \Gamma(p+1, 1/x^2)} \times \exp \left\{ \frac{1}{2} x^2 \left( 1 - \frac{x^2}{\chi^2} \right) \right\} \]

\[ G(x; \mu, \sigma_L, \sigma_R) = N \times \left\{ \exp \left( \frac{(x - \mu)^2}{2 \sigma_L^2} \right) \text{ if } x < \mu \right\} \left\{ \exp \left( \frac{(x - \mu)^2}{2 \sigma_R^2} \right) \text{ if } x \geq \mu \right\} \]

where \( N \) is the normalization.

\(^3\)The Legendre moment of momentum for a given axis.

\(^4\)The \( \Delta \) moment of momentum for a given axis.

\(^6\)The scalar sum of all momenta within a cone of a given opening angle about a given axis.
PDF$^b(m_{ES}) = \frac{T_{\text{cont}}}{2} \left( 1 + A_{\text{cont}} \right) \text{ARGUS}(m_{ES}; c^b, \chi^b, p^b) + \frac{T_{\text{peak}}}{2} \left( 1 + A_{\text{peak}} \right) G(m_{ES}; \mu^b, \sigma_L^b, \sigma_R^b), \quad (4)

PDF$^{\bar{b}}(m_{ES}) = \frac{T_{\text{cont}}}{2} \left( 1 - A_{\text{cont}} \right) \text{ARGUS}(m_{ES}; c^{\bar{b}}, \chi^{\bar{b}}, p^{\bar{b}}) + \frac{T_{\text{peak}}}{2} \left( 1 - A_{\text{peak}} \right) G(m_{ES}; \mu^{\bar{b}}, \sigma_L^{\bar{b}}, \sigma_R^{\bar{b}}) \quad (5)

where

\begin{align*}
T_{\text{cont}} &= n^b_{\text{cont}} + n^{\bar{b}}_{\text{cont}}, \quad (6) \\
T_{\text{peak}} &= n^b_{\text{peak}} + n^{\bar{b}}_{\text{peak}} \quad (7)
\end{align*}

are the total number of events of both flavors described by the ARGUS distribution and the two-piece normal distribution and

\begin{align*}
A_{\text{cont}} &= \frac{n^b_{\text{cont}} - n^{\bar{b}}_{\text{cont}}}{n^b_{\text{cont}} + n^{\bar{b}}_{\text{cont}}} \quad (8) \\
A_{\text{peak}} &= \frac{n^b_{\text{peak}} - n^{\bar{b}}_{\text{peak}}}{n^b_{\text{peak}} + n^{\bar{b}}_{\text{peak}}} \quad (9)
\end{align*}

are the flavor asymmetries of events described by the ARGUS distribution and the two-piece normal distribution, respectively. The superscript $b$ and $\bar{b}$ indicate whether the parameter belongs to the $b$ quark containing $B$ meson.

FIG. 1. The $m_{ES}$ distributions along with fitted probability density functions, for: $B^0$ and $B^-\bar{\epsilon}$ sample (top left), $B^0$ and $B^+\bar{\epsilon}$ sample (top right), $B^-\bar{\epsilon}$ sample (middle left), $B^+\bar{\epsilon}$ sample (middle right), $B^0$ sample (bottom left), and $B^0$ sample (bottom right). Data are shown as points with error bars. The ARGUS distribution component, two-piece normal distribution component and the total probability density function are shown with dotted lines, dashed lines, and solid lines, respectively.
TABLE II. Summary of $A_{\text{CP}}$ results along with $A_{\text{det}}$ and systematic uncertainties due to peaking background contamination (D) for each $B$ sample. The $A_{\text{CP}}$’s in the last column are calculated using Eq. (3). The first error is statistical, the second (if present) is systematic.

($B^0$ and $B^-$) distribution or the $\bar{b}$ quark containing $B$ meson distribution ($B^0$ and $B^+$), respectively. In particular, $n_b^{\text{peak}}$ and $n_b^{\text{peak}}$ are the numbers of events in the peaking (Gaussian) part of the distribution. Similarly, $n_{\text{cont}}^{b}$ and $n_{\text{cont}}^{\bar{b}}$ are the numbers of events in the continuum (ARGUS) part of the distribution. The shape parameters for ARGUS distributions are the curvatures ($\nu^b$ and $\nu^{\bar{b}}$), the powers ($p^b$ and $p^{\bar{b}}$), and the endpoint energies ($e^b$ and $e^{\bar{b}}$). The shape parameters for two-piece normal distribution are the left-side widths ($\sigma^b_L$ and $\sigma^{\bar{b}}_L$), and the right-side widths ($\sigma^b_R$ and $\sigma^{\bar{b}}_R$).

It should be noted that $A_{\text{peak}}$ is related to $A_{\text{CP}}$ defined in Eq. (1) by the relation shown in Eq. (3). To obtain $A_{\text{peak}}$, we perform a simultaneous binned likelihood fit for both $B$ flavors. The ARGUS endpoint energies $e^b$ and $e^{\bar{b}}$ are fixed at 5.29 GeV/$c^2$. All other shape parameters for the ARGUS distributions and the two-piece normal distributions are allowed to float separately. Fig. 1 shows the $m_{\text{ES}}$ distributions, along with fitted shapes. Table II summarizes the results for $A_{\text{peak}}$.

VII. DETECTOR ASYMMETRY

Part of the difference between $A_{\text{peak}}$ and $A_{\text{CP}}$ comes from the difference in $K^+$ and $K^-$ efficiencies. The $K^+$ PID efficiency is slightly higher than the $K^-$ PID efficiency; the difference also varies with the track momentum. The cause of this difference is the fact that the cross section for $K^-$-hadron interactions is higher than that for $K^+$-hadron interactions. This translates to the $K^-$ having a greater probability of interacting before it reaches the DIRC, thereby lowering the quality of the $K^-$ Cherenkov cone angle measurement, which affects the PID performance.

The first order correction to $A_{\text{CP}}$ from $K^+/K^-$ efficiency differences is given by

$$A_{\text{det}} = \frac{\nu_b - \nu_{\bar{b}}}{\nu_b + \nu_{\bar{b}}}. \quad (10)$$

where $\nu_b$ and $\nu_{\bar{b}}$ are the number of events for each flavor after all selections, assuming the underlying physics has no flavor asymmetry.

We use a sideband region ($m_{\text{ES}} < 5.27$ GeV/$c^2$) which consists mostly of $e^+e^- \rightarrow q\bar{q}$ events to measure $A_{\text{det}}$. We do not expect a flavor asymmetry in the underlying physics in this region. We count the number of events in the sideband region for each flavor and use Eq. (10) to determine $A_{\text{det}}^{\text{sideband}}$.

However, since the difference in $K^-$ and $K^+$ hadron cross section depends on $K$ momentum and the $K$ momentum distributions of the side band region and the peaking region ($m_{\text{ES}} > 5.27$ GeV/$c^2$) slightly differ, $A_{\text{det}}^{\text{sideband}}$ and $A_{\text{det}}$ need not be identical. The variation of $A_{\text{det}}$ for any $K$ momentum distribution can be bounded by the maximum and minimum value of the ratio between $K^+$ and $K^-$ efficiencies ($\epsilon_{K^+}/\epsilon_{K^-}$) in the $K$ momentum range of interest:

$$\frac{1}{2} \left( \min_{p_K} \frac{\epsilon_{K^+}}{\epsilon_{K^-}} - 1 \right) \leq A_{\text{det}} \leq \frac{1}{2} \left( \max_{p_K} \frac{\epsilon_{K^+}}{\epsilon_{K^-}} - 1 \right). \quad (11)$$

The final states with no charged $K$ can be considered as having a special value of $p_K$ where $\epsilon_{K^+}$ and $\epsilon_{K^-}$ are identical.

We use highly pure samples of charged kaons from the decay $D^{*+} \rightarrow D^0\pi^+$, followed by $D^0 \rightarrow K^-\pi^+$, and its charge conjugate, to measure the ratio of efficiencies for $K^+$ and $K^-$. We find that the deviation from unity of $\epsilon_{K^+}/\epsilon_{K^-}$ varies from 0% to 2.5% depending on the track momentum.

The bound given in Eq. (11) implies that the distribution of the differences between any two detector asymmetries chosen uniformly within the bound is a triangle distribution with the base width of 2.5%.

The standard deviation of such a distribution is $2.5\%/\sqrt{24} = 0.5\%$. We use $A_{\text{det}}^{\text{sideband}}$ as the central value for $A_{\text{det}}$ and this standard deviation as the systematic uncertainty associated with detector asymmetry. Table II lists the results of $A_{\text{det}}$.

VIII. PEEKING BACKGROUND CONTAMINATION

Our fitting procedure does not explicitly separate the generic $B\bar{B}$ backgrounds and cross feed from the signal. Both backgrounds have small peaking components, as shown in Fig. 2, so the yield for each flavor used in calculating $A_{\text{peak}}$ contains both signal and these peaking backgrounds. We quantify the effect and include it as a source of systematic uncertainty.

Let the number of signal events for $b$ quark containing $B$ mesons and $\bar{b}$ quark containing $B$ mesons be $n_b$ and $n_{\bar{b}}$ and
the number of contaminating peaking background events misreconstructed as $b$ quark containing $B$ mesons and $\bar{b}$ quark containing $B$ mesons be $\beta_b$ and $\beta_{\bar{b}}$. The difference between $A_{\text{peak}}$ and $A_{\text{CP}}$ due to peaking background contamination is given by

$$D = R \times \delta A,$$

(12)

where $R$ is the ratio of the number of peaking background events to the total number of events in the peaking region, given by

$$R = \frac{\beta_b + \beta_{\bar{b}}}{n_b + n_{\bar{b}} + \beta_b + \beta_{\bar{b}}},$$

(13)

and $\delta A$ is the difference between the true signal asymmetry and the peaking background asymmetry, given by

$$\delta A = \frac{n_b - n_{\bar{b}}}{n_b + n_{\bar{b}}} - \frac{\beta_b - \beta_{\bar{b}}}{\beta_b + \beta_{\bar{b}}}. \quad (14)$$

We estimate $R$ using the MC sample. We use the sum of the expected number of cross-feed background events and expected number of generic $B\bar{B}$ events with $m_{\text{ES}} > 5.27$ GeV/c$^2$ for each flavor as $\beta_b$ and $\beta_{\bar{b}}$. We obtain $n_b$ and $n_{\bar{b}}$ from the total number of expected signal events for each flavor.

Since the peaking background events are from misreconstructed $B$ mesons, the $m_{\text{ES}}$ distribution of the peaking background has a very long tail. It resembles the sum of an ARGUS distribution and a small peaking part. The fit to the total $m_{\text{ES}}$ distribution is the sum of a two-piece normal distribution and an ARGUS distribution. A significant portion of peaking background is absorbed into the

FIG. 2. The contributions to the total $m_{\text{ES}}$ distributions (gray lines with triangle markers) from the signal $B \rightarrow X_s \gamma$ (gray lines with circle markers), the continuum background (gray lines with x markers), the cross-feed background (gray lines with no marker), and the generic $B\bar{B}$ background (solid black lines) according to the MC sample for: $B^0$ and $B^{-}$ sample (top left), $B^0$ and $B^+$ sample (top right), $B^{-}$ sample (middle left), $B^+$ sample (middle right), $\bar{B}^0$ sample (bottom left), and $B^0$ sample (bottom right).
ARGUS distribution causing our estimate of $R$ to be overestimated.

We bound the difference in asymmetry, $\delta A$, using the range of values predicted by the SM: $-0.6\% < A_{\text{CP}}^{\text{SM}} < 2.8\%$. This gives $|\delta A| < 3.4\%$. This value is also very conservative, since the amount of cross-feed background in the signal region is approximately five times the amount of generic $B\bar{B}$ background, and we expect the flavor asymmetry of the cross-feed events to be similar to that of the signal. The asymmetry from the generic $B\bar{B}$ background is expected to be small.

To provide a check of our estimate of the cross-feed contribution to $A_{\text{peak}}$, we extract $A_{\text{peak}}$ from pseudo MC experiments with varying amounts of cross-feed background asymmetry and observe the shift from the true value of the signal asymmetry. A shift due to cross feed is expected in this study, since we allow the cross-feed asymmetry to be different than for the signal. The shift is about half the value estimated using the method described above. The difference is expected because the cross feed (and generic $B\bar{B}$) has a very long tail, so that only part of it will be included in the peaking component, the remainder gets absorbed in the ARGUS component, as we have noted above. Thus, we obtain a result that is expected, but in the end we use a more conservative estimate for the systematic uncertainty in the asymmetry from peaking background. We do this because we wish to avoid relying on the MC model for the peaking part of the cross feed. For $A_{\text{CP}}$ of the charged and neutral $B$, this estimate is conservative enough to cover a large possible range of $|\Delta A_{X,J}| < 15\%$ that could shift the value of $A_{\text{peak}}$ via the cross feed of the type $B^0 \rightarrow X_{J}\gamma$ misconstructed as $B^- \rightarrow X_{J}\gamma$ ($B^0 \Rightarrow B^-$) and $B^- \rightarrow X_{J}\gamma$ misconstructed as $B^0 \rightarrow X_{J}\gamma$ ($B^- \Rightarrow B^0$). Table III lists the values of $R$, $\delta A$ and $D$.

### IX. RESULTS

Following Eq. (3), we subtract $A_{\text{det}}$ from $A_{\text{peak}}$ to obtain $A_{\text{CP}}$. The statistical uncertainties are added in quadrature. Systematic uncertainties from peaking background contamination and from detector asymmetry are added in quadrature to obtain the total systematic uncertainty. We find

$$A_{\text{CP}} = +(1.7 \pm 1.9 \pm 1.0)\%,$$

where the uncertainties are statistical and systematic, respectively. Compared to the current world average, the statistical uncertainty is smaller by approximately 1/3 due to the improved rejection of peaking background described above.

The measurement of $A_{\text{CP}}$ is based on the ratio of the number of events, but $A_{\text{CP}}$ is defined as the ratio of widths. In order to make the two definitions of $A_{\text{CP}}$ equivalent, we make two assumptions. First, we assume that there are as many decaying $B^0$ mesons as decaying $\bar{B}^0$ mesons, i.e. there is no $CP$ violation in mixing. This has been measured to be at most a few $10^{-3}$ for $B$ mesons [8]. Second, since the ratio of the number of events is essentially the ratio of the branching fractions under the first assumption, we assume that the lifetime of $b$- and $\bar{b}$-containing $B$ mesons are identical so that the ratio of the branching fractions is equal to the ratio of the decay widths. This is guaranteed if we assume $CPT$ invariance. The isospin asymmetry has negligible effect on $A_{\text{CP}}$: The effect from the difference of $B^0$ and $B^+$ lifetime and from $\Delta A_{X,J}^\gamma$, is suppressed by a factor of isospin efficiency asymmetry, which we find to be on the order of 2%. The total effect is thus on the order of $10^{-4}$, which is below our sensitivity.

Using the values of $A_{\text{CP}}$ for charged $B$ and neutral $B$ in Table II, we find

$$\Delta A_{X,J} = +(5.0 \pm 3.9 \pm 1.5)\%,$$

where the uncertainties are statistical and systematic, respectively. The statistical and systematic uncertainties on $\Delta A_{X,J}$ are obtained by summing in quadrature the uncertainties on the charged and neutral $A_{\text{CP}}$ measurements.

The systematic uncertainty for $\Delta A_{X,J}$ is also validated with an alternative method of estimating the multiplicative effects from the peaking background contamination on $\Delta A_{X,J}$, taking into account each component of the cross feed. In particular, the cross feeds of the types $\bar{B}^0 \Rightarrow B^-$ and $B^- \Rightarrow \bar{B}^0$ produce shifts that are proportional to $\Delta A_{X,J}$. This is because such a cross feed adds a contribution from the other asymmetry, and hence introduces a shift that dilutes the measured $\Delta A_{X,J}$. If $\Delta A_{X,J} = 0$, then there is no shift from cross feed. A similar proportionality of the shift on $\Delta A_{X,J}$ occurs for generic $B\bar{B}$ background, assuming negligible asymmetry in this background, and in the limit of equal background fractions to $B^0$ and $B^-$. We use a conservative value for the peaking background composition of $2:2:1$ ($\bar{B}^0 \Rightarrow \bar{B}^0; B^- \Rightarrow \bar{B}^0; \text{generic } B\bar{B}$) and the value of cross-feed contamination ratio $R \sim 1/4$. We also assume that the contributions from $B^0 \Rightarrow B^-$ and $B^- \Rightarrow \bar{B}^0$ are equal. We find the total effect to be conservatively at most $1/2 \Delta A_{X,J} = 1.3\%$. The estimate is in agreement with the quadrature sum of the peaking background contamination systematics for charged and neutral $B$ asymmetry, which is $\sqrt{1.0\%^2 + 0.8\%^2} = 1.3\%$.

---

8The ratio of the difference between charged and neutral $B$ efficiency to the sum of the two.
In the calculation of $\Delta A_{X,T}$, we also assume that the fragmentation does not create an additional asymmetry. This is generally assumed in this type of analysis. This is particularly important for the $\Delta A_{X,T}$ measurement since the final states are not all isospin counterparts. With this assumption, we can use $A_{CP}$ for 10 charged $B$ final states and $A_{CP}$ for 6 neutral $B$ final states as $A_{CP}$ for charged $B$ and neutral $B$, respectively.

Using the formula,

$$\Delta A_{X,T} = 0.12 \times \frac{\Lambda_{78}}{100 \text{ MeV}} \text{Im}(C_{8g}/C_{7g}),$$

(17)
given in [9], we can use the measured value of $\Delta A_{X,T}$ to determine the 68% and 90% confidence limits (C.L.) on $\text{Im}(C_{8g}/C_{7g})$. The interference amplitude, $\Lambda_{78}$, in Eq. (17) is only known as a range of possible values,

$$17 \text{ MeV} < \Lambda_{78} < 190 \text{ MeV}.$$  

(18)

We calculate a quantity called minimum $\chi^2$ defined by

$$\text{minimum } \chi^2 = \frac{\min_{\Lambda_{78}}[(\Delta A_{T_8} - \Delta A_{\text{Exp}})^2]}{\sigma^2},$$

(19)

where $\Delta A_{\text{Exp}}$ is the theoretical prediction of $\Delta A_{X,T}$ for given $\text{Im}(C_{8g}/C_{7g})$ and $\Lambda_{78}$ using Eq. (17), $\Delta A_{\text{Exp}}$ is the measured value, $\sigma$ is uncertainty on the measured value, and the minimum is taken over the range of $\Lambda_{78}$ given in Eq. (18). Figure 3 shows the plot of minimum $\chi^2$ versus $\text{Im}(C_{8g}/C_{7g})$. It has two notable features. First, there is a plateau of minimum $\chi^2 = 0$. This is the region of

![FIG. 3](image1)

**FIG. 3.** The minimum $\chi^2$ for given $\text{Im}(C_{8g}/C_{7g})$ from all possible values of $\Lambda_{78}$. 68% and 90% confidence intervals are shown in dark gray and light gray, respectively.

$\text{Im}(C_{8g}/C_{7g})$ where we can always find a value of $\tilde{\Lambda}_{78}$ within the possible range [Eq. (18)] such that $\Delta A_{\text{Exp}}$ matches exactly $\Delta A_{\text{Exp}}$. Second, the discontinuity at $\text{Im}(C_{8g}/C_{7g}) = 0$ comes from the fact that the value of $\Lambda_{78}$ that gives the minimum value is different. When $\text{Im}(C_{8g}/C_{7g})$ is small and positive, we need a large positive $\Lambda_{78}$ to be as close as possible to the measured value, while when $\text{Im}(C_{8g}/C_{7g})$ is negative, we need a small positive value of $\Lambda_{78}$ to not be too far from the measured value.

The 68% and 90% confidence limits are then obtained from the ranges of $\text{Im}(C_{8g}/C_{7g})$, which yield the minimum $\chi^2$ less than 1 and 4, respectively. We find

$$0.07 \leq \frac{C_{8g}}{C_{7g}} \leq 4.48, \quad 68\% \text{ C.L.},$$

(20)

$$-1.64 \leq \frac{C_{8g}}{C_{7g}} \leq 6.52, \quad 90\% \text{ C.L.}$$

(21)

The dependence of minimum $\chi^2$ on $\text{Im}(C_{8g}/C_{7g})$ as shown in Fig. 3 is not parabolic, which would be expected from a Gaussian probability. Care must be taken when combining it with other constraints. Since the confidence intervals obtained are dominated by the possible values $\Lambda_{78}$ at the low end, improvement of limits on $\Lambda_{78}$ will narrow the confidence interval. We therefore also provide a confidence interval for $\text{Im}(C_{8g}/C_{7g})$ as the function of $\Lambda_{78}$ in Fig. 4.

![FIG. 4](image2)

**FIG. 4.** The 68% and 90% confidence intervals for $\text{Im} \frac{C_{8g}}{C_{7g}}$ and $\tilde{\Lambda}_{78}$. 092001-11
X. SUMMARY

In conclusion, we present a measurement of the direct $CP$ violation asymmetry, $A_{CP}$, in $B \rightarrow X_{s}\gamma$ and the isospin difference of the asymmetry, $\Delta A_{X_{s}\gamma}$, with 429 fb$^{-1}$ of data collected at the $T(4S)$ resonance with the BABAR detector. $B$ meson candidates are reconstructed from 10 charged $B$ final states and 6 neutral $B$ final states. We find $A_{CP} = +(1.7 \pm 1.9 \pm 1.0)\%$, in agreement with the SM prediction and with the uncertainty smaller than that of the current world average. We also report the first measurement $\Delta A_{X_{s}\gamma} = +(5.0 \pm 3.9 \pm 1.5)\%$, consistent with the SM prediction. Using the value of $\Delta A_{X_{s}\gamma}$, we calculate the 68% and 90% confidence intervals for $\text{Im}(C_{8g}/C_{7\gamma})$ shown in Eqs. (20) and (21), respectively. The confidence interval can be combined with existing constraints on $C_{7\gamma}$ to provide a constraint on $C_{8g}$.

ACKNOWLEDGMENTS

We would like to thank Gil Paz for very useful discussions. We are grateful for the extraordinary contributions of our PEP-II colleagues in achieving the excellent luminosity and machine conditions that have made this work possible. The success of this project also relies critically on the expertise and dedication of the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and the kind hospitality extended to them. This work is supported by the U.S. Department of Energy and National Science Foundation, the Natural Sciences and Engineering Research Council (Canada), the Commissariat à l’Energie Atomique and Institut National de Physique Nucléaire et de Physique des Particules (France), the Bundesministerium für Bildung und Forschung and Deutsche Forschungsgemeinschaft (Germany), the Istituto Nazionale di Fisica Nucleare (Italy), the Foundation for Fundamental Research on Matter (The Netherlands), the Research Council of Norway, the Ministry of Education and Science of the Russian Federation, Ministerio de Economía y Competitividad (Spain), the Science and Technology Facilities Council (United Kingdom), and the Binational Science Foundation (U.S.-Israel).
