Over the six years since the discovery¹ of the γ-ray burst GRB 980425, associated² with the nearby (distance, ∼ 40 Mpc) supernova 1998bw, astronomers have fiercely debated the nature of this event. Relative to bursts located at cosmological distances, (redshift, z ∼ 1), GRB 980425 was under-luminous in γ-rays by three orders of magnitude. Radio calorimetry³,⁴ showed the explosion was sub-energetic by a factor of 10. Here, we report observations of the radio and X-ray afterglow of the recent z = 0.105 GRB 031203⁵–⁷ and demonstrate that it too is sub-energetic. Our result, when taken together with the low γ-ray luminosity,⁷ suggest that GRB 031203 is the first cosmic analogue to GRB 980425. We find no evidence that this event was a highly collimated explosion viewed off-axis. Like GRB 980425, GRB 031203 appears to be an intrinsically sub-energetic γ–burst. Such sub-energetic events have faint afterglows. Intensive follow-up of faint bursts with smooth γ–ray light curves⁸,⁹ (common to both GRBs 031203 and 980425) may enable us to reveal their expected large population.

On 3 December 2003 at 22:01:28 UT, the INTEGRAL satellite detected⁵,⁷ a seemingly
typical long-duration ($\Delta t \approx 20$ sec) $\gamma$-ray burst. Within 6 hours, the *Newton X-ray Multiple Mirror (XMM) Observatory* detected\(^\text{10,11}\) an X-ray source with flux (2–10 keV band), $F_X = 3.95 \pm 0.09 \times 10^{-13}$ erg cm\(^{-2}\) s\(^{-1}\), fading gradually $\propto t^\alpha$ with $\alpha = -0.4$. Using the Very Large Array (VLA), we discovered a radio source at $\alpha(J2000)=08^h02^m30.18^s$ and $\delta(J2000)= -39^\circ51'03.51''$ (±0.1 arcsec in each axis), well within the 6-arcsecond radius error circle of the XMM source. A subsequent XMM observation\(^\text{12}\) confirmed the gradual decay of the X-ray source. From our analysis of the XMM data we find the flux $\propto t^{-0.4}$ between the two epochs and the spectral flux density, $F_{\nu,X} \propto \nu^\beta$, is fit by $\beta = -0.81 \pm 0.05$ with an absorbing column density, $N_H = 6.2 \times 10^{21}$ cm\(^{-2}\). Taken together, the transient X-ray and radio emission are suggestive of afterglow emission.

In addition to monitoring the afterglow in various radio bands (Table 1 and discussion below) we obtained an observation of the source with the *Advanced CCD Imaging Spectrometer (ACIS)* instrument aboard the *Chandra X-ray Observatory (CXO)*. The CXO observations began on 22 January 2004 at 21:35 UT and lasted about 22 ksec. We detected a faint source, count rate in the 2–10 keV band of $5.6 \times 10^{-4}$ s\(^{-1}\), at $\alpha(J2000)=08^h02^m30.159^s$ and $\delta(J2000)= -39^\circ51'03.51''$ (±0.18 arcsec in each axis), precisely coincident with the VLA source. Using the XMM model parameters stated above we obtain $F_X = 6.4 \times 10^{-15}$ erg cm\(^{-2}\) s\(^{-1}\), implying a faster decline ($\alpha = -1 \pm 0.1$) between the second XMM and Chandra observations.

The primary interest in this burst is that the radio and X-ray afterglow coincides at the sub-arcsecond level\(^\text{13}\) with a nearby ($z = 0.1055$) galaxy,\(^\text{6}\) making it the nearest GRB with the exception of the peculiar GRB 980425.\(^\text{2}\) At this redshift, the isotropic $\gamma$–ray energy release is $10^2$ times smaller\(^\text{7}\) than that of the nearest classical event GRB 030329 ($z = 0.169$)\(^\text{14}\) and yet a factor of $10^2$ larger\(^\text{1,2}\) than that of GRB 980425.

The afterglow properties of GRB 031203 also appear to be intermediate between classical cosmological GRBs and GRB 980425: the isotropic X-ray luminosity of GRB 031203 at $t \approx 10$ hours is $L_X = 9 \times 10^{42}$ erg cm\(^{-2}\) s\(^{-1}\), nearly $10^3$ times fainter than that observed\(^\text{15}\) for classical GRBs but a factor of $10^2$ brighter\(^\text{1}\) than that of GRB 980425. In the centimetre band, the peak luminosity is $L_{\nu,8.5\ GHz} \approx 10^{29}$ erg s\(^{-1}\) Hz\(^{-1}\), fainter\(^\text{16}\) by a factor of $10^2$ than that of most radio afterglows but comparable\(^\text{3}\) to that of GRB 980425. Since $L_X$ and peak radio luminosity of an afterglow can be used\(^\text{17,15}\) as rough proxies for
the afterglow energy, the data suggest that GRBs 031203 and 980425 are sub-energetic in comparison with classical GRBs.

As a next step, we applied the simplest afterglow model\textsuperscript{18,19} (a spherical relativistic blastwave shocking a constant density circumburst medium and accelerating relativistic electrons; the afterglow emission arises from synchrotron emission of shocked electrons) to the afterglow data and obtain a satisfactory fit (Figure 1). On the timescales best probed by the radio data – days to months – we see no evidence for a collimated (jet) geometry commonly seen\textsuperscript{20} in the afterglows of cosmological GRBs.

From our modeling we confirm that the blast wave is sub-energetic, finding an inferred afterglow energy of $E_{\text{AG}} \approx 1.7 \times 10^{49}$ erg. The circumburst particle density $n \approx 0.6 \text{ cm}^{-3}$, is not atypical of that inferred\textsuperscript{17} for other GRBs. The blastwave is expected to become\textsuperscript{21} non-relativistic on a timescale, $t_{\text{NR}} \approx 34(E_{\text{AG,50}}/n_0)^{1/3} \text{ d}$, where we adopt the notation $q \equiv 10^x q_x$. The observational signatures\textsuperscript{22} of this transition, a steeper decay of the spectral peak frequency ($\nu_m \propto t^{-1.5} \rightarrow t^{-3}$) and an increase in the spectral peak flux ($F_{\nu_m} \propto t^0 \rightarrow t^{3/5}$) are consistent with the data (Figure 1).

Here we use $E_{\text{AG}}$ to denote the kinetic energy remaining in the blast wave after the prompt $\gamma$-ray energy release. In turn, the $\gamma$-ray emission arises from ultra-relativistic (bulk Lorentz factor, $\Gamma \gtrsim 100$) ejecta within the blastwave. Thus, a more complete picture of the explosion energy is visualized through a two-dimensional plot of $E_{\text{prompt}}$, the beaming-corrected prompt energy release versus $E_{\text{AG}}$ (Figure 2).

The two nearest events, GRBs 031203 and 980425, are clearly sub-energetic outliers in Figure 2. Furthermore, we draw the reader’s attention to several additional similarities: GRBs 031203 and 980425 (1) show no evidence for jets;\textsuperscript{3} (2) possess simple $\gamma$-ray light curves\textsuperscript{1,7}; and with respect to cosmological (“classical”) bursts the two events (3) violate\textsuperscript{7} the $E_{\text{prompt}} - E_{\text{peak}}$ relation\textsuperscript{23} and (4) are outliers in the luminosity - spectral lag relation.\textsuperscript{9} This discussion motivates the question: How are these two events related to cosmological GRBs?

It has been suggested (e.g. ref 24) that all GRB explosions have the same energetics and explosion geometry. In this framework, sub-energetic bursts are simply events viewed away from the jet axis. Such bursts should have a soft $E_{\text{peak}}$ and also exhibit a rise in the inferred $E_{\text{AG}}$ as shocked ejecta eventually come into our line of sight. For GRB 031203,
$E_{\text{peak}} > 190 \text{ keV}$ (ref. 7), comparable to cosmological GRBs for which we have observational evidence favoring an on-axis viewing angle. Moreover, we see no evidence for an increase in $E_{\text{AG}}$ during the timescale of the radio observations ($\sim 150$ days). Similarly, there is no evidence that $E_{\text{AG}}$ is increasing for GRB 980425 despite dedicated radio monitoring$^{25}$ of the source since 1998. With no indication of being off-axis explosions, we presently conclude that GRBs 031203 and 980425 are intrinsically sub-energetic events.

Astronomers have had to wait six years to discover a sub-energetic event similar to GRB 980425, despite a large population (as implied by their proximity). The bulk of the population has escaped our attention due to their faint $\gamma$-ray and afterglow emission which challenge our current detection limits. The $\textit{Swift}$ satellite mission, with its higher $\gamma$-ray sensitivity (compared to current missions) and improved localization capability (enabling rapid identification of afterglow counterparts) is expected to revolutionize our understanding of cosmic explosions.

Table 1. Radio observations made with the Very Large Array (VLA). Observations commenced on 5 December 2003 UT. For all observations we used the standard continuum mode with $2 \times 50$ MHz bands. At 22.5 GHz we used referenced pointing scans to correct for the systematic $10 - 20$ arcsec pointing errors of the VLA antennas. We used the extra-galactic sources 3C 147 (J0542+498) and 3C 286 (J1331+305) for flux calibration, while the phase was monitored using J0828-375. The data were reduced and analyzed using the Astronomical Image Processing System. The flux density and uncertainty were measured from the resulting maps by fitting a Gaussian model to the afterglow emission.
Figure 1: Radio lightcurves of the afterglow of GRB 031203. All measurements are summarized in Table 1 and include 1 − σ error bars. The solid lines are models of synchrotron (afterglow) emission from spherical ejecta expanding into a uniform circumburst medium. The models include a contribution from the host galaxy, which is well-fit by $F_{\text{host}} \approx 0.4(\nu/1.4 \text{ GHz})^{-0.6}$ mJy (dashed lines) and is consistent with the star formation rate inferred from optical spectroscopy of the host. In applying the models, the X-ray observations are considered upper-limits since they are most likely dominated by (non-synchrotron) emission arising from the associated supernova SN 2003lw, as evidenced by the unusually slow flux decay at early time and the flat spectral index ($F_{\nu,X} \propto t^{-0.4}\nu^{-0.8}$ as opposed to $\propto t^{-1}\nu^{-1.3}$ for GRBs). This was also the case for the X-ray emission of GRB 980425/SN 1998bw ($F_{\nu,X} \propto t^{-0.2}\nu^{-1}$). For our best-fit model, we find $\chi^2_r = 8.9$ (38 degrees of freedom), dominated by interstellar scintillation. The blastwave transitions to the non-relativistic regime at $t_{NR} \approx 23$ d. From the derived synchrotron parameters (at $t = 1$ d): $\nu_a \approx 3.2 \times 10^8$ Hz, $\nu_{m} \approx 3.6 \times 10^{12}$ Hz and $F_{\nu_a} \approx 0.04$ mJy we find an isotropic afterglow energy, $E_{\text{AG, iso}} \approx 1.7 \times 10^{49} \nu_{c,15.5}^{1/4}$ erg, a circumburst density $n \approx 0.6 \nu_{c,15.5}^{3/4} \text{ cm}^{-3}$ and the fractions of energy in the relativistic electrons (energy distribution $N(\gamma) \propto \gamma^{-p}$ with $p \approx 2.6$) and magnetic field of $\epsilon_e \approx 0.4 \nu_{c,15.5}^{1/4}$ and $\epsilon_B \approx 0.2 \nu_{c,15.5}^{-5/4}$, respectively. Here, $\nu_c = 3 \times 10^{15} \nu_{c,15.5}$ is the synchrotron cooling frequency which is roughly constrained by the (non-synchrotron) SN 2003lw X-ray emission. Extrapolation of the synchrotron model beyond $\nu_c$ underestimates the observed X-ray flux by a factor of $\lesssim 10$ which is comparable to the discrepancy for SN 1998bw (found by extrapolating the radio model by Li & Chevalier (p = 2.5, $\epsilon_B = 10^{-3}$) beyond $\nu_c$ and comparing with the X-ray data at $t \sim 12$ days).

Figure 2: Two-dimensional energy plot for cosmic explosions. The energy in the prompt emission, $E_{\text{prompt}}$, and in the afterglow, $E_{\text{AG}}$, have been corrected for beaming based on the jet-break time observed for each burst, except in the cases of GRB 980425, XRF 020903 and GRB 031203 for which there is no evidence for a collimated outflow. For these three cases we plot the isotropic values of $E_{\text{prompt}}$ and $E_{\text{AG}}$ and use an arrow to indicate they represent upper limits on both axes. The arcs mark lines of constant $E_{\text{prompt}} + E_{\text{AG}}$ as a guide to the reader. Most cosmological GRBs tend to cluster around $E_{\text{prompt}} + E_{\text{AG}} \approx 2 \times 10^{51}$ erg while GRBs 031203 and 980425, the nearest two bursts in the sample, are clearly sub-energetic. With the exception of SN 1998bw, associated with GRB 980425, there are no local Ibc supernovae with
detected $\gamma$-ray emission, however the kinetic energy in the ejecta (excluding the photospheric energy yield), is generally found\textsuperscript{29} to be $E_{\text{AG}} \lesssim 3 \times 10^{48}$ erg (bottom left corner). Histograms of $E_{\text{AG}}$ and $E_{\text{prompt}}$ are shown in the bottom and side panels, respectively, for cosmological GRBs and local Ibc SNe. The striped energy bins show the locations of GRBs 980425 and 031203.
