Bandwidth of Linearized Electrooptic Modulators

Uri V. Cummings and William B. Bridges, Life Fellow, IEEE, Fellow, OSA

Abstract—Many schemes have been proposed to make high dynamic range analog radio frequency (RF) photonic links by linearizing the transfer function of the link’s modulator. This paper studies the degrading effects of finite transit time and optical and electrical velocity dispersion on such linearization schemes. It further demonstrates that much of the lost dynamic range in some modulators may be regained by segmenting and rephasing the RF transmission line.

Index Terms—Bandwidth, electrooptic, linearized, modulators, photonic-link.

I. INTRODUCTION

ELECTROOPTIC intensity modulators have inherently nonlinear transfer functions which may limit the dynamic range of the photonic link through the production of harmonic and intermodulation distortion. Many schemes have been proposed to reduce the distortion byproducts of these modulators by linearizing their transfer functions; for example see the review paper by Bridges and Schaffner [1], and the references therein. The proposed applications for the resulting high dynamic range links include antenna remoting, photonic-coupled phased-array antennas, and cable television transmission.

Linearizing a modulator is a challenge. All of the proposed linearization schemes involve the cancellation of selected distortion terms, and this cancellation depends critically on modulator device parameters. Electrical biases very likely will require active control, and in some modulators, radio frequency (RF) or optical levels will require more accuracy than is realizable with current fabrication techniques.

For applications higher than 1 GHz, traveling wave electrode structures are mandatory to overcome the limitations resulting from interelectrode capacitance and finite transit time. A further difficulty with some popular electrooptic materials, such as lithium niobate, is that the electrical and optical waves travel at different velocities over the finite interaction length of the device, a result of material dispersion. This property limits the modulation-index × voltage product at high frequencies.

Given the critical dependence of the linearization scheme on modulator parameters, it is a fair question to ask, “How will velocity mismatch effect the linearization results?” This paper addresses that question for several popular modulator types. The summary result is that good velocity matching is essential to successfully linearize some but not all of the modulators. The details differ significantly from one modulator type to another. This paper treats the frequency dependence of six modulator configurations: a standard Mach–Zehnder modulator (MZM), a dual parallel Mach–Zehnder modulator (DPMZM) and a dual series Mach–Zehnder modulator (DSMZM), a simple directional coupler modulator (DCM) at two different bias points, and a directional coupler modulator linearized with two additional dc biased directional couplers in series optically (DCM2P). The results of linearizing these modulators (except for the DSMZM) without regard for transit time were reported in [1]. Now, we report the comparisons including transit time and velocity mismatch.

II. LINK MODEL

This paper assumes the same simplified photonic link and parameters as [1], but now adds the parameters for the finite frequency calculations. They are the effective index mismatch \( \Delta n \), the modulator length \( L_m \), and the frequency \( f_0 \). The link consists of a laser, an electrooptic modulator, a length of fiber, and a detector. The model excludes electronic preamplification and postamplification. Table I shows all of the parameters associated with this link. These parameters are assumed to have no frequency dependence in the model. The parameters for the active length and the velocity mismatch are typical for LiNbO_3 modulators using simple parallel strip electrodes with no velocity matching. That is, \( \eta_{\text{microstrip}} \approx 4.0 \) and \( \eta_{\text{optical}} \approx 2.2 \), and thus \( \Delta \eta \approx 1.8 \). Velocity matching will result in a lower value of \( \Delta \eta \).

As in [2], the results are calculated numerically, since no closed-form solution exists for the transfer function of some modulator types. A program, written in C, calculates the frequency-dependent gain and dynamic range. A two-tone electrical test signal, with frequencies \( f_1 \) and \( f_2 \) drives the modulator. The Fourier transform of the output is evaluated to

\[

\end{array}
\]
find the gain, the harmonic content, and the intermodulation content of the link.

Let $P(f_m, t)$ be the electrical signal power after the detector, given the modulator RF drive power $p_m$. Let $\hat{P}(f_m, f_1)$ be the Fourier transform of $P(f_m, t)$.

The gain is

$$\text{Gain}_{\text{dB}} = 10 \{ \log[\hat{P}(p_m, f_1)] - \log(p_m) \}. \quad (1)$$

The small signal gain is obtained by evaluating (1) at sufficiently small $p_m$ that the log-log plot of $\hat{P}(p_m, f_1)$ is linear with slope one. In practice, a good value of $p_m$ for this calculation is the geometric mean of $p_0$ (the power that drives the modulator voltage to about $V_0$) and the precision of double precision floating point numbers, or about $-100$ dBm.

The spur free dynamic range, DR dB, is the power interval that spans the input power level at which the signal is just distinguishable from the noise and the input power level at which the strongest distortion term becomes distinguishable from the noise. The calculation of DR dB is

$$R_{\text{dB}}(p_m) = 10 \max \left\{ \left\{ \log[\hat{P}(p_m, 2f_1 - f_2)] - \log[\hat{P}(p_m, 2f_1)] \right\} - \text{noise}_{\text{dB}} \right\} \quad (2)$$

$$p_0 = \min(p_m) \left| r(w, p_m) = 0 \right| \quad (3)$$

$$\text{DR}_{\text{dB}} = 10 \log[\hat{P}(p_0, f_1)] - \text{noise}_{\text{dB}}. \quad (4)$$

$R_{\text{dB}}(p_m)$ is the maximum of the relevant distortion terms minus the noise level in dB. Of the roots of $R_{\text{dB}}(p_m)$, $p_0$ is the root that occurs at the lowest power level. DR dB is the difference between $p_0$ and the input power level at which the signal intersects the noise floor. Since the log-log plot of the signal has slope one, this interval is equivalent to the signal power minus the noise power at the RF drive power at which the distortion power equals the noise level which is (4). Fig. 1 describes the dynamic range calculation for a simple Mach–Zehnder modulator. Since there is effectively no second-harmonic distortion, $R_{\text{dB}}$ equals the intermodulation product. $R_{\text{dB}}$ crosses the noise floor only once at an input power level of $p_0 = -26$ dBm. Since the signal has slope one, the dynamic range may be found from the difference between the signal and $p_0$ either horizontally or vertically in the plot, giving the familiar dynamic range triangle.

A. Computation of Modulators with Velocity Dispersion

The frequency dependent output of any modulator with a known dc transfer function is calculable. Farwell gives a detailed computational method for this in [2]. The mathematics are straightforward. Let $A_{\text{int}}(t)$ and $A_{\text{out}}(t)$ be the input and output complex amplitudes of the optical wave in a modulator. Let $H(V, l_m)$ be the transfer function, where $V$ is the normalized modulator drive voltage and $l_m$ is the active length of the modulator. If the optical and electrical waves travel at the same velocity, or if the operating frequency is so low that $V$ is effectively constant over $l_m$, then the output is given by

$$A_{\text{out}}(t) = H[V(t), l_m] A_{\text{in}}(t). \quad (5)$$

Even if there is significant velocity dispersion while the two waves travel the distance $l_m$, over a short enough section of the guide, the change in the complex optical amplitudes may be described with the dc transfer function. This is the basis for the frequency dependent calculation. Let $x$ be the coordinate along the optical waveguide, and let $t$ be time. Then

$$A(x, t) \rightarrow A(x, t). \quad (6)$$

The optical and electrical signals are now functions of two variables, $x$ and $t$. In (6) the elapsed time equals the incremental length divided by the electrical velocity $\Delta t = \Delta x / v$. Let there be $N$ equally spaced increments of $x$ and $M$ equally spaced increments of $t$, and let $x_0 = 0$ and $x_N = l_m$. The modal width is divided into $N$ sections over which the optical and electrical fields are approximately constant. The finite product of the resulting $N$ unitary dc transfer matrices gives the overall transfer function from $A_{\text{in}}(t)$ to $A_{\text{out}}(t)$. Let $A(x_0, t) = A_{\text{in}}(t)$, and $A(x_N, t) = A_{\text{out}}(t)$, and note that $A_{\text{out}}(t) = 0$ for $t < x_N / v$. The approximate modulator
The transfer function is

\[ A_{\text{out}}(t_j) \approx \left\{ \prod_{k=0}^{N-1} H \left[ V(x_k, t_j - \frac{x(N-1-k)}{\nu}) \frac{l_m}{N} \right] \right\} A_{\text{in}}(t). \tag{7} \]

The function \( V(x, t) \) representing the two tone test is

\[ V(x_k, t_j) = p_{\text{in}} \left[ \cos \left( \frac{j}{M} x - \frac{j}{N} \frac{\gamma}{f_1} \right) + \cos \left( \frac{j}{M} x - \frac{j}{N} \frac{\gamma}{f_2} \right) \right] \tag{8} \]

\[ \gamma = f_0 \Delta n l_m. \tag{9} \]

The parameter \( \gamma \) depends on the operating frequency \( f_0 \), the difference between the optical and electrical indices, \( \Delta n \), the active length \( l_m \), and the velocity of light \( c \). It is important to note that the calculation results depend solely on \( \gamma \) and not on \( \Delta n, l_m \), and \( f_0 \) independently. Thus the results of different lengths or relative wave velocities at different frequencies will be the same if \( \gamma \) is the same. The curves shown below are universal in the sense that they apply to more than the “worst case” velocity mismatch, which is \( \Delta n = 1.8 \) for lithium niobate modulators. Any change in \( \Delta n \) or \( l_m \) leads to a rescaling of the frequency axis for the gain and dynamic range plots.

Equation (7) is general and is the basis for the frequency dependent computations in the model. However, when the active region of a modulator consists of only simple phase shifts, as it does for the Mach–Zehnder modulator, a further simplification may be made. The transfer function is just a diagonal matrix of exponentials. Instead of multiplying exponentials, their arguments are summed. This is equivalent to integrating the location variable out of the voltage function. That is

\[ A_{\text{out}}(t) = H \left[ \int_0^{l_m} V(x, t - \frac{l_m - x}{\nu}) \, dx \right] l_m A_{\text{in}}(t) \tag{10} \]

\[ A_{\text{out}}(t_j) \approx H \left[ \sum_{k=0}^{N-1} V(x_k, t_j - \frac{x(N-1-k)}{\nu}) l_m \right] A_{\text{in}}(t). \tag{11} \]

The approximation introduced in (11) comes from the substitution of a summation for an integral, the relationship between \( A_{\text{out}} \) and \( H \) shown in (10) is exact. It may seem odd to use an approximation for a function for which a trivial analytic solution exists [integral of (8)]. However, this is done to mirror the calculation technique for directional couplers and to support the modeling of modulator voltage functions which may not have an analytic integral representation.

In the C-program mentioned above, the temporal increments, \( M \) are restricted to be powers of two, so that a radix-2 fast Fourier transform (FFT) algorithm may be used for the spectral analysis.\(^1\) Fig. 2 shows the convergence of the gain of a Mach–Zehnder modulator as a function of spatial increments \( N \) at 5, 10, 20, and 40 GHz. The error is the magnitude of the calculated gain (not in dB) minus the analytical value normalized by the dc analytical value for the gain. The curves of the log-log plot are for 5, 10, 20, and 40 GHz.

thus the \( y \)-axis value “one” corresponds to a 3 dB error and “0.1” corresponds to a 0.4 dB error in the calculated gain. The curves in Fig. 2 are linear until the error is six-to-seven orders of magnitude below the dc value of the gain (since the plot is log-log, constant slopes do not indicate geometric convergence). The convergence saturates at a normalized error of about \( 10^{-6} \) because the RF drive power for the small signal gain calculation was arbitrarily chosen to be \(-100 \) dBm. Whether in the calculation for gain or dynamic range, the numbers have components that differ by 6–7 orders of magnitude. Since these components occupy the same mantissa, there is a loss in accuracy not recovered by the floating decimal point. Double precision numbers must be used to attain a satisfactory accuracy. It is interesting to note that the calculated points form a horizontal line across the curves in the linear regime. This indicates that doubling \( \gamma \) (by doubling the frequency for instance) exactly requires a doubling of the modulator sections to achieve the same error. Efficient code allows the calculation hundreds of frequency points with a 128-point FFT and a comparable number of spatial increments in seconds on a contemporary desk-top machine (120 MHz Pentium processor).

\[ \text{III. MACH–ZEHNDE R AND DIRECTION AL COUPLER MODULATORS} \]

The most common electrooptic modulator is the Mach–Zehnder interferometer (MZM). It has a sine-squared transfer function, and the gain is a sinc function of the frequency-length-index product, \( \gamma \). When biased at the half-wave voltage, \( V = 0.5 V_{\pi} \), it attains its maximum linearity and dynamic range. All even-order harmonics are identically zero. The intermodulation distortion product solely determines the dynamic range, even in a super-octave system. The dynamic range is independent of frequency; the signal decays with frequency, but the intermodulation product decays identically. Thus, the range of RF drive powers (in dB), over which their are no spurs above the noise, shifts with a change in frequency, but it does not expand or

\( ^1 \) It is customary to use the FFT algorithm which is \( O(N \log(N)) \) instead of the DFT algorithm which is \( O(N^2) \). However, it should be noted that the algorithm to compute the modulator output is \( O(N^2) \), so the time spent in the FFT algorithm is inconsequential.
contract. Given its analytical simplicity and widespread use, the Mach–Zehnder is used first to evaluate the accuracy of the numerical calculation, and then it is used for a comparison to the linearized modulators.

Fig. 3 shows the calculations for gain and dynamic range of a simple MZM. The gain has the form $[\sin(\pi \gamma)/(\pi \gamma)]^2$ with zeros at multiples of 16.2 GHz (where $\gamma = 1$ for the canonical parameters from Table I), and a low frequency link gain of $-25.5$ dB (also appropriate for the link parameters). The dynamic range is flat except for a null and singularity near the gain null. This is a simple numerical artifact, resulting from the finite frequency difference between the two tones in the driving function. The signal, $f_1$, and the intermodulation product, $2f_1 - f_2$, are at slightly different frequencies, and hence, they null at different frequencies. The dynamic range goes to zero at the signal null and it goes to infinity at the distortion null.

Fig. 4 shows the analogous calculations for a directional coupler modulator. The low frequency gain is $-24.8$ dB, 0.7 dB better than Mach–Zehnder. The first null of the gain of the directional coupler occurs at 26 GHz, $\gamma = 1.6$, compared to 16 GHz for the MZM. The first lobe of the gain curve does not correspond to the sinc function of the Mach–Zehnder. However, subsequent nulls are periodic with a 16 GHz period, resulting from the underlying $\gamma$ of the directional coupler. The frequency at which the gain has fallen by 3 dB is 40% higher than that of the Mach–Zehnder modulator with the same index-length product.

The dynamic range compares unfavorably to that of the Mach–Zehnder. At low frequency it is similar to that of the MZM, and it is approximately flat with frequency. However there is a kink in the curve at 1.8 GHz (left vertical arrow), after which the dynamic range decays rapidly with frequency. Unlike the Mach–Zehnder, where all even-order derivatives of the transfer function are identically zero when the modulator

---

2 The comparison of the gain bandwidth product between the MZM and the DCM assumes that $V_c = V_l$; that is, the modulators have the same normalization voltages. While these voltages should be similar in the same manufacturing process, it is hard to directly compare them since the electrode geometries and crystal orientations of the two modulator types may differ.

---

IV. Broad-Band Linearized Modulators

Dynamic range values are calculated for two linearized broad-band, or superoctave, modulators: the dual parallel Mach–Zehnder (DPMZM) and the directional coupler with two passive sections (DCM2P) which are described in [4] and [5], respectively. The DPMZM has two identical, single Mach–Zehnder modulators in parallel optically and electrically but with unequal levels of optical and RF power driving the two modulators. Both modulators are biased at the $0.5V_c$ point, but with opposite slopes, so the modulators are 180 degrees out of phase. Most of the optical power and a small fraction of the RF power drive one modulator. A small amount of optical power and the majority of the RF power drive the other modulator, creating relatively larger distortion products than in the first modulator. The two signals are combined incoherently in the photodetector. The RF and optical splits are adjusted so that the distortion terms cancel exactly, but the
signals do not. Since these two paths are in parallel, the effects of velocity mismatch apply equally to each Mach–Zehnder. Thus, the distortion terms still precisely cancel regardless of frequency, and this is the result shown in Fig. 5. While the DPMZM is robust to velocity mismatch, in practice it is hard to make broadband. A precise RF split must be maintained over the desired frequency band. If it varies, the dynamic range will decrease at all but the narrow frequency at which the RF split is optimized.

The linearized directional coupler with two passive sections can be adjusted to provide high dynamic range with both intermodulation and second harmonic reduction in the absence of velocity mismatch. However, it suffers severely from velocity mismatch as shown in Figs. 5 and 6. By 80 MHz it is no better than the ordinary Mach–Zehnder and by 8 GHz it is 18 dB worse than the ordinary MZM. Fig. 6 shows the first 50 MHz of the DCM2P dynamic range in more detail. Unlike the DPMZM, in the DCM2P the mismatch between the RF drive and the modulated signal upsets the critical distortion cancellation conditions.

It has previously been reported [1] that the distortion cancellation condition is critically sensitive to the modulator parameters, particularly bias voltage. The voltage on the bias electrodes must be maintained to a very high accuracy. The accuracy required depends on the operating bandwidth, also explained in [1]. This requires active bias stabilization. Given the critical bias conditions and the fact that the distortion cancellation sections are in series, unlike the DPMZM, the rapid degradation with dynamic range is reasonable. The original experiments on this modulator were performed at audio frequencies where these effects would not be noticed [5]. Subsequently, measurements at 1 and 2 GHz [6] were single-frequency measurements, with the bias values reoptimized for the operating frequency; no bandwidth measurements around 1 and 2 GHz were made.

V. SUBOCTAVE LINEARIZED MODULATORS

For suboctave applications, the second harmonic may be ignored; the third-order intermodulation product alone determines the dynamic range. Two suboctave modulators are analyzed in this section.

1) The dual series Mach–Zehnder modulator (DSMZM), as described in [7], which has two MZM’s in series optically, the same bias voltage on each pair of electrodes, and a single RF electrode covering both modulators. Unlike the MZM, in the directional coupler, the intermodulation product nulls at a different voltage ($V_a$) than the signal ($V_s$). Thus no extra electrode sections (as in the DCM2P) are needed to make a suboctave directional coupler.

Fig. 7 shows the dynamic range as a function of frequency for the DSMZM and SDCM compared to the standard MZM reference (horizontal dotted line). Both of these modulators suffer from the effects of velocity mismatch and transit time. However, unlike the DCM2P, the DSMZM shows an advan-

3There are other cascaded Mach–Zehnders proposed in the literature. In some there are different bias voltages on the two electrodes. In [8] there is a time delay between the first and second modulator so that the RF drive and the modulated signal are rephased at the second Mach–Zehnder. While this version may be more common in the literature, for the purposes of a fair comparison, this modulation scheme is addressed in the section on periodic rephasing below. Additionally, in [9] a mixed directional coupler and Mach–Zehnder scheme purports to minimize the second and third harmonic.
CUMMINGS AND BRIDGES: BANDWIDTH OF LINEARIZED ELECTROOPTIC MODULATORS

Fig. 8. Reoptimization of the suboctave linearized directional coupler modulator (SDCM). Slightly adjusting the bias voltage around 0.79 \( V \), fully recovers the low-frequency dynamic range optimum, but only over a narrow bandwidth.

Fig. 9. Reoptimization of the dual series Mach–Zehnder modulator (DSM-ZM). Adjusting the bias voltage fully recovers the low-frequency dynamic range optimum, but only over a narrow bandwidth.

Fig. 10. Dynamic range comparison with 1 MHz noise bandwidth of five modulator configuration: the superoctave dual parallel Mach–Zehnder modulator (DPMZM), the superoctave directional coupler modulator linearized by two passive couplers in series (DCM2P), the suboctave dual series Mach Zehnder (DSMZM), the suboctave linearized directional coupler (SDCM), and the standard directional coupler modulator (DCM).

VI. THE EFFECTS OF NOISE

Noise effects linearized modulators somewhat differently than standard modulators. In a standard MZM, the noise bandwidth reduces the dynamic range by \((BW)^{2/3}\). In Fig. 1 the signal is a line with slope one, and the third-order intermodulation product is a line with slope three. The “noise floor” is a third, horizontal line which forms a triangle with the signal and the intermodulation line. The length of the base of this triangle is the dynamic range (in dB). The vertical position of the noise line is proportional to the \(\log(BW)\), so from simple geometry, it is clear that the dynamic range goes as \((BW)^{2/3}\). However, in a linearized modulator the third-order intermodulation product at \((2f_2 - f_1)\) has been nulled. The dominant intermodulation term is at \((3f_2 - 2f_1)\), and it grows as the fifth power of the RF drive. Thus the noise bandwidth reduces the dynamic range by \((BW)^{4/5}\). (More complicated linearization schemes can result in even steeper slopes for intermodulation, as discussed in [1]). The excess dynamic range, \(X\), of a linearized modulator over a ordinary modulator is

\[ X = C - \frac{4}{3} \log(BW) \]  

(12)

where \(BW\) is the bandwidth in Hertz, and \(C\) is a constant in dB equal to the difference between the dynamic range of a linearized modulator and a standard modulator with a 1-Hz noise bandwidth. This equation is only valid in the approximation that the signal and intermodulation curves are straight lines. For a comparison of the suboctave DCM versus the standard MZM, \(C\) equals 26 dB. For a 1 MHz noise bandwidth, \(X = 18\) dB. The dynamic range is often given for a 1-Hz noise bandwidth, and this simple scaling rule is applied to find the dynamic range of a system with a realistic bandwidth.

Apart from the different scaling rules, the noise bandwidth has an additional effect on linearized modulators. The dynamic range becomes less sensitive to device variations, either bias voltages or fabrication parameters, as the noise bandwidth increases. This makes it easier to maintain the distortion cancellation than is implied by some of the previous figures. Fig. 10 shows the dynamic range for the four modulators discussed above, but now with a 1-MHz noise bandwidth. The DPMZM and the MZM reference lines are flat as in the 1-Hz bandwidth case. The simple DCM is flat out to the
frequency where the second harmonic exceeds the intermodulation distortion, as in Fig. 3. However, the crossover now occurs at 3.8 GHz instead of 1.8 GHz. The DSMZM, SDCM, and DCM2P dynamic ranges, which all roll off with frequency, now do so at a slower rate than in the 1-Hz bandwidth case. While the DCM2P still rolls off too quickly to be a useful modulator, the suboctave modulators are starting to show reasonable frequency performance. A similar reduction in peak dynamic range, with a broadening of the bandwidth over which it occurs, is also obtained in the bias reoptimized curves of Figs. 8 and 9.

VII. BANDWIDTH RECOVERY THROUGH PERIODIC REPHASING

One method of overcoming the degradation in dynamic range due to velocity mismatch is to break the transmission line into a number of segments and rephase the signal at the beginning of each segment. This is velocity-matching “on the average.” The technique has been used successfully in a number of forms, for example, [10]–[12]. The program written for this study is easily modified to make calculations for such periodically rephased modulators, since the modulator is already broken up into a cascade of matrices. Thus, the modulator is incrementally velocity mismatched for a few matrices and is then rephased for the next section, and so on. Fig. 11 shows the results of such a calculation for the simple DCM link with the parameters used above, but with the modulator’s transmission line having 1, 2, 3, and 4 segments. The 1-segment curve repeats the result in Fig. 4 (no rephasing) for reference. With only two segments (one rephasing), the bandwidth over which the dynamic range is flat improves vastly, and using four segments gives an essentially flat dynamic range. Of course, it would still be preferable to use a standard MZM for broadband links since it does not require rephasing.

A similar dramatic improvement is obtained in the SDCM, biased at the 0.79 Vgs point, as shown in Fig. 12. The curve from Fig. 7 is shown for reference along with curves for two-, three-, and four-electrode segments. The curve for one segment initially shows a deep roll-off in dynamic range and then a more gradual roll-off, with only 5 dB of dynamic range improvement over the standard MZM remaining at 8 GHz.

With just two segments, the roll-off is made gradual over the whole range. With four segments, there is 18 dB of dynamic range improvement remaining at 8 GHz. This figure assumes a 1-Hz noise bandwidth. When a 1-MHz noise bandwidth is used, the roll-off is more gradual. For instance, the dynamic range of the two-electrode segment SDCM is better than the two-electrode DSMZM (shown in Fig. 13) up to 5.9 GHz.

A very interesting result of the application of rephasing is seen in the dual series Mach–Zehnder (DSMZM) with multiple electrode segments. Note that two (and any even number) segment give frequency independent dynamic range.

Fig. 11. Dynamic range versus frequency for the standard directional coupler modulator (DCM) with multiple electrode segments. The arrows show the breaks between the intermodulation and the second-harmonic limitation of the dynamic range.

Fig. 12. Dynamic range versus frequency for the suboctave linearized directional coupler (SDCM) with multiple electrode segments.

Fig. 13. Dynamic range versus frequency for the the suboctave dual series Mach–Zehnder (DSMZM) with multiple electrode segments. Note that two (and any even number) segment give frequency independent dynamic range.
velocity matching, by somehow making $\Delta n \rightarrow 0$ is preferable if possible, since there is no $\sqrt{N}$ penalty.

We wish to remind the reader that all the results obtained in this study may be applied to modulators with any degree of velocity matching by rescaling the frequency axis by the change in $\gamma$, the frequency-length-index product.

Schawlow Medal from the Laser Institute of America in 1986, and the IEEE LEOS Quantum Electronics Award in 1988. He is a member of the National Academy of Engineering and the National Academy of Sciences, and a Fellow of the Optical Society of America (OSA) and the Laser Institute of America. He was a Sherman Fairchild Distinguished Scholar at Caltech, Pasadena, CA, in 1974–1975, and a Visiting Professor at Chalmers Technical University, Göteborg, Sweden, in 1989. He has served on various committees of both IEEE and OSA and was formerly Associate Editor of the IEEE Journal of Quantum Electronics and the Journal of the Optical Society of America. He was the President of the Optical Society of America in 1988, a member of the United States Air Force Scientific Advisory Board 1985–1989, and a member of the Board of Directors of Uniphase Corporation 1986–1998.
