LIGHT CURVES OF CORE-COLLAPSE SUPERNOVAE WITH SUBSTANTIAL MASS LOSS USING THE NEW OPEN-SOURCE SUPERNOVA EXPLOSION CODE (SNEC)

ABSTRACT

We present the SuperNova Explosion Code (SNEC), an open-source Lagrangian code for the hydrodynamics and equilibrium-diffusion radiation transport in the expanding envelopes of supernovae. Given a model of a progenitor star, an explosion energy, and an amount and distribution of radioactive nickel, SNEC generates the bolometric light curve, as well as the light curves in different wavelength bands assuming black body emission. As a first application of SNEC, we consider the explosions of a grid of 15 $M_\odot$ (at zero-age main sequence) stars whose hydrogen envelopes are stripped to different extents and at different points in their evolution. The resulting light curves exhibit plateaus with durations of $\sim 20 - 100$ days if $\gtrsim 1.5 - 2 M_\odot$ of hydrogen-rich material is left and no plateau if less hydrogen-rich material is left. The shorter plateau lengths are unlike the Type IIP supernova light curves typically observed in nature. This suggests that, at least for zero-age main sequence masses $\lesssim 20 M_\odot$, hydrogen mass loss occurs as an all or nothing process, perhaps pointing to the important role binary interactions play in observed mass-stripped supernovae (i.e., Type Ib/c events). These light curves are also unlike what is typically seen for Type III supernovae, arguing that simply varying the amount of mass loss cannot explain these events. The most stripped models begin to show double-peaked light curves similar to what is often seen for Type Ib supernovae, confirming previous work that these supernovae can come from progenitors that have a small amount of hydrogen and a radius of $\sim 500 R_\odot$.

Subject headings: hydrodynamics — radiative transfer — supernovae: general

1. INTRODUCTION

During the last half century the number of observed supernovae (SNe) has increased exponentially (Minkowski 1964; Cappellaro 2014). Much of this progress has been fueled by recent surveys, such as the Lick Observatory Supernova Search (LOSS, Leaman et al. 2011; Smith et al. 2011), the Sloan Digital Sky Survey (SDSS, Frieman et al. 2008), and the Palomar Transient Factory (PTF, Rau et al. 2009). In addition to providing more complete and detailed samples of well-known classes of SNe (Type Ia, Ib/c, II), these surveys have found a wide range of previously unknown explosive events, from superluminous SNe (Quimby et al. 2011) to rapid SN-like transients (Perets et al. 2010; Kasliwal et al. 2010, 2012; Foley et al. 2013; Inserra et al. 2015). This has opened our eyes to the broader range of astrophysical explosions that can exist in nature.

Progress in explosive, transient observations has been closely followed by progress in analytic and numerical light curve modeling. For example, for SNe IIP, this has ranged from analytic scalings (Arnett 1980; Chugai 1991; Popov 1993) to detailed numerical works (e.g., Livio et al. 2000; Stritzinger et al. 2000; Kasen & Woosley 2009; Bersten et al. 2011; Dessart et al. 2013). These investigations focused on understanding the general imprint of progenitor characteristics (mass, radius, abundance and mixing of $^{56}$Ni, etc.) on the shape and luminosity of SN light curves. In other cases, detailed comparisons have been made between SNe II and numerical models (Arnett 1988; Shigeyama et al. 1988; Woosley 1988; Utrobin 1993 for SN 1987A, Nomoto et al. 1993; Bartunov et al. 1994; Shigeyama et al. 1994; Young et al. 1995; BLinnikov et al. 1998 for SN 1993es, Baklanov et al. 2005; Utrobin 2007 for SN 1999em).

The combination of growing samples of SNe and other previously unknown transients has motivated us to develop a new code for numerical studies of the light curves of SN and SN-like explosions. Called the SuperNova Explosion Code (SNEC), this general purpose code will allow the user to take a stellar model (or other ad-hoc density profile and other thermodynamic and compositional information), input energy to generate an explosion, follow the hydrodynamic response, and produce light curves. The current iteration of SNEC is spherical-symmetric (1D), and uses Lagrangian hydrodynamics and equilibrium-diffusion (one-temperature) radiation transport. It also follows other basic physics needed for light curves such as ionization and heating from $^{56}$Ni. This will help bridge the gap between the most sophisticated radiative transfer codes currently being utilized (BLinnikov & Bartunov 1993; Moriya et al. 2011; Hillier & Dessart 2012; Kasen & Woosley 2009) and simpler semi-analytic investigations. Our work is very much in the same spirit as the work of Bersten et al. (2011), whose code, however, is not open source.

A crucial aspect of SNEC is that it is open source and publicly available, so that light curve modeling is accessible and reproducible for the broader community. It can be used for a wide range of studies, from generating typical SN light curves as an educational tool to making light curves for novel explosion scenarios. Modeling explosions and light curves involves a wide range of physics and necessary approximations that are often too complex to be described in detail in journal publica-

10 May 2015
tions. Hence, making code available and results reproducible is crucial for the advancement of the field.

An important strength of a code like SNEC is the ability to systematically and quickly explore changes in stellar properties to learn how they impact the resulting light curves. This is especially useful for investigating the underlying mechanisms behind the photometric diversity of SNe II light curves, such as the SNe IIP (with nearly constant plateau luminosity for a period \(\sim 100\) days past maximum, and the most common type), SNe IIL (with linearly declining magnitude), and SNe I Ib (which show signatures of hydrogen present, but with a light curve generally more similar to SNe IIb\(^5\)). In particular, the connection between SNe IIP and SNe IIL has long been a point of contention in the SN community. Early on, it was suggested by Barbon et al. (1979) and corroborated by Blinnikov & Bartunov (1993) that the morphological differences might be explained by altering the envelope masses while keeping the explosion mechanism the same (however, see Swartz et al. 1991 for an alternative picture). In this explanation, SNe IIL would simply have less hydrogen-rich envelope mass than SNe IIP. Nevertheless, SNe IIL must still have appreciable hydrogen present, otherwise they would become SNe Ib/c instead. This suggests that there may exist a continuous range of hydrogen mass stripping and thus a continuous range of events between canonical SNe IIP and SNe IIL. Furthermore, SNe Ib have been inferred to have a small amount of hydrogen present \((\sim 0.01 \sim 0.1\, M_\odot)\, Woosley et al. 1994; Bersten et al. 2012; Nakar & Piro 2014\), and thus in principle with sufficient mass loss a transition should be seen all the way to SNe IIb. The question is whether additional ingredients are needed beyond just increased mass loss to reproduce their main features.

Motivated by these questions, we investigate the mass-loss hypothesis for the origin of these well-known SN II classes as a first application of SNEC. We use presupernova stellar models generated with the open-source MESA code (Paxton et al. 2011, 2013). Besides providing excellent control in generating models and investigating mass stripping, MESA has been used for generating preexplosion models for other light curve studies (e.g., Dessart et al. 2013), which allows us to compare directly with these studies as a further check of SNEC. Although we find that varying levels of hydrogen mass stripping shortens the plateau of the light curves, we conclude that simply varying the amount of mass loss alone cannot explain the full range of properties of SNe IIL. In the most mass stripped cases, we begin to see double-peaked light curves reminiscent of some SNe IIn, suggesting that this transition occurs more naturally. Further work will be needed for a more complete investigation of SNe IIn properties.

In Section 2, we describe SNEC in detail. We follow, in Section 3, with our study of massive stars with various levels of stripping. In Section 4, we show the light curves resulting after explosion of these stars. We conclude in Section 5 with a summary of our findings and a discussion of future work. In Appendices A and B, we discuss SNEC in comparison with the work of Bersten et al. (2011) and Dessart et al. (2013), respectively.

2. SNEC

We describe SNEC with a focus on SN IIP light curve modeling. Although we anticipate that SNEC will continue to evolve and improve as it is utilized for new projects and more physics is added, the discussion below will provide some necessary background and summarize SNEC’s general features. A more detailed description that also includes the finite-difference form of the equations and implementation details is available on the SNEC webpage, http://stellarcollapse.org/SNEC.

2.1. 1D Lagrangian LTE Radiation Hydrodynamics with Ionization

Lagrangian hydrodynamics in spherical symmetry, supplemented with a radiation diffusion term, written to the first order in \(v/c\) (see, e.g., Mihalas & Mihalas 1984; Mezzacappa & Bruenn 1993; Bersten 2010), results in a mass conservation equation (continuity equation),

\[
\frac{\partial r}{\partial m} = \frac{1}{4\pi r^2\rho},
\]

in an energy equation,

\[
\frac{\partial e}{\partial t} = \frac{P}{\rho} \frac{\partial \ln \rho}{\partial t} - 4\pi^2 Q \frac{\partial v}{\partial m} - \frac{\partial L}{\partial m} + \epsilon_{N_\text{I}},
\]

and in a momentum equation,

\[
\frac{\partial v}{\partial m} = \frac{Gm}{r^3} - 4\pi r^2 \frac{\partial P}{\partial m} - 4\pi \frac{\partial (r^2 Q)}{\partial m}.
\]

Here \(m = \int_0^r 4\pi r^2 \rho(r') dr'\) is the mass coordinate, \(r\) is the radius, \(t\) is the time, \(\rho\) is the density, \(c\) is the specific internal energy, \(P\) is the pressure, \(v = dr/dt\) is the velocity of the matter, \(Q\) is the artificial viscosity, \(\epsilon_{N_\text{I}}\) is the specific energy deposited due to the radioactive decay of \(^{56}\text{Ni}\), and \(G\) is the gravitational constant. The radiative luminosity \(L\) is

\[
L = -(4\pi r^2)^2 \frac{\lambda a c}{3\kappa} \frac{\partial T^4}{\partial m},
\]

where \(a\) is the radiation constant, \(c\) is the speed of light, \(\lambda\) is the flux-limiter and \(\kappa\) is the Rosseland mean opacity. For capturing shocks, we use a simple von Neumann-Richtmyer artificial viscosity (von Neumann & Richtmyer 1950)

\[
Q \equiv \begin{cases} C\rho(\partial v/\partial l)^2 & \text{if } \partial v/\partial l < 0, \\ 0 & \text{otherwise}, \end{cases}
\]

where \(l\) is an integer grid coordinate, and \(C = 2\). Following Bersten et al. (2011), we use the flux limiter of Levermore & Pomraning (1981),

\[
\lambda = \frac{6 + 3R}{6 + 3R + R^2},
\]

where

\[
R = \frac{4\pi r^2}{\kappa T^4} \left| \frac{\partial T^4}{\partial m} \right|.
\]
is linearized in $\delta T$. We use $\theta = 1/2$ for all simulations presented in this paper. Using an initial guess for the temperature at the next time step, we iteratively solve for $\delta T$, inverting a tridiagonal matrix each time, until the fractional change in temperature is less than a set tolerance ($10^{-7}$ in the current version of the SNEC). We do not take the dependence of the opacity $\kappa$ on temperature into account in the implicit update and rather use the opacity from the previous time step when solving for the temperature at the next step.

SNEC assumes local thermodynamical equilibrium (LTE), imposing the same temperature for radiation and matter. This assumption is not valid at shock breakout and during and after the transition phase from optically thick to optically thin ejecta. In SNe IIP, it is reliable only during the plateau phase of the light curve (see the discussions in Blinnikov & Burtnov 1993; Bersten et al. 2011). However, the comparison performed by Bersten (2010) between her LTE code and a multi-group code suggests satisfaction agreement along the entire light curve.

As a boundary condition for Equation (3), we adopt $P = 0$ at the center of the boundary cell, so half a grid cell outside the star. For Equation (2) we assume that the luminosity at the surface is equal to the luminosity at the closest interior grid point, i.e., that the diffusive term, $\partial L/\partial m$, at the outer boundary is equal to zero. At the inner boundary, we take the velocity and the bolometric luminosity to be zero. In the modeling of core-collapse SN light curves, the inner boundary is typically not at $m = 0$ due to the presence of a neutron star (or a black hole), which is excluded from the grid. Setting the inner velocity to zero excludes any possibility for fallback of material on the remnant in our models.

To close the system of hydrodynamic equations, we employ the analytic equation of state (EOS) given by Paczyński (1983), hereafter the Paczyński EOS. The Paczyński EOS contains contributions from radiation, ions, and electrons, and takes into account electron degeneracy approximately. We repeat some of our model calculations with theb the tables of Holt et al. (2000). The set of Saha equations, together with the condition of charge neutrality and number conservation of nuclei of a given chemical element (enumerated by index $k$), may be combined into a single transcendental equation for the average charge $\bar{z}_{k}$ of element $k$ with atomic number $Z_{k}$ as

$$1 - \bar{z}_{k} = \frac{z_{k} \prod_{j=1}^{i} f_{k,j}}{\sum_{i=1}^{z_{k}+1} (Z_{k}n_{k})^{i}} \left(1 + \frac{\prod_{j=1}^{i} f_{k,j}}{z_{k} \prod_{i=1}^{j} (Z_{k}n_{k})^{i}} \right)^{-1} = 0,$$ \hspace{1cm} (8)

with

$$f_{k,i+1} = \frac{g_{k,i+1}}{g_{k,i}} \left[ \frac{2 \pi m_{e} k_{B} T}{h^{2}} \right]^{3/2} \exp \left( \frac{I_{k,i}}{k_{B} T} \right),$$ \hspace{1cm} (9)

where $i$ is the number of the ionization state (0 corresponds to the neutral atom), $Z_{k}$ is the atomic number of element $k$, $n_{k}$ is the number density of element $k$, $g_{k,i}$ is the statistical weight of the $i$-th ionization state of element $k$, $I_{k,i}$ is the (positive) ionization energy for the ionization process $i \rightarrow (i+1)$, $m_{e}$ is the electron rest mass, $h$ is Planck's constant and $k_{B}$ is Boltzmann’s constant. Equation (8) is solved iteratively at each call to the EOS, after which the ionization fractions $\alpha_{k,i}$ are found as

$$\alpha_{k,0} = \frac{Z_{k}}{Z_{k} n_{k}} \left( \frac{\prod_{j=1}^{i} f_{k,j}}{Z_{k}^{i} n_{k}^{i}} \right)^{-1},$$ \hspace{1cm} (10)

$$\alpha_{k,i+1} = \frac{\alpha_{k,i} f_{k,i+1}}{Z_{k} n_{k}}.$$ \hspace{1cm} (11)

Although one can consider as many elements as necessary at the expense of computational time, for the present work we focus on the ionization of hydrogen and helium. The specific internal energy is calculated as

$$\epsilon = \epsilon_{\text{ion}} + \epsilon_{\text{el}} + \epsilon_{\text{rad}} + \Delta \epsilon_{\text{ion}},$$ \hspace{1cm} (11)

where $\epsilon_{\text{ion}}, \epsilon_{\text{el}},$ and $\epsilon_{\text{rad}}$ are the contributions from ions, electrons, and radiation, respectively, and

$$\Delta \epsilon_{\text{ion}} = \frac{1}{\rho} \sum_{k} \left[ n_{k} \sum_{i=1}^{z_{k}} \left( \alpha_{k,i} \sum_{j=0}^{i-1} I_{k,j} \right) \right]$$ \hspace{1cm} (12)

is the ionization energy whose zero point for each element $k$ is the neutral atom.

2.2. Opacities

The Rosseland mean opacity $\kappa$ is an essential input to our light curve models. In the high temperature regime ($10^{3.75}$ K < $T < 10^{8.7}$ K), we use the OPAL Type II opacity tables (Iglesias & Rogers 1996) for solar metallicity ($Z_{\odot} = 0.02$ here). These tables allow for an increase in the mass fractions of two chosen metals (in our case, carbon and oxygen) by deducting an amount of helium to keep the sum of the mass fractions equal to unity. At low temperatures ($10^{2.7}$ K < $T < 10^{5.5}$ K), we use the tables of Ferguson et al. (2005). These tables are available for solar composition, but not for enhanced carbon and oxygen mass fractions compatible with the OPAL tables. In the overlap region between the OPAL and the Ferguson et al. tables ($10^{3.75}$ K < $T < 10^{4.5}$ K), we give preference to the low-temperature opacity tables, because they take into account the contribution from molecular lines (this contribution is not included in the OPAL tables). For carbon and oxygen enhanced compositions, there are regions of low temperature and density for which opacity values are not available. In these regions, the opacity is generally most sensitive to temperature, and thus we set the opacity to the nearest value that is available at the same temperature. Most of the opacities set this way are below the opacity floor (see below), so that this deficiency in the tables has a small impact on the light curve evolution. At worst, it may affect the transition between the plateau and the $^{56}$Ni dominated part of SN IIP light curves when the photosphere first moves into carbon/oxygen-rich regions.
The Rosseland mean opacity that we obtain from the OPAL and Ferguson et al. tables does not describe all possible sources of opacity needed for simulating SN light curves. As has been argued in previous works (see Karp et al. 1977; Young 2004; Blinnikov 1996; Bersten et al. 2011), the tabulated Rosseland mean opacity calculated for a static medium may underestimate the contribution of the line opacities in the rapidly expanding matter of the exploding star, plus it does not contain possible non-thermal ionization and excitation by gamma rays. Due to these missing effects, it is common practice to use a so-called opacity floor, effectively imposing a minimum possible value for the opacity. Presently, there is no universally agreed-upon prescription for how to choose this opacity floor for a given composition and velocity. In previous work, different values of the opacity floor were chosen based either on simplified physical arguments (e.g., Shigeyama & Nomoto 1990) or based on comparisons with results obtained with multi-group or line-transfer codes (e.g., Bersten et al. 2011). For SNe IIP, the values of the opacity floor for the hydrogen-rich envelope and the metal-rich core of the star, as well as the location and shape of the transition between the core/envelope opacities, can strongly influence the shape of the resulting light curve. Qualitatively (as shown in Bersten 2010 and confirmed by our simulations), a lower value of the opacity floor in the envelope of the star increases the plateau luminosity and decreases the duration of the plateau, and vice versa. The luminosity of the plateau and its duration are important observed photometric quantities that are used for statistical studies of SNe IIP (as, e.g., in Anderson et al. 2014\textsuperscript{6}). Hence, it is important to keep the uncertainties in the opacity and their propagation into variations in the light curve in mind when comparing modeling results with observations.

In the work of Bersten et al. (2011) on SN IIP light curves, the opacity floor was set to 0.01 cm\(^2\) g\(^{-1}\) for the "envelope" and 0.24 cm\(^2\) g\(^{-1}\) for the "core." Since Bersten et al. (2011) are not specific in defining what constitutes the core and envelope, and because this prescription introduces large opacity discontinuities, we take a different approach in SNEC. We choose the opacity floor to be linearly proportional to metallicity \(Z\) at each grid point, and set it to 0.01 cm\(^2\) g\(^{-1}\) for solar composition \((Z = 0.02)\) and to 0.24 cm\(^2\) g\(^{-1}\) for a pure metal composition \((Z = 1)\).\textsuperscript{7} Note that we do not include the opacity floor in the calculation of the optical depth and position of the photosphere (as in Bersten et al. 2011). This is justified by the fact that the opacity floor is used to account for line effects, which have minor influence on the shape of most of the continuum spectrum. However, we note that in the blue part of the spectrum (e.g., in the \(U\) and \(B\) bands), the continuum may be affected by the numerous lines of iron-group elements (see, e.g., Figure 8 of Kasen & Woosley 2009).

2.3. Radioactive \(^{56}\)Ni and Bolometric Luminosity

Radioactive \(^{56}\)Ni in core-collapse SNe is synthesized by explosive nuclear burning of intermediate-mass elements during the first seconds of the SN explosion in the inner regions of the star. It is mixed outward by hydrodynamic instabilities triggered by the shock's propagation through the envelope (see, e.g., Kifonidis et al. 2003, 2006; Wongwathanarat et al. 2015). The gamma rays, emitted in the \(^{56}\)Ni \(\rightarrow\) \(^{56}\)Co \(\rightarrow\) \(^{56}\)Fe decay process, diffuse and thermalize, providing an additional source of energy \(\epsilon_{\text{Ni}}\) in Equation (2).

The present version of SNEC does not include a nuclear reaction network and the amount and distribution of synthesized \(^{56}\)Ni is provided by the user. While this is a technical limitation that will be removed in future versions of SNEC, one should keep in mind that nucleosynthetic yields are sensitive to (1) how the explosion is launched, (2) where (in mass and spatial coordinate) it is launched, (3) to uncertainties in the structure and composition of the layers in which explosive burning occurs (e.g., Young & Fryer 2007). Specifying the \(^{56}\)Ni yield by hand removes these uncertainties from our models and has the added benefit of allowing the user complete control of radioactive heating which can be useful for exploring how it impacts light curves.

For the gamma rays released in \(^{56}\)Ni and \(^{56}\)Co decay, we follow the gray transfer approximation of Swartz et al. (1995), solving the transfer equation in the form

\[
\frac{dI'}{dt} = I' - X_{\text{Ni}},
\]

where \(\tau\) is the optical depth along a given ray, \(X_{\text{Ni}}\) is the mass fraction of \(^{56}\)Ni, \(I' = \left(\frac{4\pi}{\kappa_{\gamma}}\right)I\) and \(I\) is the energy-integrated intensity. The effective gamma-ray opacity is assumed to be purely absorptive and independent of energy, \(\kappa_{\gamma} = 0.06 Y_e\) cm\(^2\) g\(^{-1}\), where \(Y_e\) is the electron fraction. The time-dependent rate of energy release per gram of radioactive nickel, \(\epsilon_{\text{rad}}\), is equal to

\[
\epsilon_{\text{rad}} = 3.9 \times 10^{10} \exp\left(-t/\tau_{\text{Ni}}\right) + 6.78 \times 10^9 \exp\left(-t/\tau_{\text{Co}}\right)
\]

where \(\tau_{\text{Ni}}\) and \(\tau_{\text{Co}}\) are the mean lifetimes of \(^{56}\)Ni and \(^{56}\)Co, equal to 8.8 and 113.6 days, respectively. The local heating rate in each grid point is equal to \(\epsilon_{\text{Ni}} = \epsilon_{\text{rad}}d\), where \(d\) is the deposition function

\[
d = \frac{1}{4\pi} \int I' d\omega,
\]

where \(\omega\) is the solid angle. We do not take into account the energy from positrons released in the radioactive decay of \(^{56}\)Co (which occurs for 19\% of the decays). The total kinetic energy of positrons per \(^{56}\)Co decay is \(\sim 0.12\) MeV versus \(3.61\) MeV emitted via gamma rays (see Nadyozhin 1994). Therefore, neglecting this contribution constitutes an error of order 3 – 4\% in the overall energetics of the \(^{56}\)Ni decay (Swartz et al. 1995).

Finally, we calculate the observed bolometric luminosity as suggested in Young (2004). It consists of two parts, the luminosity at the photosphere and the luminosity due to the absorption of gamma rays from \(^{56}\)Ni/\(^{56}\)Co decay above the photosphere

\[
L_{\text{obs}} = L_{\text{photo}} + \int_{m_{\text{photo}}}^{M} S_{\text{dep}}(m) dm.
\]

Here \(m_{\text{photo}}\) is the mass coordinate of the photosphere, \(M\) is the total mass of the star, \(S_{\text{dep}}\) is the energy per gram per second deposited by gamma rays. The location of the photosphere is defined by the optical depth \(\tau = 2/3\), and \(L_{\text{photo}}\) is found from Equation (4) at the photosphere location.
3. PROGENITOR MODELS WITH VARYING HYDROGEN-RICH ENVELOPE MASSES

3.1. Motivation and Overall Strategy

As a first application of SNEC we investigate the light curves of SNe from massive stars that have lost varying (but large) amounts of their hydrogen-rich envelope during their evolution. We use SNEC to explode presupernova models that we generate with the open-source stellar evolution code MESA (release version 6794; Paxton et al. 2011, 2013). The employed MESA input files and the final presupernova profiles are available at http://stellarcollapse.org/SNEC.

Massive stars may lose large fractions of their hydrogen-rich envelopes via steady line-driven winds, via stable or unstable binary mass transfer, or, possibly, through pulsational instabilities and eruptions (see, e.g., Smith 2014 for a recent review). The demographics of SN types combined with initial-mass-function considerations suggest that line-driven winds alone cannot account for the fraction of observed stripped-envelope SNe (Smith et al. 2011). One of the other avenues of mass loss may be required to partially or completely remove hydrogen-rich envelope to account for the fraction of observed Type Ibb and Ib/c SNe. Since virtually all massive stars are born in binaries and up to 70% of them will interact with their companion (Sana et al. 2012), binary interaction may be the top contender for how massive stars shed their hydrogen-rich envelopes. It is possible that binary interactions (and other mass-loss mechanisms) can result in various degrees of envelope stripping and that there is a broad distribution of hydrogen-rich envelope masses at the presupernova stage of stars of any given zero-age main sequence (ZAMS) mass.

Our goal here is to study the effects of substantial mass loss during massive star evolution on presupernova structure and the resulting SN light curve. We assume that the mass is lost rapidly (e.g., in an unstable mass transfer event or through some instability), but sufficiently slowly that the star can re-adjust to a new equilibrium after the mass loss event. Rather than attempting to self-consistently simulate various highly uncertain mass loss mechanisms, we instead conduct a controlled experiment in stellar astrophysics by systematically stripping material from the envelope of a fiducial $M_{\odot}$ star at different points of its evolution. We note that Bayless et al. (2014) carried out a similar study of the effects of mass stripping on Type II SN light curves. However, they considered a 23-$M_{\odot}$ progenitor model and stripped it only at the presupernova stage.

Figure 1 shows the evolutionary track on the Hertzsprung-Russell diagram for the 15-$M_{\odot}$ reference model. Rapid mass loss is most likely to occur in the post-MS evolution because the envelope expands and becomes only weakly bound to the compact core. When precisely the mass loss event occurs and how much mass is lost will depend on the process causing mass loss and possibly widely varying parameters such as the details of binary configuration. In order to account for our ignorance of the details of the mass loss event, we consider three points (indicated by symbols in Figure 1; see also Table 1) in the post-MS evolution of our reference model that probe different envelope structures and span envelope radii from $\sim 80 R_{\odot}$ to $\sim 640 R_{\odot}$:

- **mSGB** series: These models are stripped at $T_{\text{eff}} = 10^4$ K, which marks the middle of the subgiant branch
- **hMR** series: These models are stripped when the radius first surpasses the half-maximum radius (hMR) of the reference model, $R \sim 375 R_{\odot}$. At this point, the envelope region outside a mass coordinate of $m \sim 9.5 M_{\odot}$ is convective while deeper layers are radiative. There is hydrogen shell burning and a small core helium burning region.
- **MCE** series: These models are stripped when the maximum radial extent of the convective envelope is reached (MCE, at a stellar radius of $R \sim 638 R_{\odot}$). The outer $\sim 8 M_{\odot}$ of the star are fully convective at this point. There is hydrogen shell burning and a small core helium burning region.

In each series of models, we strip in units of $1 M_{\odot}$, but stop before we reach the hydrogen shell burning region and keep at least $1 M_{\odot}$ of the radiative layer that surrounds it. Note that if we considered Roche-lobe overflow in a binary system as the mechanism for mass loss, then only the outer convective layers could be lost in an unstable Roch-lobe overflow event, but stripping of radiative layers would not occur dynamically (cf. Hilditch 2001).

The time spanned by mSGB–hMR–MCE is only of or-
MCE, respectively. After stripping, about ~10^6 yrs of evolution are left until core collapse.

### 3.2. MESA Simulations

We employ MESA release version 6794 ( Paxton et al. 2011, 2013) and assume solar metallicity Z_{⊙} = 0.019. We use the Ledoux criterion for convection and follow the mixing parameter choices of Sukhbold & Woosley (2014), who set the mixing length parameter \( \alpha_{\text{mlt}} = 2.0 \), the overshooting parameter \( f_{ov} = 0.025 \), and semiconvection efficiency \( \alpha_{sc} = 0.01 \), and do not consider thermonuclear mixing. We use the wind mass loss prescription of Vink et al. (2000, 2001) for the hot MS phase and that of de Jager et al. (1988) for the cool giant phase, both with \( \eta = 1.0 \). We limit MESA’s timestep by enforcing fractional changes in structure and thermodynamics variables of less than 10^{-3} per timestep (\texttt{varcontrol.target} = 10^{-3}) and, in addition, use a customized timestep control that enforces a timestep that is always smaller than the model’s Kelvin-Helmholtz time. We use MESA’s standard setting for rezooming, \texttt{mesh.deltaCoeff} = 1.0, and \texttt{mesh.deltaCoeffForHighT} = 1.5, which coarsens the resolution at \( T > 10^9 \) K and, thus, in the core region, where we do not currently trust MESA results (see below). These standard resolution setting provide a sufficiently finely resolved envelope for our SNec explosion and light curve simulations.

For simplicity and speed of execution, we simulate all models with MESA’s default 21-isotope nuclear reaction network \texttt{approx21} until the onset of core collapse, which is commonly defined as the point when the infall velocity reaches 1000 km s^{-1}. We note that much larger (100 – 1000 isotope) networks are needed for an accurate treatment of late oxygen burning and silicon burning and of the pre-collapse neutronization in the degenerate core (e.g., Sukhbold & Woosley 2014; Arnett, private communication). Since the treatment of these late burning stages has a large effect on the core region out to the carbon-oxygen – helium interface (Sukhbold & Woosley 2014), the core structure of our MESA models is not reliable. Core collapse and postbounce supernova simulations that focus on the explosion mechanism suggest that the structure in the inner 1.4 – 2.5 M⊙ may determine if neutrino-driven explosions fail or succeed (O’Connor & Ott 2011; Ugliano et al. 2012; Ertl et al. 2015). However, for our explosion study with SNec, details of the core structure are not essential, since the outer regions and the hydrogen-rich envelope determine the light curve. We also artificially launch explosions and introduce 56Ni by hand (see Section 2).

### 3.3. Stripping Procedure

We first evolve copies of the unstripped reference model to the onset of core collapse, and to the three stripping points: mSGB, hMR, and MCE (see Table 1 and Fig. 1). At these stripping points, we then restart and use MESA’s module \texttt{adjust_mass} to “instantaneously” remove the specified amount of mass. The new smaller value of the total mass is reached using 80 MESA “pseudo-evolution” steps (i.e., the structure is evolved using timesteps, but the time coordinate is held constant). During each step, MESA removes the largest amount of mass from the envelope that it can while still finding a hydrostatic solution to the structure equations. In most cases, \( \sim 75 \) are sufficient to reach the desired mass and the last \( \sim 5 \) have mass loss set to zero. Both during and at the end of the pseudo-evolution, the structure is always in global hydrostatic equilibrium, therefore, when the regular evolution resumes, no readjustment occurs.

We strip mass in 1 M⊙ steps and continue the evolution of each model to the onset of core collapse. We refer to the unstripped reference model simply as “unstripped,” and name the stripped models according to [stripping point][number of M⊙ stripped]M. For example, “hMR_5M” stands for a model that had 5 M⊙ stripped at hMR.

### 3.4. Resulting Presupernova Structure

We summarize the presupernova structure of our model set in Table 2 and Figure 2. The unstripped reference model reaches the presupernova stage as a 12.28 M⊙ RSG with a hydrogen-rich envelope mass of \( M_H \sim 7.18 \) M⊙. The stripped models have envelopes of systematically lower mass, approximately proportional to the amount of mass removed. While \( M_H \) varies by more than a factor of seven (\( M_H \sim 0.31 – 0.38 \) for the most stripped models) within a model series, the final stellar radius varies only by a factor of ~2. Hence, the envelopes become increasingly dilute (lower-density) with increasing stripping. Following the \( T_{eff} \) criterion of Georgy (2012), our models with less than 6 M⊙ die as RSGs while models from which we strip 6 M⊙ or 7 M⊙ die as yellow supergiants (YSGs). It is apparent from Figure 2 that the choice of stripping point has almost negligible influence on the final mass and structure of the remaining hydrogen-rich envelope. Differences in \( M_H \) and radius \( R \) are generally \( \lesssim \) 5% between models from different series that had the same amount of mass removed. An exception are the most extreme \_M7 cases (7 M⊙ of hydrogen-rich material stripped) that show a \( \sim 20 \% \) variation in their final \( M_H \) from 0.31 M⊙ in model MCE_7M, 0.32 M⊙ in model mHR_7M, to 0.38 M⊙ in model mSGB_7M. The envelope in the latter model temporarily becomes compact when helium ignites in the core, which leads to overall less wind mass loss after stripping. The
Table 2
Summary of the presupernova structure of the MESA models. $M_{\text{pre-SN}}$ is the total presupernova mass, $M_h$ is the mass of the hydrogen-rich envelope, and $M_{He}$, $M_{CO}$, and $M_{Fe}$ are the helium, carbon/oxygen, and iron core masses, respectively. We place the iron core boundary at the first location going inward where the electron fraction $Y_e < 0.49$, following the definition of Dessart et al. (2013). $E_b$ is the binding energy of the material outside $1.4 M_\odot$ (the mass coordinate of the inner boundary in our SNEC explosion models) given in units of $\text{Bev}$, $1 \text{B} = 10^{19} \text{erg}$. $\xi_{2.5}$ is the compactness parameter of O’Connor & Ott (2011) and $R$, $L$, and $T_{\text{eff}}$ are the presupernova stellar radius, luminosity, and effective temperature. $t_{\text{SB}}$ is the time of shock breakout in hours after the onset of the thermal bomb.

The iron core mass ($\sim 1.5 - 1.6 M_\odot$) and density profile is nearly identical in all models. They reach core collapse at central densities in the range $0.93 - 1.48 \times 10^{10} \text{g cm}^{-3}$. The iron core mass ($\sim 1.5 - 1.6 M_\odot$) and density profile is nearly identical in all models. They reach core collapse at central densities in the range $0.93 - 1.48 \times 10^{10} \text{g cm}^{-3}$. Since the electrons in the iron core are relativistically degenerate and the core specific entropy and electron fraction are roughly the same in all models, the iron core structure is very similar throughout the model series. More interesting are the large variations in the density profiles in the silicon and oxygen/carbon layers above the iron core, between $\sim 1.5 M_\odot$ and $\sim 3.3 M_\odot$, as shown in Figure 2. The presupernova structure in these layers appears to be very sensitive to both the amount of envelope mass stripped and the stripping point in the evolution. However, there are no identifiable trends that could be linked to amount of mass stripped and stripping point. Sukhbold & Woosley (2014) pointed out that the structure in these layers is very sensitive to (1) the treatment of nuclear reactions and weak interactions (neutrino cooling, neutronization) and (2) the treatment of mixing and overshooting. Both (1) and (2), in turn, influence the number and extent of convective shell burning episodes/regions in the silicon and oxygen/carbon layers. Our results indicate that variations in the time and amount of mass loss can also influence this part of presupernova stellar structure. The density distribution in the affected regions determines the compactness parameter of O’Connor & Ott (2011),

$$\xi_M = \frac{M/M_\odot}{R(M)/1000 \text{km}},$$

with the commonly adopted reference value $M = 2.5 M_\odot$.
The explosion is initiated by applying a “thermal bomb” to the innermost region of the model, just above the mass cut in a way similar to previous work (e.g., Blinnikov & Bartunov 1993; Bersten et al. 2011; Aufderheide et al. 1991). The energy of the bomb is added to the right-hand-side of Equation (2) during a chosen time interval and in a range of mass from the inner boundary, both exponentially attenuated. For our fiducial model, summarized in Section 4.2, the bomb is spread over \(0.02 \, M_\odot\) and injected in 1 sec. The thermal bomb mechanism, implemented this way, typically gives a few percent more energy to the system than dialed-in, due to the smooth exponential attenuation. This small excess in energy is recorded and accounted for in SNEC’s global energy balance. We find that SNEC conserves total energy to better than 1% in a full-physics model followed to 150 days past explosion.

An alternative way of phenomenologically modeling an SN explosion is the “piston mechanism,” which has been used, for example, in the work by Eastman et al. (1994), Utrobin (2007), Kasen & Woosley (2009) and Dessart et al. (2013). For the same amount of injected energy, the thermal bomb and piston mechanism give nearly identical light curves, as was discussed in Bersten et al. (2011) and confirmed by our own simulations. However, when a reaction network is included, piston and thermal bomb may result in different nucleosynthetic yields (Young & Fryer 2007). We have implemented a piston in SNEC, but do not use it in this work, since the thermal bomb makes it easier to control the energy of the explosion.

It has long been realized in SN light curve modeling that sharp gradients in the composition profiles of the progenitors may result in artificial light curve features that are not observed in real SNe. For example, Utrobin (2007) points out a pronounced bump at the end of the plateau, followed by an abrupt decrease of the bolometric luminosity for a model with unmixing chemical composition (see their Figure 16). Two- and three-dimensional simulations of shock propagation in core-collapse SN explosions (e.g., Kifonidis et al. 2003, 2006; Wongwathanarat et al. 2015) show that effective mixing occurs during the shock propagation through the progenitor due to the Rayleigh-Taylor and Richtmyer-Meshkov instabilities. In this process, hydrogen and helium get mixed into the inner layers, while metal-rich clumps, and, in particular, \(^{56}\)Ni, may penetrate outwards up to \(\sim 3000 \, \text{km} \, \text{s}^{-1}\) and more in the velocity profile. Lacking a physical mechanism for the mixing in our one-dimensional code, we apply an artificial “boxcar” averaging, as used, for example, in Kasen & Woosley (2009)
and Dessart et al. (2012, 2013). We run a boxcar with a width of 0.4 M⊙ through the model four times until we obtain a smooth profile (details of this procedure are available in the SNEC notes document on the SNEC website). As an example, Figure 3 depicts the non-mixed (top panel) and mixed (bottom panel) mass fractions of hydrogen, helium, oxygen, and carbon in the unstripped reference model.

Finally, we assume a fixed amount of 56Ni of 0.05 M⊙ in all our models, which is roughly the average amount deduced for SNe IIP (which have a range of ~ 0.01–0.1 M⊙, see Kasen & Woosley 2009; Smartt et al. 2009). We distribute it uniformly in the interval between the excised mass of 1.4 M⊙ and some chosen mass coordinate (5 M⊙ for the reference runs, which is near the edge of the helium core) at the expense of other elements before smoothing the composition.

4.2. Fiducial Light Curve of the Unstripped Reference Progenitor Model

Figure 4 shows the light curve of the unstripped reference model. The explosion was initiated at t = 0 with a thermal bomb resulting in an asymptotic kinetic energy of $E = 10^{51}$ erg (as described in §4.1). We added $M_{\text{Ni}} = 0.05 M_{\odot}$, mixed up to a mass coordinate of 5 M⊙ (but not into the hydrogen envelope, though boxcar smoothing introduces some nickel into the hydrogen-rich region.). These are the fiducial explosion parameter choices used throughout this study.

The light curve of the unstripped reference model shows all the traditional hallmarks of a typical SNe IIP (e.g., Falk & Arnett 1977; Eastman et al. 1994; Filippenko 1997). Shock breakout occurs when the optical depth is less than $\sim e^{-1}$ at a time of 2.03 days after the onset of explosion. The bolometric luminosity peaks at $L = 3.4 \times 10^{45}$ erg s$^{-1}$ with an effective temperature of $T_{\text{eff}} = 1.7 \times 10^{5}$ K. The subsequent cooling phase (discussed in detail in Nakar & Sari 2010) lasts for ~ 19 days. At this point, the ejecta have expanded and cooled so much that hydrogen recombination sets in (starting already at $T \sim 7500$ K) and powers the plateau phase with very slowly decreasing effective temperature that varies from $\sim 6000$ K at ~ 35 days down to $\sim 5000$ K at ~ 90 days. The recombination wave and, consequently, the photosphere moves inward in mass coordinate, but due to the overall expansion stays at roughly constant radius, resulting in a relatively small variation in luminosity during the recombination phase of the plateau from day $\sim 19$ to day $\sim 80 – 90$. The slow decline that is apparent in the plateau phase shown in Figure 4 occurs because of the combined effects of the photo-
The plateau ends when the photosphere reaches the helium core. Helium recombines at $T \gtrsim 10^4$ K whereas the photospheric temperature is $T \sim 5000$ K, recombination accelerates dramatically, and both the radius of the photosphere and the luminosity decrease rapidly. Note that it is common in the SN II theoretical light curve literature to define the plateau duration as the time from shock breakout to the drop when the photosphere reaches the helium core (Kasen & Woosley 2009; Popov 1993). We adopt this definition of plateau duration in this paper. The small “knee” or “bump” feature in the drop of the fiducial light curve around day 90 in Figure 4 is due to the additional luminosity input from radioactive $^{56}$Co (from the $^{56}$Ni$\rightarrow^{56}$Co$\rightarrow^{56}$Fe decay chain) that is uncovered as the photosphere sweeps through the helium core throughout which $^{56}$Ni was mixed initially. This feature is sensitive to the degree and implementation of mixing and is unlikely to be robust (see next Section 4.3). Finally, the tail of the light curve, after day $\sim$100, is powered exclusively by the radioactive decay of $^{56}$Co.

4.3. Sensitivity of the Fiducial Light Curve to Mixing, Thermal Bomb Parameters, and Nickel Distribution

The red curve in Figure 4 highlights the effect of steep compositional gradients on the light curve in comparison with the result obtained with compositional smoothing (black graph; “boxcar averaging”; Section 4.1) that we use to mimic multidimensional mixing during the explosion. If exploded without smoothing, hydrogen-rich material transitions discontinuously to helium-rich material (cf. Figure 3), which leads to more rapid recombination, a more abrupt drop of the photosphere radius, and a steeper decline of the luminosity. Although observations of most SNe do not generally reveal such abrupt drops, some subclasses of SNe may have rapidly dropping photospheric velocities as discussed by Piro & Morozova (2014) because of this same effect of rapid helium recombination. For all other light curves presented in this paper, we use the smoothed composition profiles.

In Figure 5, we explore the sensitivity of the fiducial light curve to (top panel) variations in the amount of mass over which the thermal bomb is spread and (bottom panel) variations in the duration over which the energy is injected. While the details of the energy injection will depend on the actual physical explosion mechanism (e.g., Bethe 1990; Janka 2012), it is reassuring that the light curve is fairly insensitive to both mass spread and duration of energy injection and notable differences in the light curve appear only for unreasonably long times of energy input. In multi-dimensional core-collapse supernova simulations, most of the energy is injected within the very first $\sim$1 s (e.g., Bruenn et al. 2013).

Finally, Figure 6 shows the dependence on $^{56}$Ni mixing. The overall effect of $^{56}$Ni mixing is modest. The general trend is that with the initial mixing of $^{56}$Ni to increasing mass coordinates, the contribution to the luminosity of the $^{56}$Ni$\rightarrow^{56}$Co$\rightarrow^{56}$Fe decay chain becomes more prominent. At later times, the luminosity due to radioactive decay becomes smaller with increasing mixing due to the fact that more gamma rays escape from the model without being absorbed (as also described by Young 2004; Utrobin 2007; Bersten et al. 2011). Note that if $^{56}$Ni is mixed far into the hydrogen-rich envelope, the “knee” feature at the end of the plateau disappears. This is consistent with the findings of Kasen & Woosley (2009), who mixed $^{56}$Ni into the hydrogen-rich envelope in their models.

4.4. Light Curves as a Function of Mass Stripping

Figure 2 demonstrates that the structure of the hydrogen-rich envelope and of the outer helium core are essentially independent of the point at which we remove mass for the set of stripping points we choose in this study (cf. §3.4). This suggests that the resulting light curves should be independent of the stripping point and we check this assertion later in this section. Here, we operate under the assumption that it is true and focus our discussion on the model series stripped at the middle of the subgiant branch (mSGB).

In the top panel of Figure 7, we show bolometric mSGB series light curves obtained for a final ejecta kinetic energy of $E_{\text{kin}} = 10^{51}$ erg and $M_{\text{Ni}} = 0.05 M_\odot$ (and all other explosion parameters as specified in §4.1). The early, shock breakout and cooling part of the light curves is shown in Figure 8. Shock breakout itself is not well resolved (i.e., the photosphere is in the outermost grid cell) and thus the light curves in this phase are unreliable (cf. Ensmann & Burrows 1992). Once the photosphere begins to move inward into the expanding envelope, the light curves predicted by SNEC become robust. Models with greater amounts of mass stripped have higher luminosities in the cooling phase and decay more rapidly. In
more stripped models, the SN shock has to propagate through less envelope mass that is more tenuously distributed. This results in a higher shock velocity at early times (and earlier breakout; as shown in Figure 9), which leads to a hotter photosphere and a more rapid expansion of the ejecta. This translates directly to a higher initial luminosity and a more rapid decay of the light curve.

From the top panel of Figure 7 we see that as long as there is a substantial amount of hydrogen-rich material left, a clear (if very short) plateau due to recombination can be made out. In our mSGB model series, this is until models mSGB\_4M and mSGB\_5M, from which we strip 4\(M_\odot\) and 5\(M_\odot\) and which have 2.67\(M_\odot\) and 1.61\(M_\odot\) of hydrogen-rich material left, respectively. The two most stripped models of this series, models mSGB\_6M and mSGB\_7M, have only 0.74\(M_\odot\) and 0.38\(M_\odot\) of very tenuous hydrogen-rich envelope left, respectively. This does not appear to be sufficient to lead to any plateau and the photosphere recedes very quickly in these models. Instead, models mSGB\_6M and mSGB\_7M show a clear peak between \(\sim 20 - 30\) days that is analogous to the nickel-powered peak that is seen in all types of hydrogen-deficient (i.e., Type I) SNe.

Figure 7 shows that stripping of hydrogen-rich envelope mass also has an effect on the late-time radioactively powered part of the light curve. The late-time light curves exhibit changes with mass stripping because there is earlier leakage of gamma rays from the more highly stripped models. This is shown by the lower panel of Figure 7. It shows the unstripped reference model and the most stripped model (mSGB\_7M\(_{\odot}\)) in comparison with the total amount of heating deposited in each model due to the radioactive \(^{56}\text{Ni} \rightarrow ^{56}\text{Co} \rightarrow ^{56}\text{Fe}\) decay chain. The most stripped model has less radioactive heating at late times.

Figure 10 compares the bolometric light curves of models stripped at the middle of the subgiant branch (mSGB, the model series we focus on), half-maximum radius (hMR), and maximum radial extent of the convective envelope (MCE); cf. §3.1 and Table 1. The light curves of models with the same amount of mass stripped at different times are nearly identical, supporting our initial assertion on the basis of Figure 2. Any variation between light curves of models stripped at mSGB, hMR, and MCE is arguably smaller than the level of systematic uncertainty inherent to SNEC’s approximate (i.e., equilibrium diffusion) way of predicting these light curves. The robustness of the light curves suggests that comparisons with observations may allow reliable conclusions about the amount of hydrogen left after (rapid) mass loss events. However, we note that we exclusively consider post-MS mass loss. Early large-scale mass loss events on the MS may lead to different

Figure 8. The same bolometric light curves as in Figure 7, but instead focusing on early times around shock breakout. Time is given relative to the onset of the thermal bomb driving the explosion. Solid parts of the curves start from the time at which the photosphere moves inwards in the grid space, while dashed parts indicate that the photosphere is located in the outermost grid cell and is spatially poorly resolved. Note that more stripped models have a higher luminosity in the post-breakout cooling phase and a faster evolving light curve.

Figure 9. Photospheric velocities \(v_{\text{ph}}\) in the mSGB model series, including the unstripped reference model. These velocities are reliable only until the photospheric temperature drops below \(T \sim 10^3\) K below which we cannot accurately estimate the location of the photosphere due to low-\(T\) opacity limitations in SNEC. We indicate the unreliable part of \(v_{\text{ph}}\) by plotting it in dashed lines. Note that the temperature drops most rapidly in the most stripped models that lack a plateau phase (cf. Figure 7).

Figure 10. Bolometric light curves for all models from the three different MESA series, described in the Tables 1 and 2. The explosion setup is identical in all cases and as described in §4.1. All models are stripped after they have left the main sequence, but the precise point of stripping has little influence on the resulting light curve.

From the top panel of Figure 7 we see that as long as there is a substantial amount of hydrogen-rich material left, a clear (if very short) plateau due to recombination can be made out.
outcomes, which should be explored in future work.

In Figure 11, we plot approximate absolute magnitudes of the mSGB series light curves in the IRVB- and $U$-bands and in Figure 12, we focus on the $V$-band. We obtain the band light curves by assuming black body emission from the photosphere and using the bolometric corrections from Ofek (2014). When interpreting these light curves, one should keep in mind two important caveats: (1) When the whole ejecta becomes optically thin, the luminosity has a large contribution of $^{56}$Ni/$^{56}$Co from above the photosphere. For this reason, we terminate the curves at the points where the luminosity contribution due to $^{56}$Ni/$^{56}$Co above the photosphere amounts to more than 5% of the total luminosity. (2) As was demonstrated in Kasen & Woosley (2009), the $U$- and $B$-bands of the light curves cannot be adequately reproduced by a one-temperature equilibrium-diffusion code like SNSEC, because these bands are strongly influenced by iron group line blanketing after a few tens of days (see, e.g., Figure 8 of Kasen & Woosley 2009). This causes a much faster decline of the $U$- and $B$-band light curves. However, the $IR$- and $V$-bands are still similar to a single temperature black body spectrum, and thus these bands are more accurately captured by SNSEC.

Finally, we study the sensitivity of our light curves to doubling the explosion energy to $2 \times 10^{51}$ erg and to doubling the amount of initially present $^{56}$Ni to 0.1 $M_\odot$ in Figure 13. The qualitative light curve changes are overall as expected from previous work (e.g., Young 2004; Utrobin 2007; Kasen & Woosley 2009): More energetic explosions have brighter, but faster evolving light curves and an increased amount of $^{56}$Ni prolongs the plateau and results in a higher late-time luminosity. Increasing the amount of $^{56}$Ni also results in a more pronounced second light curve peak in the most-stripped models mSGB.6M and mSGB.7M. We summarize the connection between these calculations and observed SN light curves in the discussion below.

5. DISCUSSION AND CONCLUSIONS

We presented the new open-source SuperNova Explosion Code (SNSEC) for investigating supernova (SN) explosions and the resulting light curves. SNSEC, while currently limited to equilibrium (single temperature) radiative diffusion, is the first such code that is publicly available and this paper will serve as a reference and starting point as SNSEC is utilized and improved by both us and the broader community in the future.

As a first application of SNSEC, we studied the explosions of $M_{\text{ZAMS}} = 15 M_\odot$ ($M_{\text{ZAMS}}$ is the mass at zero-age-main sequence (ZAMS)) stars with varying levels of rapid post-MS mass loss at different times in the stars’ evolution from the main sequence to the supergiant stage. We evolved these stars to the onset of core collapse with the open-source MESA stellar evolution code and then exploded them with SNSEC using a thermal bomb resulting in an asymptotic explosion energy of $10^{53}$ erg. At three different times during the evolution to the supergiant stage, we systematically stripped hydrogen-rich material in units of $1 M_\odot$, leaving in the most extreme case only a thin radiative hydrogen-rich layer above the hydrogen shell burning zone. In this experiment in massive star evolution, we find that the time of stripping has essentially no influence on the structure of the envelope and thus most of the SN light curve. Stars with more than $1.5 - 2 M_\odot$ of hydrogen-rich material left die as red supergiants with $R \gtrsim 900 R_\odot$ and our most stripped star (0.31 $M_\odot$ of hydrogen-rich envelope left) dies as a yellow supergiant with a still extended, very tenuous envelope of $R \sim 550 R_\odot$.

We find that the time of stripping and the amount of mass stripped has a big but not clearly systematic effect on the structure of the layers immediately surrounding the iron core (mass coordinate $\sim 1.5 - 3.3 M_\odot$). The structure in this particular region has been shown to be highly relevant for deciding the ultimate outcome of core collapse (explosion/no explosion, black hole/neutron star remnant; O’Connor & Ott 2011; Ugliano et al. 2012; Ertl et al. 2015). Our results suggest the need for a detailed study of the sensitivity of presupernova stellar structure to large amounts of rapid mass loss (e.g., via unstable mass transfer in a binary).

The light curves resulting from our set of presupernova models show SN IIP-like morphology for models with more than $\sim 1.5 - 2 M_\odot$ of hydrogen-rich envelope material left at the presupernova stage. The most stripped models ($\lesssim 1.5 M_\odot$ of hydrogen-rich envelope left) have higher luminosity in the post-breakout cooling phase, but show no plateau, but a second peak around 20–30 days due to energy input from the radioactive decay of $^{56}$Ni/$^{56}$Co that is uncovered by the rapidly receding photosphere in these models.

In those models that show a plateau in their bolometric lightcurves, the duration of the plateau phase varies in the range $\sim 20 - 100$ days (we include both the cooling and the recombination phases of the plateau in the plateau duration; Kasen & Woosley 2009; Popov 1993), with plateau length decreasing with decreasing mass of hydrogen-rich envelope material. In nature, most SNe IIP show plateaus of $\sim 80 - 100$ days (e.g., Poznanski et al. 2009; Arcavi et al. 2012) while the completely mass stripped SNe Ib/c show no plateau at all. SNe Ib/c with short to intermediate-length plateaus of our stripped models are not observed in nature. SNe Ib/c also lack the extended high-luminosity post-breakout cooling phase that our most stripped models show at early times and have in common with their plateau-producing counterparts. Both SNe IIP and SNe Ib/c are relevant to our study given the inference that many SN IIP progenitors have ZAMS masses around $\sim 15 M_\odot$ (Smartt et al. 2009) and arguments that most SNe Ib/c must come from a similar mass range (Smith et al. 2011). The lack of observed short and intermediate-length plateaus suggests that in nature hydrogen mass loss is an all or nothing process, at least for the ZAMS masses we consider. This is perhaps not surprising given that for $M_{\text{ZAMS}} \lesssim 20 M_\odot$, radiative driven winds are rather weak in normal prescriptions and appreciable mass loss can probably only occur from events like binary interactions, which would not be expected to, say for example, rip off just $\sim 50\%$ of the mass.

Our most stripped models still have $\approx 0.3 - 0.4 M_\odot$ of hydrogen present and thus should make some connection with SNe Ib. Indeed, the light curves of these progenitors show two distinct peaks, similar to the morphology of many SN Ib, where the first peak comes from the shock cooling of the remaining surface hydrogen and the second from radiative heating (Woosley et al. 1994; Bersten et al. 2012; Nakar & Piro 2014). However, in detail, they have some differences with double-peaked SNe Ib. The width of the first peak is too large, which is likely due to our models having too much hydrogen still present (Nakar & Piro 2014). In addition, the second peak in our light curves is too dim in comparison to observed SNe Ib. This is caused by not having enough $^{56}$Ni, which is not surprising since SNe Ib are inferred to have $\approx 0.1 - 0.3 M_\odot$ of $^{56}$Ni (Lyman et al. 2014) while our models have 0.05 $M_\odot$. 

Another interesting connection to consider is how our results relate to SNe IIL (those hydrogen-rich SNe with a linearly declining phase instead of a plateau). There has been a long-standing discussion on whether they form a continuous range of events from SNe IIL to SNe IIP, then a natural physical mechanism to consider is gradual loss of the outer hydrogen, where SNe IIL would be on the hydrogen-poor side. At least for the ZAMS mass range we consider here, this does not appear to be the case. First, our results show that intermediate levels of hydrogen mass loss simply shorten the plateau length which is different from SNe IIL, which appear to have roughly normal duration, but steeply declining "plateaus" when they are followed for a sufficient amount of time (Valenti et al. 2015). Second, SNe IIL are on average more luminous than SNe IIP by \( \sim 1.5 \text{ mag} \) in the optical during the first \( \sim 10 \text{ days} \) (Patat et al. 1993, 1994; Anderson et al. 2014; Faran et al. 2014; Sanders et al. 2015). Our more stripped models show slightly higher luminosities at early times, but not nearly extreme enough. Overall, however, our findings, in combinations with recent observations (Valenti et al. 2015), appear to argue that perhaps SNe IIL do not necessarily have less hydrogen, but the hydrogen mass is distributed in a different way. The brighter early light curves would argue that SNe IIL have material at a larger radius (Piro & Nakar 2013). The occurrence of narrow line features in SNe IIn that might otherwise look somewhat like an SN IIL (Smith et al. 2015) might argue for some contribution from circumstellar material. SNEC is well-suited for addressing these ideas in a systematic way in future work since various...
mass and density distributions can easily be implemented to investigate what is in fact needed to reproduce SN IIL light curves.

Future work will be directed toward exploiting SNEC’s current capabilities for the systematic and reproducible light curve modeling for a broad range of SN explosions, but also toward improving SNEC’s transport solver and opacity microphysics. In a first step, we will upgrade SNEC to handle separate radiation and matter temperatures with the long-term goal of constructing an open-source multi-group radiation-hydrodynamics code. Of course, input from the community will be especially critical for steering SNEC’s further evolution and we look forward to the community’s feedback.

We acknowledge helpful discussions with W. D. Arnett, M. Bersten, A. Burrows, L. Dessart, C. Fryer, M. Modjaz, E. S. Phinney, D. Radice, S. N. Shore, N. Smith, A. Soderberg, and C. Wheeler. We thank M. Bersten for providing us with the initial conditions necessary to reproduce her results on SN 1999em and also for generously answering our questions. We thank L. Dessart for helping us better understand the discrepancies between SNEC light curves and his results. Some of the ideas underlying this study were inspired by discussions at Palomar Transient Factory Theory Network workshops at the Sky House, Los Osos, CA. SNEC is available as open source from [http://stellarcollapse.org/SNEC](http://stellarcollapse.org/SNEC). We thank Frank Timmes for allowing us to use and distribute with SNEC his equation of state and Saha solver routines. We thank the OPAL opacity project, in particular Carlos Iglesias, allowing us to distribute their interpolation routines and opacity tables with SNEC. We thank Jason Ferguson for allowing us to distribute the low-temperature opacity tables of Ferguson et al. (2005) with SNEC. This work is supported in part by the National Science Foundation under award Nos. AST-1205732 and AST-1212170, by Caltech, and by the Sherman Fairchild Foundation. The computations were performed on the Caltech compute cluster Zwicky (NSF MRI-R2 award no. PHY-0960291), on the NSF XSEDE network under allocation TG-PHY100033, and on NSF/NCSA Blue Waters under NSF PRAC award no. ACI-1440083.

**Figure 13.** Bolometric light curves for the mSGB model set as in Figure 7, but with variations in explosion energy and $^{56}$Ni mass. The time is given relative to the onset of energy injection by the thermal bomb. Top panel: Comparison of light curves of models with the fiducial final kinetic energy ($2 \times 10^{51}$ erg, dashed curves) and with twice that energy ($2 \times 10^{51}$ erg, solid curves). Increasing the explosion energy leads to brighter, more rapidly evolving explosions in agreement with previous work. Bottom panel: Comparison of light curves of models with the fiducial $^{56}$Ni mass (0.05 $M_\odot$, dashed curves) and with twice that amount of $^{56}$Ni (0.1 $M_\odot$, solid curves). More nickel leads to extended plateaus and brighter radioactive tails. The qualitative changes due to variations in explosion energy and $^{56}$Ni mass are in agreement with what was found in previous work (e.g., Kasen & Woosley 2009; Young 2004).

Among the existing SN light curve codes, the work of Bersten et al. (2011) is the most similar to ours, so the results obtained by the two codes should be comparable. In this appendix, we present the results obtained with SNEC using the progenitor model for SN 1999em from the work of Bersten et al. (2011), kindly provided by the authors (details of the structure and composition by the two codes should be compatible. In this appendix, we present the results obtained with SNEC, together with the observational data for SN 1999em. Overall we find satisfactory agreement. The two light curves are shown in the Figure 14, the left panel shows the bolometric light curves generated with SNEC and the right panel shows the expansion velocity at the position of the photosphere, calculated with SNEC using the progenitor model and the same grid setup as described above for the same progenitor model as in Figure 14. The typical grid setup in our SNEC models, we find that this level of photosphere resolution similar to the surface of the progenitor star in order to ensure good resolution of the photospheric region as early in the explosion as possible. A detailed analysis of the very early light curve shape around shock breakout was carried out by Ennsman & Burrows (1992). In particular, these authors compared the results obtained with a two-temperature radiation-hydrodynamics treatment and with a one-temperature flux-limited equilibrium diffusion treatment similar to SNEC. They concluded that the two approaches give consistent results for light curve and photospheric velocity in the case in which we follow Bersten et al. (2011) and do not take the opacity floor (cf. §4.1) when locating the opacity floor for the purpose of determining its velocity. The dashed curve shows the case in which we take the opacity floor into account. In the former case, we find good agreement with Bersten et al. (2011) (see their Figure 6), while in the latter, we overpredict the photospheric velocity starting around day 30.

The typical grid setup in our SNEC calculations focuses resolution close to the surface of the progenitor star in order to ensure good resolution of the photospheric region as early in the explosion as possible (cf. §4.1). A detailed analysis of the very early light curve around shock breakout was carried out by Ennsman & Burrows (1992). In particular, these authors compared the results obtained with a two-temperature radiation-hydrodynamics treatment and with a one-temperature flux-limited equilibrium diffusion treatment similar to SNEC. They concluded that the two approaches give consistent results for light curve and photospheric temperature, provided the surface grid resolution is sufficiently fine so that at the onset of shock breakout a few tens of grid cells are covering the optically thin region outside the photosphere. In our SNEC models, we find that this level of photosphere resolution is not practical for the large model grid we are considering. However, even with our standard gridding, we find that after the first few hours of the explosion, our standard resolution is sufficient to resolve the photosphere and produce a reliable light curve in the cooling phase after shock breakout.

In order to demonstrate this point, we plot in Figure 15 the early light curves around shock breakout obtained with SNEC using 1000 and 3000 grid cells and the same grid setup as described above for the same progenitor model as in Figure 14. The model with 3000 grid cells always has at least a few grid cells above the photosphere, whereas in the lower-resolution model, the photosphere is stuck in the outermost grid cell and becomes resolved only about one day after breakout. Once this happens, the photosphere is stuck in the outermost grid cell and becomes resolved only about one day after breakout.
Figure 14. Left panel: Bolometric light curves for the best fit model of Bersten et al. (2011) for SN 1999em. The black and red graphs show SNEC light curves generated with 1000 and 3000 grid cells, respectively. The blue circles show observational data and the blue graph is the light curve of Bersten et al. (2011) and we take both from their Figure 5. The dashed line shows the total power input due to radioactive decay. Right panel: Photospheric velocity, calculated with SNEC for the same model (using 1000 grid cells) and compared with observational data (taken from Bersten et al. 2011). The solid curve shows the case in which we follow Bersten et al. (2011) and do not take the opacity floor into account when determining the location of the photosphere. The dashed curve represents the case in which we take the opacity floor into account. Note, however, that in both cases the opacity floor is taken into account in the actual numerical solution of Equation 2.

Figure 15. Bolometric light curves around the time of shock breakout for the best fit model of Bersten et al. (2011) for SN 1999em. The black solid and blue dashed curves are SNEC light curves generated with 1000 and 3000 grid cells, respectively. The higher-resolution model always resolves the photosphere, while the photosphere is stuck in the outermost grid cell (and thus not spatially resolved) in the lower-resolution model until day $\sim 2.2$. Although the photosphere cannot be considered resolved in the lower-resolution simulation, both light curves agree quite well, even near shock breakout.

results of the 1000 and 3000 agree nearly perfectly. But even at earlier times, the two light curves agree surprisingly well. This can be understood from the fact that already shortly after shock breakout the light curve is determined by the diffusion of light from the shock heated envelope and should not depend anymore on the resolution of the surface layers.

COMPARISON WITH DESSART ET AL. (2013)

As an additional test of SNEC, we attempt to reproduce one of the light curves obtained by Dessart et al. (2013) from a set of MESA models. Dessart et al. (2013) explode their models with the Lagrangian 1D hydrodynamics code V1D (Livne 1993; Dessart et al. 2010) and map at day 10 to their non-LTE radiative transfer code CMFGEN (Hillier & Dessart 2012) that assumes homologous expansion. CMFGEN provides a much more accurate treatment of radiative transfer than SNEC is capable of. For our comparison, we choose model m15Mdot, which was evolved with enhanced mass loss. The set of parameters provided in Dessart
et al. (2013) is sufficient to generate a MESA progenitor model with similar characteristics as Dessart et al.’s model m15Mdot. The presupernova hydrogen-rich envelope mass in our version of model m15Mdot is $M_\text{H} \sim 8.13 M_\odot$ and the model’s radius is $R \sim 789 R_\odot$. Dessart et al. (2013) find $M_\text{H} \sim 7.72 M_\odot$ and $R \sim 776 R_\odot$. We attribute the differences to our version to the different release versions of MESA used by Dessart et al. (2013) and us. Given the differences in the models (and in the codes!), we do not expect perfect agreement.

Our SNEC explosions are triggered by a thermal bomb, while Dessart et al. (2013) use a piston. We tried to match the explosion parameters used by Dessart et al. (2013) (given in their Table 2) as closely as possible. In particular, we excised the inner $1.5 M_\odot$ in agreement with the location of the piston in the models of Dessart et al. (2013). We choose the explosion energy in such a way that the final total energy of the model is $1.28 \times 10^{51}$ erg. To achieve this, we inject $1.44 \times 10^{51}$ erg into the innermost $0.02 M_\odot$ over a time of 0.1 sec. In addition, we include $0.081 M_\odot$ of $^{56}$Ni, initially uniformly distributed in the mass coordinate range $1.5 - 3.5 M_\odot$. We apply boxcar smoothing, as for the other MESA models from our study. Although we do not know the precise distribution of $^{56}$Ni in the model of Dessart et al. (2013), the authors indicate that it was not strongly mixed outwards. We used the same prescription for the opacity floor as for all our other models in this study.

Figure 16 compares our SNEC light curve with the light curve obtained by Dessart et al. (2013) and shown in their Figure 7. We find encouraging agreement between the two light curves in the first ~80 days, as well as after day 140 (in the nebular phase). The transition between the plateau and the radioactive tail of the light curves is in worse agreement and the Dessart et al. plateau is 10 – 20 days longer than predicted by SNEC. There are multiple possible reasons for these differences.

On the one hand, the two progenitor models are not identical and the Dessart et al. model has less mass (by ~0.4 $M_\odot$) in its hydrogen-rich envelope than our model. However, the higher hydrogen-rich mass should result in a somewhat longer plateau (e.g. Young 2004; Kasen & Woosley 2009) in our model, which is not what we find in Figure 16. Also, one notes from Figure 16 that the two light curves would agree much better if the Dessart et al. light curve was shifted back in time by ~5 days. It is not clear what could cause such a shift. However, we point out that we find in our SNEC calculations that at day 10 the expansion is not yet homologous and more internal energy has yet to be converted into kinetic energy of expansion (this point was previously discussed by Dessart & Hillier 2011). Nevertheless, Dessart et al., who assume homologous expansion, map their radiative transfer code already at day ten. The consequences of such an early mapping should be explored.

On the other hand (Dessart, private communication), the differences may be caused by the various deficiencies of SNEC’s radiation-hydrodynamics treatment, the assumption of LTE, and in the opacities we use (cf. §2). In order to further isolate potential culprits we have carried out experiments in which we varied the explosion energy, the degree of $^{56}$Ni mixing, and the opacity floor. None of these tests produce light curves that are substantially closer to the Dessart et al. (2013) light curves than what is shown in Figure 16.

Figure 16. Comparison of the bolometric light curve of model m15Mdot of (Dessart et al. 2013) with the light curve that we obtain with SNEC for a similar progenitor model, the same explosion energy, and the same initial $^{56}$Ni mass. The Dessart et al. light curve is generated with their CMFGEN non-LTE radiative transfer code that assumes homologous expansion Hillier & Dessart (2012). CMFGEN is technically far superior to the single-temperature equilibrium diffusion treatment currently implemented in SNEC.
