ABSTRACT

We present an analysis of the 3–79 keV NuSTAR spectrum of the low-luminosity active galactic nucleus NGC 7213. In agreement with past observations, we find a lower limit to the high-energy cut-off of \(E_c > 140\) keV, no evidence for a Compton-reflected continuum and the presence of an iron Kα complex, possibly produced in the broad-line region. From the application of the MYTORUS model, we find that the line-emitting material is consistent with the absence of a significant Compton reflection if arising from a Compton-thin torus of gas with a column density of \(5.0^{+2.0}_{-1.6} \times 10^{23}\) cm\(^{-2}\). We report variability of the equivalent width of the iron lines on the time-scale of years using archival observations from XMM–Newton, Chandra and Suzaku. This analysis suggests a possible contribution from dusty gas. A fit with a Comptonization model indicates the presence of a hot corona with a temperature \(kT_e > 40\) keV and an optical depth \(\tau \lesssim 1\), assuming a spherical geometry.

Key words: galaxies: active – galaxies: individual: NGC 7213 – galaxies: Seyfert – X-rays: galaxies.

1 INTRODUCTION

The central engine of low-luminosity active galactic nuclei (LLAGNs) is thought to be powered by accretion of surrounding matter on to a supermassive black hole, similar to more powerful AGNs, like Seyfert galaxies and quasars (see Ho 2008, for a review). The X-ray spectrum of AGNs is generally dominated by a primary power-law component, which is thought to be produced by Comptonization of optical/UV photons emitted by the underlying accretion disc in a hot plasma, the so-called corona (see e.g. Haardt & Maraschi 1991; Haardt, Maraschi & Ghisellini 1994, 1997). A signature of this process is the presence of a high-energy cut-off in the X-ray emission, which has been observed in a number of sources (see e.g. Perola et al. 2002; Malizia et al. 2014; Brenneman et al. 2014; Ballantyne et al. 2014; Marinucci et al. 2014; Baloković et al. 2015; Ursini et al. 2015).

The distinctive characteristic of LLAGNs is their intrinsic faintness (\(L_{\text{bol}} < 10^{44}\) erg s\(^{-1}\)). Moreover, the mass accretion rate of LLAGNs is generally small; in terms of the Eddington ratio, most of them have \(L/L_{\text{Edd}} < 10^{-2}\) while luminous AGNs have \(L/L_{\text{Edd}} \sim 0.01–1\) (see e.g. Panessa et al. 2006; Kollmeier et al. 2006). Whether LLAGNs are simply a scaled-down version of classical AGNs is a matter of debate. A standard geometrically thin, optically thick accretion disc (Shakura & Sunyaev 1973) may power LLAGNs (Maoz 2007), as is commonly assumed for
luminous AGNs. However, radiative-inefficient accretion flows (RIAFs; see e.g. Narayan & Yi 1994) have been proposed to explain some observational properties, in particular their lack of a UV bump (see e.g. Ho 2009; Yu, Yuan & Ho 2011). Furthermore, in luminous AGNs the hard X-ray photon index and the Eddington ratio are positively correlated (see e.g. Sobolewska & Papadakis 2009), while an anticorrelation is found in LLAGNs (Gu & Cao 2009). This result is consistent with the X-ray emission of LLAGNs originating from Comptonization in RIAFs, and it suggests a similarity between LLAGNs and black hole X-ray binaries (BHXBs) in the low/medium state, where the accretion rate is low (Wu & Gu 2008). The low accretion rate might not only affect the structure of the inner accretion flow, but also that of the putative obscuring torus. The torus is predicted to disappear in low-luminosity sources by models depicting it as a clumpy wind, arising from the outer accretion disc (see e.g. Elitzur & Shlosman 2006, and references therein), or as a collection of many self-gravitating, dusty molecular clouds (see e.g. Hönig & Beckert 2007).

NGC 7213 is a nearby ($z = 0.005839$, as given in the NASA/IPAC Extragalactic Database; distance 25.80 Mpc; Pereira-Santaella et al. 2010) LLAGN with $L_{\text{bol}} = 1.7 \times 10^{42}$ erg s$^{-1}$ (Emmanoulopoulos et al. 2012) that hosts a supermassive black hole of $\sim 8 \times 10^{6}\text{ solar masses}$ (estimated from the stellar velocity dispersion, see Woo & Urry 2002), yielding an Eddington ratio of $1.4 \times 10^{-3}$. It has been historically classified as a Seyfert 1 because its optical spectrum shows broad emission lines, i.e. with a full width at half-maximum (FWHM) of a few thousand km s$^{-1}$ (Phillips 1979). However, it has also been classified as a low-ionization nuclear emission region galaxy (LINER) because of the low excitation observed in the narrow-line spectrum (Filippenko & Halpern 1984). Low-ionization lines were also detected in the soft X-ray band (Starling et al. 2005). Wu, Boggess & Gull (1983) measured a UV flux higher than the extrapolated optical flux, thus indicating a possible UV bump, but it is still weaker than in most Seyfert galaxies. More recently, Starling et al. (2005) found no evidence for an optical/UV bump using XMM–Newton/OM data.

The X-ray spectrum of NGC 7213 shows peculiarities as well. The Compton reflection component is found to be weak or absent with XMM–Newton, BeppoSAX and Suzaku observations (see e.g. Bianchi et al. 2003; Lobban et al. 2010), in contrast to what is commonly observed in Seyfert 1 galaxies. This may suggest that the accretion disc is truncated in the inner region, perhaps replaced by a Compton-thin RIAF (Lobban et al. 2010). An iron line complex is clearly detected between 6.4 and 7 keV, consisting of three narrow $\alpha$ emission lines respectively from neutral Fe, Fe XXV and Fe XXVI (see e.g. the analysis of Chandra data by Bianchi et al. 2008). Given the lack of an observed Compton reflection hump, such lines cannot originate from Compton-thick material, like the accretion disc or a parsec-scale torus. Bianchi et al. (2008) found the FWHM of the neutral Fe K $\alpha$ line to be consistent with that of the H $\alpha$ line ($\sim 2600$ km s$^{-1}$), thus suggesting a common origin in the broad-line region (BLR). Another possibility is reprocessed emission from dusty gas, which can produce strong, neutral Fe K $\alpha$ emission with a weak associated continuum (Gohil & Ballantyne 2015). Emmanoulopoulos et al. (2012) found an anticorrelation between the X-ray photon index and the X-ray luminosity that, together with the low accretion rate of the source, indicates a spectral behaviour similar to that of BHXBs in the hard state. Finally, Bianchi et al. (2003) reported a high-energy cut-off of $95^{+62}_{-45}$ keV using XMM–Newton+BeppoSAX data, while Lobban et al. (2010) found a lower limit of 350 keV using Suzaku/XIS+PIN and Swift/BAT data.

In this paper, we report on a NuSTAR observation of NGC 7213 performed in 2014 October. The primary focus of this work is modelling the broad-band X-ray spectrum of the source and constraining the origin of the X-ray emission. In Section 2, we describe the observations and data reduction. In Section 3, we present the analysis of the 3–79 keV spectrum, fitted with both a phenomenological and a realistic Comptonization model, and we study the time evolution of the iron line complex by analysing archival XMM–Newton, Chandra and Suzaku data. In Section 4, we discuss the results and summarize our conclusions.

2 OBSERVATIONS AND DATA REDUCTION

NuSTAR (Harrison et al. 2013) observed NGC 7213 starting on 2014 October 5, with a net exposure of 109 ks (Obs. Id. 60001031002). The NuSTAR data were reduced with the standard pipeline (NUPipeline) in the NuSTAR Data Analysis Software (NUSTARDAS, v1.3.1; part of the HEASOF distribution as of version 6.14), using calibration files from NuSTAR CALDB v20141107. Spectra and light curves were extracted from the cleaned event files using the standard tool nuproducts for each of the two hard X-ray telescopes aboard NuSTAR, which have corresponding focal plane modules A and B (FPMA and FPMB). The spectra from FPMA and FPMB are analysed jointly, but are not combined, allowing for a free cross-calibration constant. The source data were extracted from circular regions (radius 75 arcsec), and background was extracted from a blank area close to the source. Finally, the spectra were binned to have a signal-to-noise ratio greater than 3 in each spectral channel, and not to oversample the instrumental resolution by a factor greater than 2.5.

In Fig. 1, we show the NuSTAR/FPMA and FPMB light curves obtained in the 3–79 keV energy range. The total variation in the light curve is of the order of a few per cent. Therefore, in the following we analyse the time-averaged spectrum of the source.

3 SPECTRAL ANALYSIS

Spectral analysis and model fitting was carried out with the xspec 12.8 package (Arnaud 1996), using the $\chi^2$ minimization technique throughout. In this work, the errors are quoted at the 90 per cent confidence level, if not stated otherwise.
3.1 The NuSTAR spectrum

As a first step, we define a phenomenological model, which we describe below. We fit the NuSTAR data in the 3–79 keV range, allowing for a free cross-calibration constant between the modules FPMA and FPMB. The two modules are in good agreement, with a cross-calibration factor $K_{fp} = 0.99 \pm 0.01$ fixing the constant for the FPMA data to unity.

We modelled the continuum with a cut-off power law, modified by neutral absorption (PHABS model in XSPEC) from Galactic hydrogen with column density $N_H = 2.04 \times 10^{20}$ cm$^{-2}$ (Dickey & Lockman 1990). This simple model yields a poor fit (reduced $\chi^2 = 556/369$), with positive residuals between 6 and 7 keV, which can be attributed to the known Fe complex between 6.4 and 7 keV (Bianchi et al. 2003, 2008). Bianchi et al. (2008) found three emission lines in the Chandra/HEG spectrum, at 6.4, 6.7 and 6.966 keV. These lines are interpreted as emission from neutral Fe, Fe XXV and Fe XXVI, respectively. Chandra/HEG data provide much higher energy resolution near the Fe complex compared with NuSTAR. We thus followed the analysis of Bianchi et al. (2008) and tested for the presence of three narrow Gaussian lines fixing their energies at 6.4, 6.7 and 6.966 keV, leaving the normalizations free to vary.

The inclusion of a narrow Gaussian line at 6.4 keV yields a significantly improved fit (reduced $\chi^2 = 417/368$). Adding a second line at 6.7 keV further improves the fit (reduced $\chi^2 = 388/367$), with a probability of chance improvement less than $5 \times 10^{-3}$ according to the $F$-test. The inclusion of a third line at 6.966 keV yields a good fit (reduced $\chi^2 = 375/366$), without prominent residuals and a probability of chance improvement less than $5 \times 10^{-4}$ according to the $F$-test.

We report the results of this fit in Table 1, and in Fig. 2 we show the contour plots of the cut-off energy versus photon index. In Fig. 3, we show the data, residuals and best-fitting model. To further test the presence of a high-energy cut-off, we included the 70-month average Swift/BAT spectrum (Baumgartner et al. 2013); however, the results are essentially unchanged.

We tested for the presence of a reflection continuum by including the PEXRAV model in XSPEC, which describes neutral Compton reflection of infinite column density in a slab geometry (Magdziarz & Zdziarski 1995). This model is adequate for reflection off a standard accretion disc, given the high column densities expected for these structures (see e.g. Svensson & Zdziarski 1994). We fixed the inclination angle of the reflector to 30 deg, appropriate for a type 1 source (e.g. Nandra et al. 1997). The photon index and cut-off energy of the incident spectrum were tied to those of the primary power law. However, no improvement is found, with only an upper limit to the reflection fraction $R$ of 0.13, at 90 per cent confidence level. In Fig. 4, we show the contour plots of $R$ versus photon index. This is consistent with the iron lines originating from Compton-thin material ($N_H = 10^{23}$ cm$^{-2}$), which does not produce a prominent Compton reflection hump (Bianchi et al. 2003). To test this result further, we replaced the PEXRAV component and the neutral Fe K $\alpha$ line with the MYTORUS model, which includes Compton reflection and iron fluorescent lines from a gas torus with an opening angle of 60 deg (Murphy & Yaqoob 2009). The inclination angle of the torus was fixed at 30 deg. The column densities of the scattered and line components were linked and free to vary. The normalizations of the scattered and line components were tied to the normalization of the primary power law, i.e. the standard MYTORUS configuration (‘coupled’ reprocessor; see e.g. Yaqoob 2012). The assumed geometry corresponds to a covering fraction

Figure 4. PEXRAV reflection fraction versus photon index contours. Solid green, red and black lines correspond to 99, 90 and 68 per cent confidence levels, respectively.

Figure 5. COMPPS Compton parameter versus temperature contours. Solid green, red and black lines correspond to 99, 90 and 68 per cent confidence levels, respectively.

of 0.5. We obtain a good fit (reduced $\chi^2 = 373/363$) and we find a column density of $5.0^{+2.0}_{-1.6} \times 10^{23}$ cm$^{-2}$. This result is consistent with the estimate of $\sim 3 \times 10^{23}$ cm$^{-2}$ for the Fe K$\alpha$ line-emitting material reported in Bianchi et al. (2008).

We next replaced the cut-off power law with the Comptonization model COMPPS (Poutanen & Svensson 1996) in XSPEC. COMPPS models the thermal Comptonization emission of a hot plasma cooled by soft photons with a disc blackbody distribution. We set a spherical geometry ($\text{GEOM} = -4$ in COMPPS) for the hot plasma and a temperature at the inner disc radius of 10 eV, fitting for the electron temperature $kT_e$ and Compton parameter $\gamma = 4 \tau (kT_e/m_e c^2)$. The model yields a good fit (reduced $\chi^2 = 373/366$) with best-fitting parameters $kT_e = 295^{+70}_{-25}$ keV and $\gamma = 0.52^{+0.34}_{-0.10}$, which imply an optical depth $\tau = 0.2^{+0.07}_{-0.01}$. In Fig. 5, we show the $kT_e$–$\gamma$ contour plots.

3.2 Time evolution of the Fe K$\alpha$ line

To try to understand the origin of the Fe K$\alpha$ lines, we compared our results with past observations of NGC 7213 by re-analysing the archival XMM–Newton (2001, 2009), Chandra (2007) and Suzaku (2006) data. We fitted the 3–10 keV data sets with the baseline model described in Section 3.1, i.e. including a cut-off power law and three narrow Gaussian lines. The best-fitting parameters are consistent with those reported in Bianchi et al. (2003, 2008) and Lobban et al. (2010).

In Fig. 6, we show the time evolution of the neutral Fe K$\alpha$ line EW and flux, and of the 3–10 keV continuum flux and photon index. The continuum flux variations reach up to a factor of 2, while the line flux varies at the 1$\sigma$ confidence level only during the Chandra/HEG observation of 2007. The line EW, on the other hand, exhibits significant variations up to a factor of 1.7. The data show a hint of an anticorrelation between the continuum flux and the line EW, though we cannot formally establish a significant relation. The Spearman rank correlation coefficient is $-0.4$, but the test returns a $P$ value of 0.42, implying that the null hypothesis is not rejected. Similar results hold for the Fe XXV and Fe XXVI lines, albeit with larger uncertainties on their parameters.

4 DISCUSSION AND CONCLUSIONS

We reported results based on a NuSTAR observation of the LLAGN/LINER NGC 7213. We derived constraints on the parameters describing the high-energy (3–79 keV) spectrum, and studied variability over a few year time-scale comparing our results with archival observations of the source.

We have been able to constrain the reflection component, finding no evidence for a significant Compton reflection continuum.

Figure 5. COMPPS Compton parameter versus temperature contours. Solid green, red and black lines correspond to 99, 90 and 68 per cent confidence levels, respectively.

Figure 6. Time evolution of Fe K$\alpha$ line parameters and 3–10 keV primary flux and photon index. Panel (A): Fe K$\alpha$ equivalent width in eV units. Panel (B): Fe K$\alpha$ line flux in units of $10^{-5}$ photons cm$^{-2}$ s$^{-1}$. Panel (C): continuum 3–10 keV flux in units of $10^{-11}$ erg cm$^{-2}$ s$^{-1}$. Panel (D): 3–10 keV photon index. Error bars denote the 1$\sigma$ uncertainty. The blue solid lines represent the mean value for each parameter, while the blue dashed lines correspond to the standard deviation.

Figure 6. Time evolution of Fe K$\alpha$ line parameters and 3–10 keV primary flux and photon index. Panel (A): Fe K$\alpha$ equivalent width in eV units. Panel (B): Fe K$\alpha$ line flux in units of $10^{-5}$ photons cm$^{-2}$ s$^{-1}$. Panel (C): continuum 3–10 keV flux in units of $10^{-11}$ erg cm$^{-2}$ s$^{-1}$. Panel (D): 3–10 keV photon index. Error bars denote the 1$\sigma$ uncertainty. The blue solid lines represent the mean value for each parameter, while the blue dashed lines correspond to the standard deviation.
This is consistent with previous results (e.g. Bianchi et al. 2003; Lobban et al. 2010; Emmanoulopoulos et al. 2013). We note that the constraints on the reflection component are derived assuming a static X-ray source (Magdziarz & Zdziarski 1995; Murphy & Yaqoob 2009), but it may actually be outflowing (Beloborodov 1999; Malzac, Beloborodov & Poutanen 2001). An outflowing, energetically dominant corona can be generated by a geometrically thin, optically thick accretion disc at low accretion rates (Merloni & Fabian 2002). This scenario is consistent with the lack of a significant optical/UV bump from the disc, if the power output is dominated by the corona. Furthermore, an outflowing X-ray corona could account for the absence of a disc reflection component, since the primary emission would be beamed away from the disc. This has been suggested especially for radio-loud sources having relativistic jets, where the X-ray corona might be the base of the jet itself (see e.g. Lohfink et al. 2013; Walton et al. 2013; Ballantyne et al. 2014; Fabian et al. 2014). Although NGC 7213 is a radio-intermediate source with no clear evidence for a strong jet (Blank, Harnett & Jones 2005; Bell et al. 2011), its radio emission is found to be weakly correlated with the X-ray emission (Bell et al. 2011). Therefore, the outflowing corona scenario cannot be ruled out in this source.

We confirm the presence of an iron complex between 6.4 and 7 keV (Bianchi et al. 2003), consisting of three narrow Kα emission lines from neutral Fe, Fe xxv and Fe xxvi. The lack of a Compton reflection hump above 10 keV indicates that these lines cannot be modelled with a single black hole mass in units of 10^8 solar masses and a density of 5^10^23 cm^-3. We can only place a lower limit on the presence of a high-energy cut-off, \( E_c > 140 \) keV, consistent with the lower limit of 350 keV found by Lobban et al. (2010) using Suzaku/Swift/BAT data, and marginally consistent with the value of 95^75_55 keV found by Bianchi et al. (2003) using XMM-Newton+BeppoSAX data. Replacing the cut-off power law with a Comptonization model and assuming a spherical geometry, we estimate the coronal temperature to be \( \sim 40000 \) keV (\( kT = 295^{+79}_{-50} \) keV) and we measure an optical depth \( \tau = 0.2^{+0.7}_{-0.1} \). The lack of an upper limit on the high-energy cut-off does not conflict with the upper limit on the coronal temperature, because a cut-off power law is known to be a rough approximation of Comptonization models (see e.g. Stern et al. 1995). Instead, the high-energy turnover of a Comptonization spectrum is much sharper than an exponential cut-off (see e.g. Zdziarski et al. 2003). Moreover, a Comptonization spectrum is actually a superposition of several orders of Compton scattering spectra. When the optical depth is small, the different scattering orders are separated in energy, thus resulting in a bumpy spectral shape (see e.g. Poutanen & Svensson 1996). But the optical depth and temperature are inversely related for a given heating/cooling ratio, i.e. the ratio of the power dissipated in the corona to the intercepted soft luminosity (Stern et al. 1995; Haardt et al. 1997). This can produce an upper limit on the coronal temperature even if no exponential cut-off is required (see e.g. Petrucci et al. 2013).

The combination of a weak or absent reflected continuum, a weak UV bump and a low accretion rate suggest that the standard optically thick, geometrically thin accretion disc is truncated in the inner region of the source (Starling et al. 2005; Lobban et al. 2010). A possible explanation is that the nucleus accretes via a RIAF, with the inner edge of any standard disc restricted to large distances, \( \sim 10^5 \) gravitational radii (see e.g. Quataert et al. 1999). This is a natural suggestion for an LLAGN, since RIAFs are only
expected in sub-Eddington systems and the low radiative efficiency would explain the observed low luminosity. The X-ray emission from an RIAF is likely dominated by thermal Comptonization, in agreement with observations of X-ray binaries in the hard state (see e.g. Narayan 2005, and references therein). The soft seed photons can be synchrotron photons produced in the hot accretion flow itself (synchrotron self-Compton), or thermal photons from the outer thin disc (see e.g. Yuan & Zdziarski 2004; Nemmen, Storchi-Bergmann & Eracleous 2014). As we noted above, the X-ray variability timescale of NGC 7213 is of the order of days/weeks (Emmanoulopoulos et al. 2012). Therefore, the Comptonization process is consistent with taking place in an extended region with $kT_e > 40\,\text{keV}$ and $\tau \lesssim 1$, possibly illuminated by the outer thin disc. The relatively small optical depth is a further indication that the corona should be extended and subtend a large solid angle as seen from the disc, in order to scatter a sufficient number of soft photons to produce a substantial X-ray continuum.

Finally, our results can be compared with those on other weakly accreting AGNs observed so far by NuSTAR, namely NGC 5506 (estimated Eddington ratio as low as 0.7 $\times 10^{-2}$; see Matt et al. 2015)\(^1\) and NGC 2110 (estimated Eddington ratio of 0.25–3.7 $\times 10^{-2}$; see Marinucci et al. 2015). Matt et al. (2015) found a lower limit on the high-energy cut-off of $\sim 500\,\text{keV}$ for NGC 5506, while Marinucci et al. (2015) inferred $E_c > 210\,\text{keV}$ for NGC 2110. In these objects, then, a weak disc emission may be accompanied by a relatively high coronal temperature, in agreement with our present work on NGC 7213. The number of observed sources with good measurements of the high-energy cut-off is too small to establish any statistical correlation with other parameters. However, if the X-ray emission is due to a Comptonizing corona, a high coronal temperature is expected when the disc radiation is weak, because inverse Compton scattering is inefficient in cooling the corona. Further studies on a greater number of sources will be required to confirm this scenario by constraining the physical parameters of the disc/corona system.

**ACKNOWLEDGEMENTS**

We thank the anonymous referee for his/her helpful comments, which improved the manuscript. FU thanks Pierre-Olivier Petrucci for useful discussions and comments. This work is based on observations obtained with the NuSTAR mission, a project led by the California Institute of Technology, managed by the Jet Propulsion Laboratory and funded by NASA. This research has made use of data, software and/or web tools obtained from NASA’s High Energy Astrophysics Science Archive Research Center (HEASARC), a service of Goddard Space Flight Center and the Smithsonian Astrophysical Observatory. ---

\(^1\) This value of the Eddington ratio is obtained by assuming the highest estimate of the black hole mass in NGC 5506, namely $10^9\,\text{M}_\odot$. The mass is poorly known, with a lower limit of a few $10^6\,\text{M}_\odot$ (see Guainazzi et al. 2010), which would yield an Eddington ratio above 0.1.
