A model of dark sector where $O$(few GeV) mass dark matter particles $\chi$ are supplied by a lighter dark force mediator $V$, $m_V \ll m_\chi$, is motivated by the recently discovered mismatch between simulated and observed shapes of galactic haloes. Such models, in general, provide a challenge for direct detection efforts and collider searches. We show that for a large range of coupling constants and masses, the production and decay of the bound states of $\chi$, such as $0^{++}$ and $1^{--}$ states, $\eta_D$ and $\Upsilon_D$, is an important search channel. We show that $e^+e^- \rightarrow \eta_D + V$ or $\Upsilon_D + \gamma$ production at $B$-factories for $\alpha_D > 0.1$ is sufficiently strong to result in multiple pairs of charged leptons and pions via $\eta_D \rightarrow 2V \rightarrow 2(l^+l^-)$ and $\Upsilon_D \rightarrow 3V \rightarrow 3(l^+l^-)$ ($l = e, \mu, \pi$). The absence of such final states in the existing searches performed at BABAR and Belle sets new constraints on the parameter space of the model. We also show that a search for multiple bremsstrahlung of dark force mediators, $e^+e^- \rightarrow \chi\bar{\chi} + nV$, resulting in missing energy and multiple leptons, will further improve the sensitivity to self-interacting dark matter.

**Introduction.** Identifying dark matter is an open question of central importance in particle physics and cosmology. In recent years, the paradigm of weakly interacting dark matter supplied by a new force in the dark sector came to prominence [1, 2], motivated by a variety of unexplained astrophysical signatures. It was later shown [3, 4] that this model provides the best realization of self-interaction dark matter [5], and helps to alleviate tensions between observed and simulated shapes of dark matter haloes (see, e.g. [6]).

It is of great phenomenological interests to check whether such a dark force could be probed in laboratories. The simplest way for dark matter to interact with the standard model (SM) sector is through a vector or scalar mediators coupled to the SM fields via the kinetic mixing or the Higgs portals. For dark matter heavier than 4-5 GeV, direct detection experiments provide the strongest constraints on such models. High-energy collider probes typically require more effective production channels [7–11]. For dark matter lighter than 4-5 GeV, the limits from direct detection experiments arise from electron recoil and are much weaker. In this mass range, strong CMB constraints on dark matter annihilation naturally point to particle-antiparticle asymmetry in the dark sector. Constituents of such a dark sector, light dark matter and a light mediator, can be searched for in meson decays [12], fixed target experiments [13], mono-photon events at colliders [14], or via the production/scattering sequence in proton [15] and electron [16] beam dump experiments, or perhaps via new galactic substructures and minihalos [17]. Most of the existing searches of light particles [18] are insensitive to dark matter with $m_\chi > m_{\text{mediator}}$, and therefore would not be able to establish any candidate signal as coming specifically from the dark force carrier.

In this Letter, we show that the presence of self-interacting dark matter within the kinematic reach of existing colliders provides opportunities for the new search channels. We outline such possibilities in the minimal setup where the dark force carrier also mediates the interaction between dark matter and the SM particles. A light mediator gives an attractive force between $\chi$ and $\bar{\chi}$ particles, leading to the formation of bound states, which can be produced on-shell at colliders [1]. In addition, the production of continuum $\chi\bar{\chi}$ leads to final state radiation (FSR) of light mediators. Both channels typically result in a striking multi-lepton final state, that can be searched for at $B$-factories and fixed target experiments. It is well known that heavy flavor mesons and heavy quarkonia were instrumental for uncovering a wealth of information about the SM. Similarly, should a dark force exist, the aforementioned channels may allow for genuine tests of the detailed content of the dark sector.

**Dark matter bound states production.** We illustrate these ideas in the well-studied example of the vector mediator model. The Lagrangian for dark matter and dark photon is

$$\mathcal{L} = \mathcal{L}_{\text{SM}} + \bar{\chi}\tau^\mu(\partial_\mu - ig_D V_\mu)\chi - m_\chi \bar{\chi}\chi + \frac{1}{4} V_\mu V^\mu - \frac{\kappa}{2} F_{\mu\nu} F^{\mu\nu} + \frac{1}{2} m_V^2 V_\mu V^\mu,$$

where $\kappa$ is the kinetic mixing between the photon and the vector field $V$. The dark matter particle $\chi$ is a Dirac fermion, neutral under the SM gauge group, but charged under the dark $U(1)_D$ interaction that has a new vector particle $V_\mu$ (sometimes called a "dark photon") as a force carrier.

1 Weakly coupled dark matter bound states have been studied in various contexts [19–25].
As discussed in the introduction, sufficiently strong dark interaction strength and light dark photon will result in the formation of dark matter particles ($\chi\tilde\chi$). The two lowest $1S$ bound states, $1S_0$ ($J^{PC} = 0^{-+}$) and $3S_1$ ($J^{PC} = 1^{--}$), will be called $\eta_D$ and $\Upsilon_D$, respectively. The condition for their existence has been determined numerically \cite{20} $^2$, $1.68m_\nu < \alpha_D m_\chi$, with $\alpha_D = g_\nu^2/(4\pi)$. Their quantum numbers suggest the following production mechanisms at colliders:

$$e^+e^- \rightarrow \eta_D + \gamma; \quad e^+e^- \rightarrow \Upsilon_D + \gamma; \quad p + p \rightarrow \Upsilon_D + X \quad (2)$$

The last process represents the direct production of $\Upsilon_D$ from $q\bar{q}$ fusion. All production processes are mediated by a mixed $\gamma - V$ propagator, as shown in Fig. 1.

**FIG. 1.** Diagram for $\eta_D$ and $\Upsilon_D$ production and decay at $B$-factories.

In order to obtain the rate for the first process in (2), we calculate the amplitude of $e^+e^- \rightarrow \chi\bar{\chi}V$ with $\chi, \bar{\chi}$ having the same four momentum $p$ (with $p^2 = m_\chi^2$), and apply the projection operator,

$$\Pi_\eta = \sqrt{\frac{1}{32\pi m_\chi^3}} R_{\eta_D}(0)(\not{\gamma} + m_\chi)\gamma_5(\not{\gamma} - m_\chi), \quad (3)$$

to select the $\eta_D$ bound state \cite{28}. We find a leading-order differential cross section:

$$\frac{d\sigma^{e^+e^- \rightarrow \eta_D V}}{d\cos\theta} = \frac{4\pi\alpha_D^2\kappa^2|R_{\eta_D}(0)|^2(1 + \cos^2\theta)}{m_\chi s^{3/2}(s - 4m_\chi^2 + m_V^2)^2}|\mathbf{p}|^3, \quad (4)$$

where $\theta$ is the angle between $\eta_D$ and the initial $e^-$ in the center-of-mass (CM) frame, and $|\mathbf{p}|$ is the spatial momentum of $\eta_D$, $|\mathbf{p}| = \sqrt{|s - (2m_\chi + m_V)^2|[s - (2m_\chi - m_V)^2]/(2\sqrt{s})}$. We neglect the binding energy for $\eta_D$, and set $m_{\eta_D} \approx 2m_\chi$.

An analytic form for $R_{\eta_D}(0)$, the wave function at origin, is obtained using the Hulthén potential $V(r) = -\alpha_D e^{-\delta r} / (1 - e^{-\delta r})$ with $\delta = (\pi^2/6)m_\nu$, which is known as a good approximation of the Yukawa potential $V(r) = -\alpha_D e^{-m_\nu r}/r$ \cite{29}. In that case, $R_{\eta_D}(0) = (4 - \delta^2 a_0^2)^{1/2} a_0^{3/2}$, where $a_0 = 2/(\alpha_D m_\nu)$.

The scalar bound state $\eta_D$ dominantly decays into two dark photons, each subsequently decaying into a pair of SM particles via kinetic mixing. These decays are all prompt for the relevant region of parameter space. The above decay chain eventually results in the final states containing six charged tracks, which can be electrons, muons, or pions, depending on the dark photon mass.

We turn to the calculation of $\Upsilon_D$ production via initial state radiation (Fig. 1). In the $\Upsilon_D$ rest frame, the non-relativistic expansion can be used, taking the dark matter field in the form:

$$\chi = e^{im_\nu_t t}[\xi \sigma \cdot \mathbf{p}/(2m_\chi)]\xi^T + e^{-im_\nu t} [\sigma \cdot \mathbf{p}/(2m_\chi)]\xi^T,$$

where $\xi, \bar{\xi}$ are the 2-spinor annihilation (creation) operators for particle (antiparticle).

We use the relation between matrix element and wave function \cite{30},

$$\langle 0|\bar{\xi}^\mu \eta_D \xi |0\rangle = \sqrt{\frac{1}{2\pi}} R_{\Upsilon_D}(0) \varepsilon^\mu_{\Upsilon_D}, \quad (5)$$

where $\varepsilon^\mu_{\Upsilon_D}$ is the polarization vector of $\Upsilon_D$ and $R_{\Upsilon_D}(0) \approx R_{\eta_D}(0)$ is the radial wave function at origin. Taking into account the kinetic mixing between dark photon and the photon, we derive the effective kinetic mixing term between $\Upsilon_D$ and the photon,

$$\mathcal{L}_{\text{eff}} = \frac{1}{2} \kappa_{\Upsilon_D} F_{\mu\nu} \Upsilon_D^{\mu\nu}, \quad \kappa_{\Upsilon_D} = \sqrt{\frac{\alpha_D}{2m_\chi}} R_{\Upsilon_D}(0). \quad (6)$$

In the limit $m_\nu \ll \alpha_D m_\chi$, the term $\kappa_{\Upsilon_D}$ reduces to $\kappa_{\Upsilon_D} = \alpha_D/2$. We obtain a differential cross section:

$$\frac{d\sigma^{e^+e^- \rightarrow \Upsilon_D V}}{d\cos\theta} \approx \frac{2\pi\alpha_D^2\kappa_{\Upsilon_D}^2}{s} \left(1 - \frac{4m_\chi^2}{s}\right) \times \left[\frac{8s^2(s^2 + 16m_\chi^2)\sin^2\theta}{(s - 4m_\chi^2)(s + 4m_\chi^2 - (s - 4m_\chi^2)\cos^2\theta)^2} - 1\right] + 2$$

where $\theta$ is the the angle between $\gamma$ and the initial $e^-$ in the CM frame. In the denominator, the electron mass must be retained in order to regularize the $\theta$ integral, as $m_e = 0$ the cross section is divergent in the forward direction \cite{31}.

Compared to the $e^+e^- \rightarrow \eta_D V$ process, the $e^+e^- \rightarrow \gamma \Upsilon_D$ cross section is suppressed by a factor $\alpha_D/\alpha_D$, although the latter contains a logarithmic enhancement from the angular integral. Moreover, the cross-section $e^+e^- \rightarrow \eta_D V$ contains an additional $m_\chi^2/s$ factor, which brings additional suppression of lighter dark matter. For $\alpha_D \gtrsim 0.1$ and $m_\chi \sim \sqrt{s}$, the two processes have similar cross-sections, and we will combine them to set the limit on this model.

The $\Upsilon_D$ particle will subsequently decay into three dark photons. We calculate the differential decay rate following the approach in Ref. \cite{28} by generalizing it to the massive dark photon case,

$$\frac{d\Gamma(\Upsilon_D \rightarrow 3V)}{dx_1 dx_2} = \frac{2a_D^2 |R_{\Upsilon_D}(0)|^2}{3m_\chi^2} \times \frac{39x^8 + 4x^6 F_6 - 16x^4 F_4 + 32x^2 F_2 + 256F_0}{(x^2 - 2x_1)^2(x^2 - 2x_2)^2(x^2 + 2(x_1 + x_2 - 2))^2}, \quad (8)$$

\hfill \footnote{2 It is known that too large $\alpha_D$ would run to the Landau pole very quickly at higher scale \cite{27}. Hereafter, we focus on $\alpha_D \lesssim 0.5$, and work with leading-order results in $\alpha_D$.}
where \( x_{1,2} = E_{1,2}/m_\chi \), \( x = m_V/m_\chi \), and
\[
F_0 &= x_1^2 + (x_1 + x_2)(x_2 - 2) - 30, \\
F_1 &= (x_1^2 + x_1 x_2 - 2x_1)(3x_2 - 10) - 10x_2(x_2 - 2) - 21, \\
F_2 &= x_1^4 + 2x_1^3(x_2 - 2) + x_1^2(x_2(3x_2 - 22) + 28) + 2x_1(x_2 - 2)(x_2 - 9) + 12 \\
+ x_2(x_2 - 2)(x_2 - 2) + 24 + 24, \\
F_0 &= x_1^4 + 2x_1^3(x_2 - 2) + x_1^2(3x_2(x_2 - 3) + 7) + x_1(x_2 - 1)(x_2 - 2)(2x_2 - 3) \\
+ (x_2 - 1)^2(x_2(x_2 - 2) + 2). \tag{9}
\]

When \( x_1, x_2 \) are fixed, the relative angles between the dark photons are also fixed in the rest frame of \( \Upsilon_D \).

In the case of scalar dark matter charged under \( U(1)_D \), the ground state \( \chi_0 \) formed by a pair \( \chi^+ \chi^- \) has quantum numbers \( 1_{0^+} \) \cite{40}, and will be produced in the similar process as \( \eta_D \) in (2). On the other hand, the counterpart of \( \Upsilon_D \) is a \( p \)-wave state, and its production rate is further suppressed by the derivative of its wave function at the origin. Therefore, we expect slightly weaker bounds on scalar dark matter compared to the fermion case.

**Multi-mediator final state radiation.** Smaller values of \( \alpha_D \) or larger \( m_V/m_\chi \) ratios may prevent the existence of \( \chi \chi \) bound states. In that case, mediator states can still be produced through the FSR process \( e^+ e^- \rightarrow \chi \chi + nV \).

(One could also study this process in high-energy proton collisions \cite{10}, should a new efficient channel for \( \chi \chi \) production exist.) The FSR dark photons further decay into pairs of charged SM particles. Therefore, the typical signal consists of multiple charged tracks plus missing energy, taken away by the \( \chi \chi \) pair. The \( \Upsilon \) experiment did not trigger on two charged leptons due to overwhelming QED backgrounds. The channel with four charged leptons plus missing energy is, however, quite promising, and we suggest to perform a corresponding search at both \( \Upsilon \) and Belle. The dominant SM backgrounds for the \( 4l + \text{missing energy} \) signature may come from the \( \tau^+ \tau^- \eta^{\pm} \bar{\eta}^- \) final states, and one would expect over \( 10^4 \) such events at \( \Upsilon \) \cite{35,41}. With the same kinematic requirements described in the previous section, the lower bounds on \( m_\chi \) in the region favored by the SIDM model are shown by the thin blue curves in Fig. 2 for several choices of \( \alpha_D \).

The search for FSR production of dark photons by dark matter pair-production has additional kinematic limitations. The phase space for producing energetic charged leptons becomes smaller for larger \( m_\chi \), resulting in softer final state leptons. This feature can be read from Fig. 2, as for \( m_\chi \gtrsim 2.5 \text{ GeV} \), producing charged leptons energetic enough to pass the cuts becomes difficult. As a result, the potential lower bound on \( m_\chi \) does not change very much with the increase of \( \alpha_D \). On the other hand, the production and decay of dark bound states \( \Upsilon_D \) and \( \eta_D \) create more energetic leptons for larger \( m_\chi \). Therefore, the two search strategies are complementary to each other.

**Hadronic probes of dark sector.** Fixed target experiments with proton beams can also be used to probe a dark sector. For realistic energies of available proton
beams, the most important production channel is from the quark-anti-quark fusion, $q\bar{q} \rightarrow \Upsilon_D$. Generalizing calculations of \cite{42}, the production cross section is given by

\[
\sigma_{pp(n)\rightarrow \Upsilon_D} = \frac{4\pi^2\alpha_D^2\kappa^2_D}{s} \sum_q Q_q^2 \int_1^\tau \frac{dx}{x} \left[ f_{\bar{q}/p}(x) f_{\bar{q}/p(n)} \left( \frac{\tau}{x} \right) + f_{\bar{q}/p}(x) f_{\bar{q}/p(n)} \left( \frac{\tau}{x} \right) \right],
\]

where $\tau = m_T^2/s$, $f_{\bar{q}/p}(n)$ and $f_{\bar{q}/p}(n)$ are the relevant structure functions for this process, and $Q_q$ is the quark charge in units of $e$. Unlike $B$-factories, only muonic decays of dark bound states, such as $\Upsilon_D \rightarrow 3V \rightarrow 3(\mu^+\mu^-)$, constitute a useful signature, as backgrounds in other channels are likely to be too large. The multi-dark photon FSR channels can also be relevant for the proton beam experiments.

Among the possible candidates of proton-on-target experiments, we focus our discussion on SeaQuest \cite{43} and the planned SHIP \cite{44} facilities. Note that only a fixed target mode of operation, rather than a beam dump mode that would try to remove prompt muons, is suitable for the search of $\Upsilon_D$. Taking a point in the parameter space, $m_\chi = 2$ GeV, $\kappa^2 = 10^{-7}$, $m_V = 300$ MeV, $\alpha_D = 0.5$ and the energy of incoming proton beam of 400 GeV, we estimate a probability of producing a $\Upsilon_D$ decaying to $3(\mu^+\mu^-)$ for a 1 mm tungsten target, $P = n\sigma \tau \sim 2 \times 10^{-17}$. With $O(10^{20})$ particles on target, one could potentially expect up to $2 \times 10^3$ six muon events. The large multiplicity of signal events gives some hope that this signal could be extracted from large number of muons produced per each proton spill. Given the current uncertainties in estimating the background, we refrain from showing the potential reach of proton experiments in Fig. 2, noting that in any case, it would not cover the most interesting region for SIDM, namely $m_V \lesssim 30$ MeV.

**Outlook.** Among the various probes of dark sectors suggested and conducted in recent years, only a few are sensitive to both the dark force and dark matter at the same time. We have pointed out that in case of relatively strong self-interaction, the presence of dark force greatly facilitates the discovery of the entire sector, as it leads to the formation of dark bound states, and causes dark FSR radiation that decay into multiple charged particles of the SM. The existing searches at $\text{BaBar}$ and Belle already limit this possibility; and further advance in sensitivity can be made by searching for the missing energy plus pairs of charged particles.
