HAYWARD1, REINHARD GENZEL5, PHIL HOPKINS9, PAUL VAN DER WERF15, ROBERTO DECARLI2

ABSTRACT

We present 90 mas (37 pc) resolution ALMA imaging of Arp 220 in the CO (1-0) line and continuum at $\lambda = 2.6$ mm. The internal gas distribution and kinematics of both galactic nuclei are well-resolved for the first time. In the more luminous West nucleus, the major gas and dust emission extends to 0.2″ radius (80 pc); the central resolution element shows a strong peak in the dust emission but a factor 3 dip in the CO line emission. In this nucleus, the dust is apparently optically thick ($\tau_{2.6\text{mm}} \sim 1$) at $\lambda = 2.6$ mm with a dust emission brightness temperature $\sim 120$ K. The column of ISM at this nucleus is $N_{\text{H}_2} \gtrsim 2 \times 10^{26}$ cm$^{-2}$, corresponding to $A_V = 10^{6}$ mag and 1000 gr cm$^{-2}$. The East nucleus is somewhat more elongated with radial extent 0.3″ or $\sim 120$ pc. The derived kinematics of the nuclear disks provide a good fit to the line profiles sampled every 50 mas, yielding the emissivity distributions, the rotation curves and velocity dispersions. In the West nucleus, there is evidence of a central Keplerian component requiring a central mass of $8 \times 10^8 \text{M}_\odot$. The intrinsic widths of the emission lines are $\Delta v (\text{FWHM}) = 250$ (West) and 120 (East) km s$^{-1}$. Given the very short dissipation timescales for turbulence ($\lesssim 10^5$ yrs) if these motions are dispersive, we suggest that the local line widths may be the result of semi-coherent motions (e.g. a tightly wound spiral pattern) within the nuclear disks. The overall symmetry of the nuclear disk structures is most impressive – implying the merger timescale is significantly longer than the rotation period of the disks ($\sim 1$ Myr) so that the disks can relax.

Draft version June 1, 2016

1. INTRODUCTION

Galactic merging is a key process in the early growth and evolution of massive galaxies and in determining their structural morphology. In the era of precision cosmology, these processes remain a major uncertainty in understanding the present makeup of the visible universe. Many aspects of the evolution of merging, gas-rich nuclear disks are poorly constrained and only approximately understood in terms of the physical processes and the hierarchy of their importance. The radial mass and star formation distributions, the physical conditions (density, temperature and cloud structures) and the evolution associated with feedback from starbursts (SBs) and active galactic nuclei (AGN) remain poorly understood. And yet, all of these are vital to predicting the ultimate fate or product of the mergers (e.g. the resulting galactic morphologies) and the mode(s) of star formation and AGN fueling.

Ultra-luminous infrared galaxies (ULIRGs) are the most extreme SB galaxies. The first complete sampling of the local universe yielded 22 ULIRGs at z < 0.1 from the IRAS all sky with L$_{(1-1000 \mu m)} > 10^{12}$ L$_{\odot}$ (Sakamoto et al. 1999; Downes & Eckart 2007). At high redshift when the rate of collisions of the galaxies was higher (Rodriguez-Gomez et al. 2015) and galaxies were more gas-rich, they are much more abundant (Le Floc’h et al. 2009; Caputi et al. 2007; Magnelli et al. 2013).

Resolved studies of the merging processes must rely on the sample of local galaxies. The follow-up ground-based optical imaging reveals virtually all of the local ULIRGs to be merging galaxies or post merging systems (Armus et al. 1987; Sanders et al. 1988; Sanders & Mirabel 1996). During the merging of gas-rich galaxies, the original ISM (presumably distributed in extended galactic-scale disks) sinks rapidly to the center of the merging system due to dissipation of kinetic energy in the shocked gas and torques generated by the offset stellar and gaseous bars (e.g. Barnes & Hernquist 1992, 1996). The star formation rates in the ULIRGs are typically 10-100 times higher per unit mass of ISM compared to quiescent disk galaxies. The ULIRG-starburst activity is likely driven by concentration of gas in nuclear regions and dynamical compression of this gas in supersonic shocks.

Among the ULIRGs, Arp220 is probably the most frequently cited example, having luminosity L$_{12}$ = 1.91 × 10$^{13}$ L$_{\odot}$ (Sanders et al. 2003; Armus et al. 2009). (Here we adopt a luminosity distance D$_{L}$ = 87.9 Mpc and angular size distance D$_{A}$ = 85.0 Mpc (Armus et al. 2009).) Near infrared imaging shows two galactic nuclei, separated by 1.00′ or 412 pc (Scoville et al. 1998). CO imaging at 0.5″ resolution uncovers two counter rotating disks with radii 100 pc and dynamical masses 2 × 10$^{9}$ M$_{\odot}$ for each disk (Sakamoto et al. 1999; Scoville et al. 1997, 1998; Downes & Eckart 2007). Much of the nuclear ISM is very dense (> 10$^{4.5}$ cm$^{-3}$) and at high temperature (> 75 K) (Sakamoto et al. 1999; Downes & Eckart 2007; Matsushita et al. 2009; Greve et al. 2009; Rangwala et al. 2011; Wilson et al. 2014; Scoville et al. 2015a).

Both nuclei are optically thick at λ < 600 µm. Wilson et al. (2014) derive dust optical depths τ$_{\lambda_{600}}$ = 5.3 and 1.7 for the West and East nuclei, respectively, implying that for the West nucleus τ$_{\lambda_{600}}$ ∼ 1. These high optical depths imply that the nuclear disk structures are best probed at λ > 600 µm. Shorter wavelength observations may not penetrate the outer dust photospheres of the nuclei unless the structures are tilted to the line of sight. The fact than any near infrared radiation can be seen from the nuclei is a clear indication that the dust is in a disk-like distribution tilted to the line of sight.

Here, we present 90 mas (37 pc) resolution ALMA imaging of the inner region of Arp220 in the CO (1-0) line and the 2.6 mm continuum (108 - 114 GHz, ALMA Band 3), providing excellent resolution and sensitivity for imaging the molecular gas and the long wavelength dust continuum. The East and West nuclei are internally resolved for the first time. The dust continuum provides an independent and linear probe of the overall ISM mass (Scoville et al. 2015a,b).

2. ALMA OBSERVATIONS AND DATA REDUCTION

These ALMA Cycle 3 long baseline observations in CO (1-0) line were obtained in 2015 November for project #2015.1.00113.S. (We are also scheduled to obtain CO (2-1) and (3-2) high and low resolution imaging but those data will probably not be available until the end of 2017.) In view of the major increase in resolution provided by the high resolution CO (1-0) data, publication of this data is important and we proceed here with those preliminary results.

The observations discussed here were in receiver Band 3; the correlator was configured in the time division mode (TDM) with 4 spectral windows. Each window had a full bandwidth of 1875 MHz with 1.95 MHz resolution spectral channels. One window was configured to observe the redshifted CO (1-0) line at rest frequency of 115.2712 GHz; the remaining three spectral windows were centered at 113.253 GHz, 103.073 GHz and 101.139 GHz to image the dust continuum emission and $^{13}$CO and C$^{18}$O. The latter will be presented in our later publication with the other bands.

The observations were done in a very extended configuration with baselines up to 11 km, providing the maximum resolution presently available with ALMA. For this telescope configuration, good flux recovery is expected out to scales of ~ 0.4″ but extended emission with spatial size greater than this will be at least partially resolved out. These observations thus probe only the inner nuclei of Arp 220. The data were taken with 40 12 m antennas and the total integration time was 30 minutes (excluding calibrations).

Following delivery of data products, the data were re-reduced and imaged using the Common Astronomy Software Applications package (CASA). Self-calibration was done to improve the dynamic range. The images were made with the parameter Robust = 0, 1 and 2; only the Robust = 1 images are used here. We cleaned the images with no continuum subtraction, noted the line and absorption free channels and then created a continuum image using those channels. The continuum subtraction was then done in the image plane.

Channel averaging over 8 of the original channels was...
done to reduce noise, resulting in data with velocity resolution of 40 km s\(^{-1}\) without serious compromise relative to the intrinsic line width (\(\Delta v_{FWHM} = 100–200\) km s\(^{-1}\), see Section 5). The 1\(\sigma\) (rms) sensitivities are as follows: an rms noise of 0.6 mJy beam\(^{-1}\) in 40 km s\(^{-1}\) channels in the lower sideband at \(\sim 110\) GHz and 0.8 mJy beam\(^{-1}\) in 40 km s\(^{-1}\) channels in the upper sideband at 114 GHz.

The velocities given here are \(v_{\text{radio}} = c(v_{\text{rest}} - \nu)/v_{\text{rest}}\) relative to the LSR (not \(v_{\text{opt}} = cz = c(v_{\text{rest}} - \nu)/\nu\)). For the Arp 220 observations, we adopt \(v_{\text{radio}} = 5441\) km s\(^{-1}\) or \(cz = v_{\text{opt}} = 5542\) km s\(^{-1}\) (Sanders et al. 1991).

Table 1 lists the measured source fluxes and peak brightness temperatures for both the continuum and the CO (1-0) line and Table 2 contains the results of two-dimensional Gaussian fits to each of the sources. The total recovered CO line flux from the two nuclei is 45.4 + 27.4 = 72.8 Jy km s\(^{-1}\). This is 19% of the total single dish CO (1-0) line flux measured by Sanders et al. (1991) and Solomon et al. (1997).

3. CONTINUUM EMISSION

3.1. Infrared Dust Emission

A brief background for understanding the far infrared dust emission is warranted as a preamble to our analysis below. For this discussion we might visualize the massive dust concentrations in the nuclei of Arp 220 as spherical, with density decreasing outwards. The dust has an opacity which increases steeply at shorter wavelengths (i.e. \(\kappa_\nu \propto \nu^{1-8}\) in the far infrared/submm regime). The enormous dust column densities in the Arp 220 nuclear sources imply that the dust will be optically thick well below. For this discussion we might visualize the massive dust emission as warranted as a preamble to our analysis.

The dust at each radius is also likely to be in radiative equilibrium with the luminosity (which originates from massive stars in the nuclear starburst and/or from a central AGN). As long as these luminosity sources are centrally concentrated, the dust temperatures must increase at smaller radii.

Thus it should be anticipated – as long as the dust is optically thick into the far infrared, the longer wavelength observations will tend to probe high temperature dust closer to the central energy sources – the longer wavelengths see deeper into the enveloping dust. It would appear counter-intuitive that longer wavelength observations probe hotter regions in the nuclei at smaller radii, but because of the opacity falloff at longer wavelengths, this is in fact the case.

A cautionary corollary – lower angular resolution observations will tend to include a larger fraction of the cooler dust at large radii, and these outer regions will be less optically thick (if the gas and dust density decreases outward). In fact, one must recognize that there is no single wavelength at which one can say the source is optically thin or thick – the dust column (and optical depth) increases as the line of sight passes closer to the center; therefore the ‘apparent’ (or average) optical depth one infers from an observation is dependent on the angular resolution or beam size of the observation.

3.2. Continuum Spectra

In Table 3, we list the radio and infrared continuum measurements done at \(< 0.6\)’ resolution – sufficient to separate the two nuclei. The total integrated fluxes and peak flux per beam are given, along with the peak brightness temperature calculated from the peak flux per beam at each of the different frequencies. It should be noted that the synthesized beam sizes vary between 0.6 and 0.08\(\)’. In most cases, the interferometric integrated fluxes will recover emission on scales up to \(\sim 3\times\) the beam size but emission on larger scales will not be fully recovered. The brightness temperatures determined from the peak flux at each frequency also refer to variable source radii ranging from 0.05 to 0.3\(\)’ , corresponding to 20 to 123 pc.

In Figure 2 the fluxes are plotted and the spectral indexes for each frequency interval are shown. At low frequencies (\(\nu < 40\) GHz) the spectral index (\(\alpha\) in \(S_\nu \propto \nu^\alpha\)) is negative and the emission is predominantly non-thermal synchrotron. At \(\nu \geq 200\) GHz the dust emission

dominates and the spectral indexes ranging from \( \alpha = 2 \) (optically thick and a single dust temperature) to steeper \((\alpha > 2 \text{ to } \lesssim 4)\) if there are substantial contributions from optically thin dust. In this frequency range the maximum spectral index will be \( \sim 3.8 \), corresponding to optically thin emission with a typical Galactic ISM dust opacity coefficient \( \beta = 1.8 \pm 0.1 \) (Planck Collaboration 2011a). In Figure 2-right, the spectral indexes at the highest frequency are 2.4 (West) and 3.2 (East), indicating that most of the emission is from optically thick dust with a small addition of optically thin emission (most obvious in the East nucleus where the optical depths are not so high).

### 3.3. Dust Emission Fluxes and Brightness Temperatures

At 112.3 GHz, the continuum emission is a mixture of synchrotron and dust emission. If we extrapolate the 32 GHz flux measurements (Barcos-Muñoz et al. 2015) with a spectral index \( \alpha = -0.60 \) determined between 7 and 32 GHz (see Figure 2), then the expected non-thermal and free-free contribution at 112.3 GHz will be \( \sim 0.47 \) of the 32.5 GHz fluxes, implying 15.8 mJy and 3.1 mJy beam\(^{-1}\) in the West nucleus and 14 mJy and 1.9 mJy beam\(^{-1}\) in the East nucleus. Subtracting these...
Figure 1. The 2.6 mm continuum distribution on the East and West nuclei is shown at 0.08 × 0.1′′ resolution (33 × 41 pc). The peak values are 2.5 (East) and 11.9 mJy beam⁻¹ (West). Coordinate offsets are relative to the 2.6 mm continuum peaks (Table 1) and the contours are mJy beam⁻¹.

Figure 2. Left: The continuum fluxes measured at high resolution for the East and West nuclei of Arp 220 (Table 3). For reference the expected power laws for non-thermal synchrotron emission (NT) and Rayleigh-Jeans black body (BB) emission are shown. At long wavelengths, the dominant emission is non-thermal synchrotron emission with flux varying $\nu^{-0.5}$ to $\nu^{-0.7}$; at $\nu > 100$ GHz the dominant emission is the dust continuum with spectrum varying between $\nu^2$ in the optically thick limit and $\nu^{-3.8}$ in the optically thin limit. Right: The spectral indexes $\alpha$ (as in $S_\nu \propto \nu^\alpha$) are shown as derived from adjacent frequency points. The dust emission at $\nu > 100$ GHz is optically thick in the smallest aperture measurements and a combination of both optically thick and thin emission in larger aperture measurements.

3.4. West Nucleus Luminosity

The 121 K brightness temperature of the 112.3 GHz dust emission seen on the West nucleus is unexpectedly high, given the previous submm observations (691 GHz) of Wilson et al. (2014) which indicated $T_B = 181 \pm 27$ K on the West nucleus and optical depth $\tau_{134\mu m} \approx 5.3$. If the dust opacity varies with the standard Galactic power-law $\nu^{1.3}$, then the optical depth should be $\sim 0.038 \times 5.3 \sim 0.2$ at 112.6 GHz. The estimated 121 K brightness temperature clearly requires a higher optical depth $\tau_{2.6 mm} \approx 1$.

It is interesting to note that the implied dust photosphere, optically thick out to $\lambda \sim 2.6$ mm, with dust temperature $T_D \approx 200$ K and radius $\approx 15$ pc, must radiate...
This corresponds to 33% of the total IR luminosity $1.91 \times 10^{12} \, L_\odot$ of Arp 220 (Sanders et al. 2003; Armus et al. 2009) – all originating from R $\leq$ 15 pc.

For a geometrically thin, optically thick disk, the emitting area is $\sim 2 \pi R^2$, so for the same $T_D$ the emergent luminosity would be a factor 2 lower than Equation 1. It is interesting to note that essentially all estimates of the infrared luminosity in ULIRGs assume a spherical, i.e. isotropic source. If the infrared is in fact emitted from a thin disk which is optically thick, these luminosity estimates should be increased by a factor 1/$\cos i$.

A considerably lower temperature $T = 45 \, K$ is derived from fitting the total far infrared SED of Arp 220 (Sanders et al. 1991), implying that, at the shorter wavelengths near the 70 $\mu$m IR peak, one is sampling colder dust in a more extended photosphere. This sampling of colder dust at shorter wavelengths is as anticipated in Section 3.1 for an optically thick dust cloud – the optical depth is higher at shorter wavelengths. Hence, the $\tau \simeq 1$ surface (from which the observed photons at shorter wavelengths originate) will be at larger radius and lower $T$ (assuming a centrally heated source).

A major virtue of the longer wavelength observations reported here is the ability to penetrate the optically thick dust envelope and probe the inner regions of heavily obscured luminosity sources. The peak of the 200 K blackbody emission ($L_\nu$) is at $\lambda = 26 \mu$m but the original sources of luminosity (young stars and/or a central AGN) undoubtedly emit their energy at much shorter wavelengths in the visible, UV and X-rays.

Since the observations place an upper limit of $\sim$ 200 $K$ on the dust temperature at $R = 15 \, pc$, this implies that the luminosity originating from smaller radii cannot be much larger than $6 \times 10^{17} \, L_\odot$ – otherwise the dust would be hotter. If there is an AGN in the Western nucleus its power must be less than this. The remainder of the $\sim 1.9 \times 10^{22} \, L_\odot$ total luminosity, or about $1.3 \times 10^{12} \, L_\odot$, must originate from more distributed star formation at $R = 15 \, pc$ (36 mas radius).

3.5. West Nucleus ISM column densities and Mass

We use the observed dust opacity ($\tau_{2.6 \mu m} \simeq 1$) to estimate the column density of the West nuclear point source assuming that the dust there has similar properties to general ISM dust observed in the Galaxy. Scoville et al. (2015b) empirically calibrated the long wavelength dust emission from Herschel SPIRE with the CO(1-0) ISM masses for 28 local star forming galaxies and 12 ULIRG galaxies and with Planck measurements of the dust submm dust opacity in the Milky Way. The data are consistent with a single proportionality constant relating the rest-frame 850$\mu$m specific luminosity of the dust to the molecular ISM mass. This empirical calibration is

$$\alpha_\nu \equiv \frac{L_{\nu_{850\mu m}}}{M_{\text{mol}}} = (6.7 \pm 1.7) \times 10^{19} \, \text{erg sec}^{-1} \text{Hz}^{-1} \, M_\odot^{-1}$$

where $L_{\nu_{850\mu m}}$ is the specific luminosity of the dust at $\lambda = 850\mu$m. The mass $M_{\text{mol}}$ includes contribution for He and heavier atoms and the mass derivation employed a single standard Galactic CO-H$_2$ conversion factor.

For an optically thin mass sheet of area $A$ and surface density $\Sigma_{\text{mol}}$ ISM, Equation 2 can be recast as

$$\frac{L_{\nu_{850\mu m}}}{M_{\text{mol}}} = \frac{2 \pi A B_\nu (T_D) \tau_\nu}{\pi B_\nu (T_D) \kappa_\nu \Sigma_{\text{mol}}} = \frac{2 \pi B_\nu (T_D) \kappa_\nu}{\Sigma_{\text{mol}}} \{ \frac{\alpha_\nu}{2 \pi B_\nu (T_D)} \}$$

We use the above calibration of dust optical depth to estimate the column of gas in the nuclear source. The bulk of the ISM dust in the nearby galaxies used for the calibration is at $\sim$25 $K$ (see Scoville et al. 2015b). Using this temperature in the above equations, then implies a dust absorption coefficient at 850 $\mu$m $\kappa_{850\mu m}$ = 8.06 $\times$ 10$^{-3}$ cm$^2$ gr$^{-1}$ where the mass includes the He contribution. Scaling this opacity coefficient as $\nu^{1.8}$ (Planck Collaboration 2011a), we obtain $\kappa_{2.6\mu m} = 1.03 \times 10^{-3}$ cm$^2$ gr$^{-1}$. Putting this in terms of the H$_2$ column density, $\kappa_{2.6\mu m} = 4.51 \times 10^{-27}$ N$_{H_2}$. Thus an H$_2$ column of 2.21 $\times$ 10$^{26}$ H$_2$ cm$^{-2}$ is required in order for $\tau_{2.6\mu m} \simeq 1$. This estimate is well above the lower limit of $> 10^{21}$ cm$^{-2}$ derived by Teng et al. (2015) from non-detection in the NuSTAR bands above 20 keV.

As an aside, it is interesting to note that the mass column density of ISM $\sim$1 kg cm$^{-2}$ in the Western nucleus corresponds to a concrete wall 12 in or 0.3 m thick. This is perhaps the highest ISM density ever probed by astronomical observations. It corresponds to $N_v = 2 \times 10^{25}$ mag and would be very Compton thick.

Lastly, we note that $\tau_{2.6\mu m}$ must be $\simeq 1$ across a circular region with $R > 10 \, pc$ since the similarity of the observed dust brightness temperature and dust physical temperature requires an areal filling factor of order unity in the central resolution element. The total molecular mass is then $M_{\text{mol}} > 1.4 \times 10^9 \, M_\odot$. Clearly, these estimates are uncertain, given the assumption that the dust has standard interstellar dust properties and abundance, relative to gas in the extreme conditions at the center of Arp 220. The mass so derived is approximately a factor 2 higher than the dynamical mass in the same region (also uncertain) obtained from the CO line kinematics (see Section 5).

From the derived H$_2$ column density $N_{H_2} = 2.21 \times 10^{26}$ H$_2$ cm$^{-2}$ and line of sight path length of 30 pc, we infer a mean volume density $n_{H_2} = 2.4 \times 10^6$ cm$^{-3}$ in the central area of the West nucleus.

At these extraordinarily high ISM densities, the dust and gas will be collisionally coupled (at $n_{H_2} > 10^4$ cm$^{-3}$) and in thermal equilibrium ($T_D = T_k$). Most molecular transitions at mm/submm wavelengths will have level populations in thermal equilibrium with the H$_2$ gas. And

57 Alternatively, the Planck ratio of $\tau_{250\mu m}/N_{H_2} = 2.32 \times 10^{-25}$ cm$^2$ derived for Milky Way H$_2$ (Planck Collaboration 2011b) translates to 1.45 $\times$ 10$^{26}$ cm$^2$ H$_2$ cm$^{-2}$ adopting the same $\nu^{1.8}$ dependence of the opacity coefficient.
if the dust is optically thick into the mm regime, there will be substantial direct radiative coupling of the mm transitions to the dust radiation field. This is all consistent with the observed 187 K CO brightness temperature (see Table 1).

3.6. The East Nucleus

For the East nucleus the dust optical depth is less. Wilson et al. (2014) estimate $\tau_{434\mu m} = 1.7$ and $T = 80$ K (compared to the above-mentioned values of 5.6 and 181 K for the West nucleus). This is borne out in our 2.6 mm continuum imaging which indicates a peak of just 15 K for the dust in the East nucleus (after removing the synchrotron and free-free contributions). This suggests $\tau_{2.6mm} \sim 0.2$ (assuming $T_D = 80$ K). In this nucleus, we can’t provide the equivalent energetic constraints as in the West from our data since the dust is not optically thick at $\lambda = 2.6$ mm. However, from the ratio of $\tau_S$ derived by Wilson et al. (2014), one might infer that the East nucleus has $\sim 1/4$ the luminosity of the West nucleus. Similarly, the ratio of dust opacities in the two nuclei suggests that the mass of dust and gas in the East nucleus is $\sim 1/4$ of that in the West nucleus. Better constraints will be provided by the high resolution CO(2-1) imaging with ALMA, which is scheduled.

4. CO (1-0) LINE EMISSION

Figure 3 shows the continuum-subtracted CO (1-0) emission line profiles for the West and East nuclei obtained in apertures of 0.8 $''$ diameter centered on each nucleus. The CO emission extends up to $\sim 800$ km s$^{-1}$ in each of the nuclei and is offset in the mean by $\sim 120$ km s$^{-1}$ between the two nuclei. In the West nucleus the line profile exhibits broad wings and a single peak while in the East nucleus it is double peaked.

Images of integrated CO emission and the intensity weighted centroid velocity ($\langle V \rangle$) are shown in Figure 4. The overall morphology of the gas distribution is remarkably different in the two nuclei – in the West nucleus, the total emission is less elongated along a major axis; there is a drop in the CO emission on the central resolution element (90 mas diameter); and overall, the emission is more compact (as was the case for the dust continuum). Despite these differences, both nuclei exhibit a clear kinematic gradient, suggesting rotation. The major axis of the elongated CO intensity distribution. In the West nucleus the kinematic major axis is at PA $\simeq -110^\circ$; in this nuclear source the emission intensity distribution is hardly elongated and one does not see correlation with the major kinematic axis of either the CO or the continuum (see Table 1). The magnitude of the mean velocity gradients is impressive; in both nuclei, the shift is $\sim 500 - 600$ km s$^{-1}$ (see Figure 4-lower panels) over 0.3 – 0.4 $''$ (124 – 165 pc).

4.1. CO Hole on the West Nucleus
Figure 4. The integrated CO (1-0) line flux (top panels) and mean velocity (bottom panels) are shown. In the East nucleus the emission is clearly elongated along the major axis of the kinematics. In the West nucleus a hole is seen in the center coinciding with the dust continuum peak, likely due to dust absorption of the CO emission. These images were computed with a clipping cut to exclude from the line integrals any pixels below the 4σ noise level. The coordinate offsets are measured relative to the 2.6 mm continuum peaks (see Figure 1). The contours are labelled with Jy beam\(^{-1}\) and km s\(^{-1}\).

In the West nucleus, the central dip in the CO emission is coincident with the central dust continuum peak. The depth of the hole is approximately a factor three compared with the immediately exterior ring (see Figure 4-upper left). Since the dust continuum in the West peaks strongly in the central resolution element, this dip in the CO emission is probably not due to a deficiency or clearing of ISM at small radii. Instead, most of this drop in the CO emission is likely due to dust absorption of the line emission originating inside the central R \(\simeq 15\) pc (see Section 3.4). However, in order for the CO emission to decrease in the center relative to the dust emission, the CO must also have a lower optical depth per unit column density of ISM than the dust at \(\lambda = 2.6\) mm. Having the dust be optically thick in the center is not sufficient to produce the central dip; the CO line must be less optically thick than the dust.

In low density Galactic GMCs the CO (1-0) line typically has more than factor 10\(^4\) greater optical depth than the dust at \(\lambda = 2.6\) mm. In the Arp 220 nuclei this ratio is reduced by two orders of magnitude due to the \(~ 100\) times higher gas velocity dispersion and another factor of 20 due to the \(~ 20\) times higher gas temperature (which spreads the CO molecules over more levels). These approximate considerations suggest that the CO (1-0) line will not have a lower optical depth than the dust per unit column of ISM, unless the gas phase abundance of CO relative to dust is reduced by at least a factor 5 – 10 from the standard GMC values.

Lastly, we note that the deficiency of CO emission in the center can’t be attributed to CO self-absorption by foreground low excitation gas along the line of sight to the nuclear region. The CO emission at small radii will be predominantly at high velocities and thus is not coherent with gas close to the systemic velocity outside the nucleus. In Arp 220 East, we do see three narrow absorption features (spatially offset 0.1 to 0.2 ″ from the nucleus) within \(\pm 100\) km s\(^{-1}\) of the systemic velocity; these absorptions are sharp in velocity and never cover more than 20 km s\(^{-1}\) (e.g. Figure 3-lower left).

4.2. CO Elongation in the East Nucleus

In the East nucleus the CO emission is clearly elongated with a major/minor axis ratio $\sim$3:1 (see Figure 4-upper right) and 2:1 from the Gaussian fitting (see Table 2). If the structure is interpreted as an inclined disk, the former axis ratio implies an inclination of 70$^\circ$ to the line of sight. The East nucleus structure is clearly not axisymmetric – the peak in the CO emission is displaced $\sim 0.1''$ NE of the dust continuum peak (coordinate $\Delta \alpha, \Delta \delta = 0, 0$ in Figure 4). There is also $\sim 50\%$ more integrated CO emission luminosity on the NE side than on the SW.

4.3. Major Axis Kinematics

Figure 5 shows the distribution of CO emission and the gas kinematics along the major axes of the West and East nuclei. The central reference position is taken to be the 2.6 mm continuum peak in each nucleus. In both nuclei the velocity gradient extends over approximately 700 km s$^{-1}$. In the West nucleus, this velocity range is seen within $\pm 0.1''$ ($R = 41$ pc) of the center; in the East, it occurs within $\pm 0.4''$ ($R = 165$ pc) of the center. Figure 3 illustrates the contrast in spatial extent of the high velocity emission between the two nuclei comparing the top and bottom panels. The strip maps also clearly show the decrease in line emission on the nuclear peaks at the central velocities. At the same time, the central positions show a very large range of emission velocities: in the West, 4950 to 5700 km s$^{-1}$ and in the East, 5150 to 5700 km s$^{-1}$. This is also seen in the mean spectra for the nuclei shown in Figure 3-lower panels.

5. CO EMISSION DISTRIBUTION AND KINEMATICS

In order to understand the small scale distribution of the CO emission and to place constraints on the gas kinematics, we have modeled each of the two nuclei with rotating disks inclined to the line of sight. This model, including a parametrized rotation curve and gas velocity dispersion, was then fit to the observed CO line profiles on a well-sampled grid (50 mas spacing) in each nucleus, in order to derive the best fit radial distribution of CO line emissivity. This was carried out using the maximum likelihood procedure developed in Scoville et al. (1993) with the modification that emissivities were allowed to be different on the + and - offset sides of the major axis.

The models developed for the high resolution CO (1-0) emission provide acceptable fits to the collection of observed CO (1-0) line profiles with an overall reduced $\chi^2 \sim 4 - 6$ for both disks. The observed and model spectra are shown in Appendix A. This is a good fit, given the simplicity of the model (bi-axisymmetric with a single velocity dispersion and rotation curve). The preliminary modeling results are shown in Figure 6 and summarized in Table 4. They establish the context for the discussion of the physical structure of the disks in Section 5.2.

The noteworthy constraints from the disk line profile modeling are: 1) a central point mass $\sim 8 \times 10^8 M_\odot$ is apparently required in the West nucleus to provide a best fit to the high velocities observed in the center, but no central point mass is required for the East nucleus ($< 10^8 M_\odot$) and 2) the overall dynamical masses are $\sim 1.5 \times 10^9 M_\odot$ at radii less than 80 and 130 pc, respectively. We expect that these parameters may change somewhat when we simultaneously model the other CO transitions and include the lower resolution imaging, but they set a framework for present models. The full modeling with the complete datasets will be presented in Scoville et al. (2017).

5.1. Dynamical Masses

Lastly, we provide a note of caution on the comparison of dynamical masses with the masses determined from the CO and dust line emission. If the dynamical mass is calculated in a simple spherical approximation from $M_{dyn} = r V_{circ}^2 / G$, this mass estimate may be significantly different from that calculated from the observed kinematics assuming a disk mass distribution plus a central point mass.

The mass distribution in the nuclei of Arp 220 is very likely disk-dominated and the spherical approximation is likely to incorrectly estimate the actual mass in such a configuration. We illustrate this with a simple model (similar to Arp 220 East): having a central point mass of $5 \times 10^8 M_\odot$ and a disk of $10^9 M_\odot$ extending between $r = 20$ and 80 pc with a density varying as $r^{-2}$. Figure 7 shows the circular velocity with forces determined properly for a central mass plus the disk. The circular velocity estimated in the spherical approximation (from the enclosed mass at each radius) is also shown for comparison.

The proper estimation (solid curve) and the spherical one (dashed curve) have significantly different $v_{circ}$. The differences are due to the fact that in a thin disk configuration there is significant gravitational attraction in the outward direction by gas at larger radii. We defer a proper comparison of the emission-based mass estimates to a future paper, once we have full flux recovery of the CO and dust emission. The rotation curve shown in Figure 7 is somewhat higher than that in Table 4 – but within the range acceptable given uncertainties in the
Figure 5. Spatial-velocity strip maps along the major axes of Arp 220 East (PA = 50°) and West (PA = 265°). The coordinate offsets are measured relative to the 2.6 mm continuum peaks (see Figure 1). Positive offset coordinate corresponds to the receding (redshifted) side on the major axis; i.e., for the West nucleus, positive offset is to the west and for the East nucleus, positive offset is northeast. Thus, on the West strip map (left panel), the emission at offset = -0.4″ and 5250 km s\(^{-1}\) is emission from the East nucleus coming in, and on the East strip map (right panel), the emission at offset < -0.5″ and 5200 km s\(^{-1}\) is the West nucleus coming in. The contours are labelled with mJy beam\(^{-1}\).

Figure 6. The derived rotation curves, enclosed dynamical mass (in a simple spherical approximation \(M_R = RV_{rot}^2\)) and face-on emissivity distribution (per pc\(^2\) of area projected on the line of sight) as a function of radius are shown the Arp 220 East and West disks as derived from fitting the high resolution line profiles (see text). [The observed total-integrated-flux is the integral of this face-on emissivity corrected for inclination (i.e. multiplied by \(\cos i\)).] A central point mass of \(8 \times 10^8\) \(M_\odot\) is required in the West nucleus and only a limit of \(< 10^8\) \(M_\odot\) in the East nucleus. The CO (1-0) emissivity shown in the right panel is fairly flat with radius, except for the high emissivity central point required in the West nucleus.

inclination angle. In Section 6, we note an added uncertainty with the dynamical mass estimates – that radiation pressure on the dust may also provide substantial pressure support in the disks.

5.2. Physical Structure of the Nuclear Disks

The high resolution imaging presented here provides strong confirmation for the existence of nuclear disk structures in both nuclei of Arp 220 as first suggested by Sakamoto et al. (1999). In the Eastern nucleus the gas and dust emissions are clearly elongated and this elongation lines up with the major axis of the CO velocity gradient. In Arp 220 West, the emission is not so clearly elongated but there is a strong gradient in the CO line velocity at PA \(\sim 265°\). The lack of elongation in the emission distribution is likely due to the fact that the West nucleus is more compact and the kinematics suggest a more face-on inclination (inclination \(i = 30°\), compared to 45° in the East nucleus – Table 4).

These nuclear disks are extraordinary structures with \(\geq 10^8M_\odot\) within radii \(< 50 – 100pc\) and the two nuclei are only \(\sim 412\) pc apart. In the following, we discuss the mean ISM properties in the nuclei, the physical structure of the disks and maintenance of the disks and the energetics of the nuclear sources. At this point, lacking the full datasets, our discussion is qualitative – intended to be illustrative of the physical considerations. The present observations do not recover all of the line and continuum flux from the region since they include only long baseline data and only the \(\lambda \sim 2.6\) mm observations; we anticipate a more thorough analysis when the full observations are completed including CO 2-1 and 3-2 line emissions,
The circular velocities are shown for a mass distribution including a central point-mass (BH) of $5 \times 10^8 M_\odot$, and disk of mass $10^9 M_\odot$ distributed with an $r^{-2}$ density falloff between 20 and 80 pc. The solid curve shows the proper circular velocity obtained by integration over the disk mass distribution, and the dashed curve the spherical approximation, i.e., calculating $v_{circ} = (GM_{BH}/r)^{1/2}$. The dot-dashed curve is the Keplerian rotation curve associated with the central point mass. The dip at 20 pc is due to the net outward attraction in the inner regions of the disk; the cusp at 80 pc is due to there being no such outward attraction disk beyond 80 pc.

Figure 7. The circular velocities are shown for a mass distribution including a central point-mass (BH) of $5 \times 10^8 M_\odot$, and disk of mass $10^9 M_\odot$ distributed with an $r^{-2}$ density falloff between 20 and 80 pc. The solid curve shows the proper circular velocity obtained by integration over the disk mass distribution, and the dashed curve the spherical approximation, i.e., calculating $v_{circ} = (GM_{BH}/r)^{1/2}$. The dot-dashed curve is the Keplerian rotation curve associated with the central point mass. The dip at 20 pc is due to the net outward attraction in the inner regions of the disk; the cusp at 80 pc is due to there being no such outward attraction disk beyond 80 pc.

happily with complete flux recovery. The observations reported in this paper do not include short spacing data and hence they do not recover flux associated with the large scale structures $>0.5''$ or 200 pc.

Lonsdale et al. (2006) report VLBI at 18 cm wavelength and $\sim 1$ pc resolution, detecting 49 point-like sources which they interpret as supernova remnants (SNR). The sources are tightly clustered in the two nuclei – with 75% of the sources in two regions: $0.25 \times 0.15''$ (West nucleus) and $0.3 \times 0.2''$ (East nucleus). In both cases these rectangles are aligned with the PA derived above for the disks. The estimated SN rate is $4 \pm 2$ based on the appearance of new SN between the epochs of the observations. The fact that 22 of the 49 SNR are in the East nucleus and 27 in the West nucleus strongly suggests that the total star formation rates are similar for the two nuclei, i.e. 45% vs 55% and that relatively little SF occurs in the much larger region of Arp 220.

5.3. Summary of Observational Parameters

For the purpose of the numerical evaluations in the discussion below we adopt approximate estimates for the masses, radii and luminosities for Arp 220 – these are meant only for physical perspective in the discussion and are probably uncertain by factors of two or more. For the ISM masses, we adopt $\sim 1.5 \times 10^9 M_\odot$ for each of the Arp 220 disks with their radial extents being 80 and 130 pc for the West and East nuclear disks, respectively (Table 4). The velocity dispersions derived from the line profile fitting are $\sigma_v = \Delta v_{FWHM}/2.3 \simeq 110$ and 50 km s$^{-1}$, respectively; these are of course the 1-dimensional line-of-sight velocity dispersions to be used in the analysis below for the disk vertical equilibrium ($\sigma_{3d} = \sqrt{3}\sigma_{1d}$). In the brighter West nucleus the central point-like concentration has a mass of between $8 \times 10^8$ and $3 \times 10^9 M_\odot$ as derived from the gas kinematics and the dust emission, respectively. Resolution of this discrepancy may be possible with the higher resolution 1.3 mm observations which will allow a better constraint on the kinematics and the true dust temperatures in that source. Below, we adopt $10^9 M_\odot$ for the unresolved mass within $R < 15$ for this extreme concentration.

The total infrared luminosity of Arp 220 is $1.9 \times 10^{12} L_\odot$. Using the mid infrared, high resolution ($\sim 0.4''$) photometry from (Soifer et al. 1999, Table 3) we take the view that the majority of this luminosity arises from the two nuclei, apportioned 2/3 (West) and 1/3 (East) (i.e. 1.2 and $0.6 \times 10^{12} L_\odot$). We caution that these estimates are approximate since the $3 - 24 \mu$m photometry (Soifer et al. 1999) is not at the $\lambda \sim 70 \mu$m far infrared luminosity peak; also the distribution of SNR is more nearly equal for the two nuclei (Lonsdale et al. 2006). Some of the overall luminosity is also likely to originate at larger radii; the above luminosities should therefore be taken as upper limits to the luminosity of each nucleus.

5.4. Disk Structure

The formation of gaseous disk structures in the nuclei of merging galaxies is likely an inevitable result of the gas sinking dissipatively into the central regions more rapidly than the main stellar component of the galaxies. This results in a gaseous bar leading the stellar bar (since the gas has sunk to smaller radii) and the stellar bar then exerts a backwards torque on the gaseous bar to further reduce its rotational angular momentum (see Barnes & Hernquist 1992, 1996). The gas forms a rotating disk since vertical motions are efficiently damped out once the gas becomes concentrated, while the angular momentum is removed on a much longer timescale.

The thickness of the disk is determined by equilibrium between the gravitational forces toward the midplane of the disk and the gas motions in the vertical direction. These gas motions will be damped if two parcels of gas collide; their bulk kinetic energy is then converted to thermal energy in shocks. The high density of the molecular gas ensures that the shocks radiate the post-shock thermal energy very efficiently. The net result is that the kinetic energy associated with vertical motions needed to maintain the thickness of the disk is radiated on a timescale similar to the collision time of the gas parcels. In order to maintain the thickness of the disk and its associated vertical motions on a longer timescale, constant replenishment of the turbulent energy is required.

The typical timescale for collision of gas parcels and the dissipation of the turbulent motions is given by the crossing time of the disk and the fraction of the disk area filled by gas parcels as viewed perpendicular to the disk:

$$\tau_{\text{dis}} = \tau_{\text{cross}}/f_a = 2H/(\sigma_v f_a).$$

Here $H$ is the scale height of the disk and $f_a$ is the areal covering factor of the disk.

5.5. Disk Area Filling

The disk areal covering factor must be of order unity. The observed CO peak brightness temperatures are com-
Figure 8. Left panel: The estimated scale heights of the West and East disks are shown based on Equation 5.6 using the rotation curves shown in Figure 6 and velocity dispersions $\sigma_v(1d) = \Delta v(FWHM)/2.3$ from Table 4, i.e. 1-d velocity dispersions were taken to be 109 and 52 km s$^{-1}$, respectively. Right panel: The disk crossing time scale ($H/\sigma_v(1d)$) which is equivalent to the turbulent dissipation timescale calculated from Equation 4 with $f_a = 1$.

5.6. Disk Thickness

For the nuclear disks we may estimate the disk thickness assuming that the vertical distribution is determined by equilibrium between the gravitational force in the $z$-direction and the observed gas 1-d velocity dispersions ($\sigma_v(1d)$). We consider two cases: 1) where the gas disk mass surface density is much less than that of the stellar disk or spheroid and 2) where the surface density is dominated by the gaseous disk (i.e. a fully self-gravitating disk). The former is appropriate for low-$z$ galactic disks, where the ISM mass is typically 5-10% of the stellar mass. The latter is likely to be most appropriate for high-$z$ galaxies with a large gas mass fraction and the gaseous disks like those in Arp 220 where the gas has been preferentially funneled to the nucleus faster than the stars.

In the non self-gravitating case, the vertical distribution of the gas will have density $\rho = \rho_0 \exp(-z^2/z_0^2)$. If we define the disk thickness ($H$) as the full thickness at which the density has dropped by a factor 1/e, then $H = 2z_0$. For a spherical distribution of stars,

$$H(r) = 2\sqrt{2} \left(\frac{\sigma_v(1d)}{V_{rot}}\right) r.$$  

(5)

For a typical low-$z$ galaxy disk where the stellar distribution is disk-like, the vertical frequency $\nu_z/V_{rot} \sim 3$ and the thickness is reduced by a corresponding factor $\sim 3$.

In a fully self-gravitating gas disk, the vertical distribution is $\rho = \rho_0 \text{sech}^2(z/(2z_0))$ with

$$z_0(r) = \frac{\sigma_v(1d)}{\sqrt{8\pi G \rho_0}}$$

(6)

where $\Sigma_{disk}$ is the mass surface density of the gas disk. For a Mestel disk, $\Sigma_{disk} = V_{rot}^2/(2\pi G r)$ and therefore,

$$z_0(r) = \left(\frac{\sigma_v(1d)}{V_{rot}}\right)^2 r.$$  

(7)

In this the case, the equivalent full thickness at which the density has dropped by 1/e is $H(r) \simeq 4.34 z_0$, i.e.

$$H(r) = 4.34 \left(\frac{\sigma_v(1d)}{V_{rot}}\right)^2 r.$$  

(8)

Figure 8 shows the disk scale thickness ($H$) variation as a function of $r$ for the West and East disks (Table 4), indicating $H$ ranging from 1 to 30 pc at $r < 30$ pc. The disk crossing times (and thus the turbulent dissipation timescales) shown in the right panel of Figure 8 are $10^5$ to $4 \times 10^5$ yrs.

In order to maintain the disk vertical structure and its observed velocity dispersion, it is required that the turbulent energy in the gas motions be replenished on a similar timescale — the sources of this input might include: 1) starburst and AGN power and the momentum associated with their radiation; 2) the pressure support provided by radiation liberated by the turbulence dissipation and 3) the gravitational potential energy released as the gas accretes inward and the potential energy associated with the decaying orbits of the two nuclei. These are discussed and evaluated in Section 5.8.

5.7. Disk Gas Properties

For the masses and radii given above we estimate the mean gas densities in the two disks. From the fitting of the line profiles across the two disks, the best fit model has approximately constant CO line emissivities as a
function of radius outside the central $R = 10$ pc, with the West disk having a factor 2-3 higher mean emissivity compared to the East disk; on the other hand, the East disk has a larger radial extent. We adopt mean disk thickness in the $z$-direction of 10 pc. The mean $H_2$ density (not correcting for He) is then given by:

$$< n_{H_2} > = \frac{M_{\text{disk}}}{4\pi R^2 H m_{H_2}}$$

$$< n_{H_2} > = \frac{10}{10^9 M_\odot} \times 4865 \left( \frac{10 \text{ pc}}{100 \text{ pc}} \right)^2 \text{cm}^{-3}. \quad (9)$$

For the mean thickness of 10 pc and density $n_{H_2} \approx 5000 \text{ cm}^{-3}$, the column density through the disk is $N_{H_2} = 1.5 \times 10^{23} \text{ cm}^{-2}$. Assuming a standard Galactic ISM gas-to-dust ratio $N_{H_2}/A_V = 1.0 \times 10^{21} \text{ cm}^{-2}$ mag$^{-1}$, we find a typical extinction $A_V = 150$ mag. The disks will thus be optically thick to any NIR-UV radiation emitted by young stars formed within the disks.

One final question is the structure of the molecular gas disk is it composed of a smooth gas distribution or discrete clouds (e.g., GMCs, or smaller clouds)? If the observed velocity dispersion $\sigma = 50 - 100 \text{ km s}^{-1}$ is due to internal motions within individual clouds and if these clouds are gravitationally bound, virialized and have uniform density, then their masses are $M_{\text{cloud}} = 5/3 R \sigma_{v, (\text{internal})}^2/G$. If $\sigma_{v, (\text{internal})} = 100 \text{ km s}^{-1}$ and one requires that their density be 10 times the mean disk density ($< n_{H_2} > = 5000 \text{ cm}^{-3}$), their masses must be $\sim 7 \times 10^7 M_\odot$ with radii $= 18$ pc. However, the area covering factor for the disk would then be inadequate ($f_a \sim 0.1$).

For higher density self-gravitating clouds, the area covering factor is even lower. Lower density self-gravitating clouds would be larger, have a more appropriate area covering factor, but then their density contrast would be sufficiently small that one might as well think of the disks as continuous, rather than a cloudy medium. We are thus led to the conclusion that the gas cannot be in discrete clouds but must be a fairly continuous medium (albeit with some clumping) distributed over the disk area.

To summarize - 1) If the gas in indeed relatively smooth (i.e., not in discrete clouds as in the Galactic disk), it must still have highly supersonic motions with Mach number $> 100$. 2) If these motions are not in the form of smoothly varying flows, then the turbulent kinetic energy dissipates on a disk crossing time $\sim 10^3 \text{ yrs}$ (Figure 8-right). 3) The turbulent kinetic energy must then be replenished within the dissipation timescale in order for the structure to last at least one rotation period of the disk. If the disk does not last this minimum time period, we should not expect to see a disk structure with the high velocity dispersion observed. 4) Alternatively, if the motions are in an ordered flow (and therefore less-dissipative), the scale over which the velocity field varies must be smaller than the spatial resolution of our observations $\sim 30$ pc.

A hybrid picture – clouds of dense gas (with low areal covering factor) embedded in a diffuse molecular medium of low column but high enough areal covering factor to account for the CO brightness temperatures – might also be viable. Most of the mass would have to be in the compact, high density clouds, to avoid having the kinetic energy associated with their bulk motion rapidly dissipated by friction as they move through the diffuse medium. In this case, a large reservoir of kinetic energy is stored in the compact clouds which stir up motions in the diffuse medium without dissipating significant kinetic energy. And of course, such clumps might not be long-lived, but rather being formed and then destroyed. Discriminating this hybrid picture from a more continuous model will require high resolution measurements of the brightness temperatures for high excitation emission lines, to assess the areal covering factor of the dense component and rare isotopes of CO to constrain the line optical depths.

5.8. Energy and Momentum Considerations

There are several sources of energy input to the gas which might replenish whatever losses there are in shock fronts: the radiative and mechanical energy and momentum input from the starburst, the gravitational potential energy resulting from shrinking of the two disks, and the final merging of the galaxy nuclei. Taking a characteristic timescale of 1 Myr (which is an upper limit to the dissipation timescale if the motions are dissipative), we may compare these sources.

The total energy in the radiation field associated with $L = 10^{42} L_\odot$ integrated over 1 Myr is $1.1 \times 10^{59}$ ergs. The total energy contained in the motions associated with the observed velocity dispersion $\sigma_v (1d) = 100 \text{ km s}^{-1}$ is $3/2 (M \sigma_v (1d)^2) = 4.5 \times 10^{56}$ ergs for $M_{ISM} = 1.5 \times 10^9 M_\odot$ (the 3 is to convert to 3-d velocity dispersion). The potential energy associated with each disk and with the binary merging galactic nuclei, is larger than that calculated above for the dispersive gas motions by a factor $(V/\sigma_v (3d))^2 \gtrsim 1$, where $V$ is the disk rotation velocity or the relative velocity of the nuclei.

Although the energy in the radiation field is vastly larger than that in the gas motions, it is more appropriate to compare the radiation momentum with that in the gas since the gas motions are more likely to be driven by the radiation pressure than by expansion of hot gas heated by the radiation field.

The radiative momentum input (L/c per unit time) integrated over 1 Myr is $3.7 \times 10^{48} \text{ gr cm sec}^{-1}$; the momentum in the gas is $3 \times 10^{49} \text{ gr cm sec}^{-1}$, i.e. an order of magnitude larger. The momentum input over the same time period from supernovae at a rate $\sim 4 \text{ yr}^{-1}$ (Lonsdale et al. 2006) (assuming 5 $M_\odot$ of ejecta in the momentum conserving phase starting at $v_{exp} \lesssim 1000 \text{ km s}^{-1}$), is $\lesssim 4 \times 10^{48} \text{ gr cm sec}^{-1}$. In summary, we conclude that if the gas motions are in fact dissipated on a disk crossing timescale there is no obvious source for their replenishment short of the large scale gravitational field.

5.9. A Semi-Coherent Disk Wave Pattern

In the last section, we found that there are no known localized sources of energy to replace that which is dissipated on a disk crossing timescale. Here we explore the possibility that the observed velocity dispersion instead reflects the amplitude of ‘coherent’ flows or waves within the disks. The flows must be semi-coherent to re-
duce dissipation. The scale over which these flows must span the full range of velocities ($\sim 2\sigma_v$) must be significantly smaller than the observational resolution of 37 pc. Clearly, this will not avoid all dissipation, since there will be some regions where the flow still has shocks, but in the absence of dispersive motions throughout, the overall dissipation might be reduced an order of magnitude. One possible scenario could be wave motions in the disks generated by the tidal field of the two merging galaxy nuclei – a dumbbell-like potential. The characteristic scale of such gravitational perturbations is $\sim 100$ pc, i.e. much larger than the required 30 pc scale. On the other hand, one expects that the energy input at long wavelengths should decay to smaller wavelengths as in a turbulent cascade.

A gas parcel moving in the $z$ direction perpendicular to the disk will execute harmonic motion relative to the mid plane with the restoring forces being that of the central point mass and the disk mass at lower $z$:

$$F_{\text{central}} = -G \frac{M_c}{r^2} \simeq G M_r \frac{z}{r^2}$$

$$F_{\text{disk}} = -4\pi G \rho z$$

where the disk is assumed to have constant mass density $\rho$ over scale height $H$ at radius $r$, and $M_r$ is the mass interior to $r$ (disk and central mass). The scale length $H$ for the harmonic motion is then

$$H = \frac{2\sigma_v^2}{\omega_c^2 + \omega_d^2}$$

$$\omega_c^2 = \frac{G M_r}{r^3}$$

$$\omega_d^2 = 4\pi G \rho.$$  \hspace{1cm} (11)

These waves would be analogous to gravity waves or alternatively, the structures could be excited by the tightly wrapped spiral patterns excited in late stage mergers by the companion nucleus.

6. RADIATION PRESSURE SUPPORT

As noted in Section 5.1, it might appear difficult to reconcile the mass estimates for ISM within the disks (as well as any central components such as a black hole or compact dust source) with the observed rotation curves assuming circular motions. However, the very high opacity of the dust will mean that there is substantial absorption and reemission of the infrared radiation and, therefore, pressure support from the radiation field, since the dust is very optically thick even at far infrared wavelengths (Scoville 2003; Thompson et al. 2005, 2015).

Assuming a disk geometry with $L_r$ and $M_r$ being the luminosity and mass as a function of radius in the disk, then the condition that inward gravitational forces are balanced by the outward radiation pressure is

$$\frac{L_r\kappa\rho}{c^2 \pi H} = \frac{GM_r\rho}{r^2},$$

implying

$$\frac{L_r}{M_r} = \frac{c^2 \pi H G}{r \kappa}.$$  \hspace{1cm} (12)

where $\kappa$ is the radiation absorption coefficient per unit mass weighted to the effective wavelength of the infrared radiation field at each radius. Using Equation 5.6 for the ratio $H / r$, Equation 6 becomes

$$\frac{L_r}{M_r} = \frac{8.6 \pi c}{\kappa G} \left( \frac{\sigma_v}{V_{\text{rot}}} \right)^2.$$  \hspace{1cm} (13)

Lastly, we require $\kappa$ at the wavelengths of the far infrared radiation in the disks. For the standard ISM gas-to-dust ratio $N_H / A_V = 2 \times 10^{21} \text{cm}^{-2}$, $\kappa_V \simeq 312 \text{cm}^2 \text{gr}^{-1}$ and for $\kappa_{IR} / \kappa_V \sim 1/30$ (Pollack et al. 1994; Scoville 2013; Thompson et al. 2015), $\kappa_{IR} \sim 10 \text{cm}^2 \text{gr}^{-1}$. Equation 6 then becomes

$$\frac{L_r}{M_r} = 312 \left( \frac{\sigma_v}{V_{\text{rot}}} \right)^2 \frac{L_{\odot}}{M_{\odot}}.$$  \hspace{1cm} (14)

For a disk of luminosity of $\sim 5 \times 10^{11} L_{\odot}$ and mass of $\sim 10^8 M_{\odot}$ as in Arp 220, the luminosity-to-mass ratio is $500 L_{\odot} / M_{\odot}$. It is therefore clear that radiation on the dust in the central regions of Arp 220 is likely to be very important in providing significant pressure support against gravity. Of course this also implies that estimates of the dynamical mass from the observed kinematics may substantially underestimate the enclosed masses. In this case, the radiation is providing significant pressure support and thus the circular velocities are smaller than would be needed to support with just the orbital motions.

The analysis above did not allow for the higher escape probability of the IR radiation in the $z$-direction (as opposed to the radial direction). However, the disks are also quite optically thick in the $z$-direction at the wavelengths of the $\sim 100 - 200$ K radiation field, so the escape probability perpendicular to the disks is not high.

7. SUMMARY DISCUSSION

These CO (1-0) and dust continuum observations with ALMA at 90 mas resolution clearly resolve the two nuclei in Arp 220. The two nuclei have rotating disks of radii 80 (West) and 130 pc (East). The West nucleus also has a massive, unresolved dust emission source in its center which is optically thick at $\lambda = 2.6$ mm; the column density of gas in this compact source is $\sim 2 \times 10^{26}$ cm$^{-2}$ assuming the dust has normal ISM dust opacity and abundance. This column corresponds to an incredible $A_V = 10^6$ mag and 1000 gr cm$^{-2}$ – equivalent to a foot thick concrete wall!

Modeling the observed CO emission line profiles is also consistent with rotating disks in each nucleus. The kinematics of the West nucleus suggest a central point mass of $\sim 8 \times 10^8 M_{\odot}$. Typical velocity dispersions in the gas are $\sigma_v / V_{\text{rot}} \sim 3$, indicating disk thicknesses between 1 and 30 pc over the range of radii. The calculated timescales for dissipation of the motions represented in the velocity dispersion is $\sim 10^5$ yrs if these motions are turbulent. Since there does not appear to be a source for renewal of the turbulent energy at this short timescale, we suggest that there may be coherent wave-like motions in the disks. Such motions might be associated with the rapid wrapping of a spiral pattern generated by the close proximity of the nuclei.

One of the most impressive aspects of the structure in the nuclei of Arp 220 is its symmetry and regularity. Despite the fact that this is a very late stage merger of
two galaxy nuclei, now only 400 pc apart, the two disks are symmetric to a factor two in brightness and their kinematics can be modeled reasonably well with axisymmetric rotation curves. This symmetry is likely implying that each of the disks has rotated several revolutions within the timescale over which they significantly change their separations. That is they have had time to relax during the merging process. For both disks, the rotation velocity is 300 km s$^{-1}$ at 50 pc radius, so this rotation period is 1 Myr; the observed symmetry therefore implies a merging timescale $\gtrsim 3$ Myr.

The above is not to say there are no asymmetries or irregularities. On the West nucleus there is a clear deficiency in the emission to the SW of the nucleus, i.e. a break in the ring of peak emission encircling the core. In addition there is also elongation of blue shifted emission to the south of the nucleus (see Figure 4). And in the East nucleus, the line emission peak is displaced $\sim 0.07''$ NE of the continuum peak ($\Delta \alpha, \Delta \delta = 0, 0$ in Figure 4).

To put the Arp 220 structures in perspective, it is useful to compare with the dense gas structures in the center of the Milky Way. There the most massive gas concentrations are the Sgr B2 and Sgr A molecular clouds (each several $10^6$ M$_\odot$ and size $\sim 30$ pc) are separated by over 150 pc. The total molecular gas mass inside 300 pc Galactic radius is $\sim 10^8$ M$_\odot$; thus only a small fraction of the area in the nuclear disk of the Milky Way is covered by dense gas, in contrast to Arp 220 where the areal filling factors are $\sim 1$.

There are several topics we have not discussed here since they are more appropriately treated once we have the full CO (2-1) and (3-2) datasets with both high and low resolution imaging for full flux recovery. These include: a comprehensive assessment and comparison of the masses (derived from line and dust emission and from the kinematics); the environs and interaction of the two nuclei; and an excitation analysis to estimate abundances, densities and temperatures in the gas. All are deferred to our later paper.

We thank Zara Scoville for proof reading the manuscript. This paper makes use of the following ALMA data: ADS/JAO.ALMA# 2015.1.00113.S. ALMA is a partnership of ESO (representing its member states), NSF (USA) and NINS (Japan), together with NRC (Canada) and NSC and ASIAA (Taiwan), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO and NAOJ.

APPENDIX

A. OBSERVED AND MODEL FIT CO SPECTRA

In Figures A1 and A2 we show the observed and model CO spectra sampled on a 50 mas grid for the West and East nuclei. The spectra are shown here so that the reader can see that even at 0.9 mas resolution the CO emission has a large velocity dispersion $\sigma_v = 110$ and 50 km s$^{-1}$ for the West and East nuclei. The appropriateness of the model fit parameters (see Section 5) can be judged by comparison of the blue (observed) and model (red) spectra. The model was a very simple semi-axisymmetric emissivity distribution with a parametrized rotation curve and a single velocity dispersion.
Figure A1. The observed and model spectra (blue and red curves, respectively) are shown for a 50 mas grid centered on Arp 220 West. The legend above each spectrum provides the angular offset.
Figure A2. The observed and model spectra (blue and red curves, respectively) are shown for a 50 mas grid centered on Arp 220 East. The legend above each spectrum provides the angular offset.
