Supplemental Information

Multiplexed Dynamic Imaging of Genomic Loci
by Combined CRISPR Imaging and DNA
Sequential FISH

Yodai Takei, Sheel Shah, Sho Harvey, Lei S. Qi, and Long Cai
MATERIAL AND METHODS

Probe design and synthesis
Telomere 59-nucleotide (nt) probe from Integrated DNA Technology (IDT) was designed with a 35-nt targeting sequence at the 3’ end, a 20-nt adapter sequence for binding of a dye-coupled adapter probe, and a 4-nt spacer in between. Subtelomere probes were designed and generated based on array-based oligopool synthesis with enzymatic amplifications (1,2) explained below.

The mm10 mouse genomic sequence (UCSC Genome Bioinformatics) was used to design subtelomere oligonucleotide probe pools in this study. To selectively label subtelomeric genomic regions, 100 kb regions at the end of each chromosome were selected (Table S1). Across those regions, a set of non-overlapping 35-nt probes were designed which suffice several constraints including 40-60% GC content, no more than 5 contiguous identical nucleotides, no “CCCTAA” or “TTAGGG” sequences to exclude the potential binding to telomeres, and at least 2-nt spaces between adjacent probes. Off targets against the mm10 mouse genome were then evaluated using BLAST+. Sequences with 18 or more contiguous bases homologous to other regions in the genome were defined as an off target here, and probes that contained 6 or more of these off targets were initially eliminated. Probes targeting identical subtelomeric regions were then evaluated together, and if the probe sets contained more than 5 off-targets within 1 Mb blocks of the genome, probes were dropped to lower the threshold. If the probe number in one probe set exceeded 400, probes were reduced up to 400 based on GC content. Note that probe sets targeting sex chromosomes were failed to be designed. In addition, proximal telomeres in each chromosome is located adjacent to satellite
regions in the mouse genome, so these regions were not used for probe designing. As a result, 19 subtelomere probe sets targeting all mouse autosomes were pooled together in this study (Table S1).

At the 5’ end of the 35-nt probe sets, 20-nt adapter sequences, which are identical in each subtelomere probe set but orthogonal among different probe sets, are attached with a 4-nt spacer in-between. For the array-based oligo library synthesis, universal sequences were attached at either 5’ or 3’ ends. Those sequences included KpnI and EcoRI restriction enzyme sites, 3-nt spacers, and 20-nt forward and reverse primer binding sequences. In total, this subtelomere oligonucleotide probe pool (CustomArray) contained 4709 probes with 117 nucleotides each. Single-stranded DNA probes were generated from this array-based oligonucleotide pool with limited cycle PCR, in vitro transcription, reverse transcription, and restriction enzyme digestion of primer binding sites.

**Cell culture and cell line construction**

E14 cells (E14Tg2a.4) from Mutant Mouse Regional Resource Centers were maintained on gelatin-coated dishes at 37°C with 5% CO₂ in Glasgow Minimum Essential Medium (GMEM), 10% FBS (HyClone, Thermo Scientific), 2 mM L-glutamine, 100 units/ml penicillin, 100 μg/ml streptomycin, 1 mM sodium pyruvate, 1000 units/ml Leukemia Inhibitory Factor (LIF, Millipore), 1x Minimum Essential Medium Non-Essential Amino Acids (MEM NEAA, Invitrogen) and 50 μM β-Mercaptoethanol as described previously (3). All constructs used in this study were cloned into PiggyBac vectors. The expression vector for dCas9-EGFP from *Streptococcus pyogenes* was constructed by inserting dCas9-EGFP (pSLQ1658 from Addgene) right after the elongation factor 1 alpha (EF1α) promoter. For the guide RNA expression vector, a mouse U6 promoter and sgRNA targeting telomeres were obtained from pSLQ1651 (Addgene). The vector, which contained EF1α-NLS-HA-NLS-hmKO2 (hmKO2 from Amalgaam), was also constructed and used for cell identification before the live tracking. Transfections were performed with FuGENE HD Transfection Reagent (Promega), and the cells were selected with G418 (Thermo Scientific) and puromycin (Thermo Scientific) sequentially. After the selection, single clones were isolated manually, and stable labeling of telomeres was verified by imaging.

**Live cell imaging**

Cells were plated on fibronectin-coated 24-well glass bottom plates (MatTek) for 2 h, prior to the live imaging. The microscope (Nikon Eclipse Ti-E) was equipped with a CCD camera (Andor iKon-M 934), a 60x oil objective lens (Nikon NA 1.40) and a stage-top incubator held at 37°C. Snapshots of dCas9-EGFP were acquired with 10 μm z-stacks stepping every 0.5 μm at 15 time points over 6 min. Note that each time point shown in the figure and movie was the starting time of the z-stacks. The Perfect Focus system of the microscope was used to automatically correct focus drift during imaging. Image acquisition was controlled with Micro-Manager software.

**DNA FISH hybridization and imaging**

Immediately after the live cell imaging, cells were fixed in 4% formaldehyde for 10 min at room temperature, washed three times with 1x PBS, and imaged in an anti-bleaching buffer
consisting of 20 mM Tris-HCl, 50 mM NaCl, 0.8% glucose, saturated trolox, 0.5 mg/ml glucose oxidase, and catalase at a dilution of 1/1000 (Sigma C3155). Cells were then permeabilized with 70% ethanol at -20 °C overnight. The following day, cells were treated with a prechilled solution of methanol and acetic acid at a 4:1 ratio at room temperature, and then with 0.1 mg/ml RNaseA (Thermo Scientific) for 1 h at 37°C. Samples were then washed and dried with 1x PBS, 70% ethanol and 100% ethanol. The samples were then heated for 10 min at 95°C in 70% formamide and 2x SSC. Cells were hybridized with the telomere and the subtelomere probe pool for 2 days at 37°C, where the final concentration of each probe was estimated as 10 nM in nuclease free water with 50% formamide, 2x SSC and 0.1 g/ml dextran sulfate. After incubation with the probes, cells were washed three times in 50% formamide, 0.1% Triton-X 100 and 2x SSC at room temperature, and hybridized with 20-nt adapter probe sets coupled to Alexa 594, 647 (Lifetech), Cy3B or Cy7 (GE Healthcare) at 10 nM final concentration for at least 1 h at room temperature in nuclease free water with 30% formamide, 2x SSC and 0.1 g/ml dextran sulfate. Cells were washed three times in 30% formamide, 0.1% Triton-X 100 and 2x SSC at room temperature, stained with DAPI and imaged in anti-bleaching buffer.

**Probe displacement and re-hybridization**

Following the imaging, cells were washed with 2x SSC, incubated in 70% formamide and 2x SSC for 30 min at room temperature for probe displacement, and then washed three times with 2x SSC. To check the probe displacement, cells were then imaged with all imaging channels in anti-bleaching buffer. Samples were re-hybridized with another set of adapter probes according to the conditions described above, stained with DAPI again and imaged in anti-bleaching buffer.

Four rounds of hybridizations were carried out in this study. The first three rounds of hybridizations were used to barcode 18 subtelomeric regions, and the final round was used to label telomeres and also to verify the identities of 3 subtelomere barcodes by reading out 3 subtelomeric regions with each region assigned to a single imaging channel.

**Data analysis**

Data analysis was carried out using ImageJ, MATLAB and Python. Each analysis is detailed below.

**Point tracking**

Cells were segmented manually using the ImageJ ROI tool. The background was subtracted from the time-lapse images using ImageJ’s rolling ball background subtraction algorithm with a radius of 3 pixels. This processing was also used for Movie S1. The points for linking in each time point were found in 3D using a LOG filter with subsequent local maxima finding. The threshold for local maxima finding was set using Otsu’s method for the first frame and adjusted slightly for subsequent frames such that the number of dots detected only varied by less than 5%. These points were linked into trajectories using the SimpleTracker function available on the MATLAB file exchange with 'MaxLinkingDistance' set to 5 and 'MaxGapClosing' set to 0. Any trajectory that did not have a point in all frames was discarded. Every point in every remaining trajectory was then fit with a 2D gaussian function using the autoGuassianSurf function available on the MATLAB file exchange to obtain the subpixel location of the point. Each track
was then assigned to a segmented cell. The calculated trajectories were then corrected to remove the motion of the cells and the microscope by subtracting the mean displacement of all points in a cell from each point in the cell for each time point.

For each trajectory, the cumulative square displacement of adjacent frames (CSD) as a function of time was calculated as

\[ CSD(n \delta t) = \sum_{i=1}^{n} \left[ (x((i+1) \delta t) - x(i \delta t))^2 + (y((i+1) \delta t) - y(i \delta t))^2 + (z((i+1) \delta t) - z(i \delta t))^2 \right] \]

where \( n \) is the number of frames, \( \delta t \) is the time interval between two adjacent frames (25 s), \( x(t) \), \( y(t) \) and \( z(t) \) are the coordinates at time \( t \).

**Image processing for barcoding**

Basic flow of the image processing for barcoding followed our recent study (2). To remove the effects of chromatic and spherical aberrations in \( xy \), multispectral beads were first used to create geometric transforms to align all fluorescence channels using MATLAB’s fitgeotrans function. Next, the background illumination profile of every fluorescence channel was mapped using a morphological image opening with a large structuring element on a set of images of an empty coverslip. The median value of every pixel for every channel of opened images was divided by the maximum value to find the division factor of every pixel in every channel. The images were corrected using the resulting intensity map and finally the images were transformed to remove chromatic aberrations. The background signal was then subtracted using the ImageJ rolling ball background subtraction algorithm with a radius of 3 pixels.

**Image registration**

The processed images were registered by first taking a maximum intensity projection along the \( z \) direction in each channel. All of the maximum projections of the channels in a single hybridization were then collapsed, resulting in 3 composite images containing all the points in a particular round of hybridization. Each of these composite images of hybridizations 2-3 were then registered to hybridization 1 using a normalized cross-correlation algorithm with the position of the maxima of the cross-correlation signifying the translation factor to align hybridizations 2-3 to hybridization 1. MATLAB’s normxcorr2 function was used to accomplish this task. Cross-correlation between the DAPI images was used to register the final control hybridization to the barcoding hybridizations.

**Barcode calling**

The potential DNA FISH signals were then found by LOG filtering the registered images and finding points of local maximum pixels above a specified threshold value found by inspection of the accuracy of dots found at a particular threshold value. Once all potential points in all channels in all hybridizations were obtained, dots were matched to potential barcode partners in 3D with all other hybridizations using a \( \sqrt{6} \) pixel search radius (1 or 2 pixel per one direction) to find symmetric nearest neighbors within the given radius. Barcode words were created by seeding the search with points from each hybridization. Point combinations that constructed only a single barcode with a given seed were immediately matched to the on-target barcode.
set. For points that matched to construct multiple barcodes, first the point sets were filtered by calculating the residual spatial distance of each potential barcode point set and only the point sets giving the minimum residuals were used to match to a barcode. If multiple barcodes were still possible, the point was matched to its closest on-target barcode with a hamming distance of 1. If multiple on-target barcodes were still possible, then the point was dropped from the analysis as an ambiguous barcode. This procedure was repeated using each hybridization as a seed for barcode finding and barcode words that were called uniquely in all hybridizations were used in the analysis. The location of these points then signified the corresponding chromosome locations. For the barcode identification analysis in this case, fitting was not performed as the spots were fairly sparse in any given channel and therefore were singly detected and matched.

**Dot matching**

CRISPR labeled dots at the last frame of the movie and after the fixation, subtelomeric dots by DNA seqFISH and telomeric dots by DNA FISH were matched by using the same matching algorithm described in the barcode calling section, with a small difference of using 6 pixels in xy. In addition, subtelomeric dots by DNA seqFISH and subtelomeric dots by single color DNA FISH readouts in hybridization 4 were matched by using the same algorithm with more stringent matching condition of within 3 pixels. Note that cells detected with more than 10 CRISPR labeled spots at the last frame of the movie were further analyzed due to the heterogeneity of CRISPR labeling efficiency in single cells, and only cells within center fields of view were analyzed to minimize the effect of uneven illumination.
Supporting Text

**Number of telomeric and subtelomeric spots**

Based on the cell cycle distribution in a mES cell population, we estimated the detection efficiency of telomeric and subtelomeric spots. Typical cell cycle distribution of mES cells is 20% cells in G1, 50% cells in S and 30% cells in G2/M phase (4). Given the number of chromosomal loci is 2 in G1, 3 in S and 4 in M/S2 phase, the number of spots expected per each region is 3.1 per cell. We observed 33.5 ± 13.8 and 40.6 ± 13.8 (mean ± standard deviation) CRISPR labeled dots per cell in live (last frame of the movie) and fixed cells, which can be estimated as 27.0 ± 11.1% and 32.7 ± 11.1% detection efficiency of telomeric spots. This indicates a relatively low efficiency of labeling in our experiment, which can be improved with further cell line engineering as shown in previous publications. Note that we detected more CRISPR labeled spots in fixed cells compared to those in live cells because of longer imaging exposure time for fixed cells. We also note that we used exposure times that allowed us to track CRISPR labeled loci over time without significant photobleaching. However, we still observed that the number of spots detected above the threshold decreased during the time-lapse movie, because of photobleaching (Fig. S1 A). Similarly, DNA FISH of the telomeres showed 32.5 ± 7.6 dots per nuclei and 26.2 ± 6.1% detection efficiency of telomeric spots. The relatively low colocalization efficiency (49.1%) of telomeric spots by CRISPR labeling and DNA FISH (Fig. S4 B) can be caused by the low labeling efficiencies estimated above.

On the other hand, from our barcoding results, the average number of subtelomeric spots per cell was 1.9 ± 0.5, and the DNA seqFISH efficiency of subtelomeric regions can be estimated as 61.3 ± 16.1%.

**Optical space estimation in nucleus**

Optical space for single-color CRISPR labeling in a single nucleus can be estimated based on our recent study (2). The estimation is calculated as

\[
N = \frac{FV}{(3p)^2Z}
\]

where \(N\) is the maximum number of unambiguous CRISPR labeled spots in a single nucleus, \(F\) is the number of channel used for CRISPR imaging, \(V\) is the volume of a single nucleus in microns, \(p\) μm is the physical size of a pixel and \(Z\) μm is the resolution in the z direction. In our experimental condition, a single nucleus can accommodate at least 1000 CRISPR labeled spots by applying a single fluorescent channel, the physical pixel size 0.3 μm, z resolution 0.5 μm and the volume of mES cell nucleus as 10 μm x 10 μm x 5 μm.

The number of CRISPR labeled spots, which can be uniquely identified by DNA seqFISH in a single nucleus, are reduced with the optical space constraint arising from the incomplete colocalization between two labeling methods. Under such conditions, the estimation is updated as

\[
N_b = \frac{FV}{(rp)^3}
\]

where \(N_b\) is the maximum number of unambiguous CRISPR labeled spots identified by DNA seqFISH in a single nucleus and \(r\) is the maximum searching pixel size per single direction for dot
matching. Given the same assumption above with 5 pixel diameter search, a single nucleus can accommodate around 150 CRISPR labeled spots that can be uniquely identified by DNA seqFISH. Note that the number of uniquely identified loci can be linearly scaled up with the increase of fluorescent channels available for the CRISPR imaging.

</table>

**Table S1:** Subtelomeric region coordinates in mm10 mouse genome, number of primary probes, sequence gap between telomere and targeted subtelomeric region, and barcoding color combinations used in this study. Sequence gap was calculated as the length between distal telomere coordinate annotated and the most adjacent subtelomeric probe in each chromosome. Due to the off targets, chromosome 2 probe set was not included in the DNA seqFISH. Cy3B, Alexa 594, 647 and Cy7 dye coupled adapter probes correspond to the numbers 1, 2, 3 and 4 in the last 4 columns. Finally, 12 subtelomeric regions (chr1, 3, 5, 6, 7, 9, 13, 15, 16, 17, 18 and 19) were read out robustly.
Supporting Figures

**Figure S1**: Number of telomeric spots detected per cell during the movie and their photon counts. (A) Decrease of number of telomeric spots detected per cell during tracking due to photobleaching. The threshold used for ‘CRISPR live cells’ in Figure 2F was used in all time points. The data are displayed as mean ± sem with 28 cells. (B) Distribution of photon counts of detected dCas9-EGFP spots and background spots at the last frame of the movie. The intensity of dCas9-EGFP spots were detected as a maximum intensity within 3x3 pixels, whereas the intensity of background spots were collected after eliminating those 3x3 pixels, and then those intensity were converted to photon counts.
Figure S2: Probe displacement and re-hybridization. (A) Schematic of probe displacement and re-hybridization with two loci. (B, C) From left to right: first round of adapter probe set hybridization, stripped cells after probe displacement with the formamide stripping method, and second round of hybridization containing different adapter probe combinations from the first hybridization in mES cells. All images are maximum intensity projections of a z-stack with Cy3B adapter probe sets, and displayed at two contrast levels (B and C) to show the completeness of stripping.
Figure S3: Comparing single color DNA FISH readouts (hybridization 4) and DNA seqFISH color barcoding (hybridizations 1-3) in mES cells. Images are maximum projections of a z-stack. Boxed regions in the left figure are magnified and corresponding regions in hybridizations 1-4 are displayed. Each color represents Alexa 647 (red), Alexa 594 (green), Cy3B (yellow) and DAPI (blue), respectively. Images with hybridizations 1-3 are digitized based on the barcode calling results. Dots appearing in hybridizations 1-3 images other than the dots colocalized to the hybridization 4 are dots corresponding to other barcodes or nonspecific binding. We observed that with the chromosome 9 subtelomeric region, 78.7% of the single color labeled loci in the fourth hybridization (53 spots analyzed) colocalized with the barcoded loci (53 spots analyzed), whereas with the chromosome 18 subtelomeric region, 73.7% of the single color labeled loci in the fourth hybridization (92 spots analyzed) colocalized with the barcoded loci (75 spots), indicating barcodes decoded efficiently in our experiments. Note that the chromosome 12 subtelomeric region was excluded from this analysis due to the insufficient signal from the Cy7 dye in DNA seqFISH.
Figure S4: Colocalization between telomeric and subtelomeric spots and their distribution in mES cells. (A) Images are maximum intensity projections of a z-stack of fluorescence images corresponding to the fourth hybridization of the DNA seqFISH. The boxed regions are magnified, and telomeric (red) and subtelomeric (green) regions are merged. Note that telomeric and subtelomeric regions do not colocalize perfectly because targeted telomeric regions are non-unique repetitive regions whereas targeted subtelomeric regions are adjacent unique regions over a range of 100 kb. Note that sequence spaces between telomeric and subtelomeric regions are provided in Table S1. (B) Comparing colocalization percentage of spots detected per cell. Red dashed lines represent expected colocalization percentage per cell. (C) Distribution of xy-distance between aligned telomere CRISPR spots, subtelomere DNA seqFISH spots and telomere DNA FISH spots. Mean and standard deviation of the distance under each condition were provided.
**Figure S5**: Number of subtelomeric spots per cell resolved by the color barcoding with three rounds of hybridizations. In total, 678 subtelomeric spots in 28 cells were analyzed. Black circles represent mean number of spots per cell. Due to the low detection efficiencies, 6 subtelomeric regions (chr14, chr11, chr4, chr12, chr8 and chr10) were excluded from the analysis. This could be caused by inefficient binding of primary probe sets or insufficient signal from Cy7 fluorophores as 5 out of those 6 subtelomeric regions contained Cy7 in their code. On average, the number of subtelomeric spots per cell was $1.9 \pm 0.5$ (mean ± standard deviation).
Figure S6: Quantified trajectories of telomeric loci from three additional single cells. (A) In those cells, 26, 23 and 20 trajectories were detected from CRISPR imaging, and 13, 9 and 9 of these trajectories (from left to right) were uniquely assigned to particular chromosomes based on the subtelomere color barcodes. Trajectories of three loci per cell were also highlighted as xy projections (inset). Projected trajectories start from (0.0, 0.0). (B) Cumulative square displacement traces as a function of time. Those traces were obtained from the three single cells shown above. Three projected loci per cell (A inset) were shown as colored traces.
Supporting Movies

Movie S1: Live imaging of telomeres in mES cells using the CRISPR labeling. Cells shown in Fig. 2B are presented. Images are maximum intensity projections of a z-stack of fluorescence images in each frame. Note that cell and stage movements are not calibrated in this movie. Scale bar represents 10 μm.
