Photoluminescence spectroscopy of single InAs quantum dots at cryogenic temperatures (≈14 K) is performed using a micron-scale optical fiber taper waveguide as a near-field optic. A lower bound on the measured collection efficiency of quantum dot spontaneous emission into the fundamental guided mode of the fiber taper is estimated at 0.1%, and spatially resolved measurements with ~600 nm resolution are obtained by varying the taper position with respect to the sample and using the fiber taper for both the pump and collection channels. © 2007 American Institute of Physics. Semiconductor quantum dots (QDs) have drawn significant recent interest due to their potential to create optoelectronic devices such as those that can generate single photons on demand.1 Methods to optically interrogate single QDs include physical isolation via microfabricated mesas2 and diffraction-limited confocal optical microscopy.3 Despite the technical challenges involved in developing tools for use at cryogenic temperatures, solid immersion lenses4 have been implemented to improve the efficiency of light collection, while near-field scanning optical microscopy (NSOM) has been used to achieve sub-100 nm spatial resolution.5 In this letter, we examine the use of optical fiber taper waveguides as a near-field optic for performing single QD spectroscopy. These micron-scale silica waveguides have been used in many studies of optical microcavities, beginning as an efficient coupler to silica microspheres.5 More recently, we have shown that they can effectively probe the spatial and spectral properties of small mode volume (V_{eff}), high refractive index semiconductor cavities.7 Other researchers have proposed8,9 and realized their use as a collection tool for spontaneous emission from atomic vapors.10 Here, we show that a fiber taper may be used to channel emission from single self-assembled QDs embedded in a semiconductor slab directly into a standard single-mode fiber with high efficiency (~0.1%), and to provide submicron spatial resolution of QDs.

The QDs we study consist of a single layer of InAs QDs embedded in an In_{0.15}Ga_{0.85}As quantum well, a so-called dot-in-a-well (DWELL) structure.11 The DWELL layer is grown in the center of a GaAs waveguide (total waveguide thickness of 256 nm), which sits atop a 1.5 μm thick Al_{0.3}Ga_{0.7}As buffer layer. The resulting peak of the ground state emission of the ensemble of QDs is located at λ=1.35 μm at room temperature. To limit the number of optically pumped QDs, microdisk cavities of diameter D=2 μm were fabricated using electron beam lithography and a series of dry and wet etching steps.12 Although the QDs physically reside in a microcavity, they are nonresonant with the cavity whispering gallery modes (WGMs). In other words, our primary interest here is general single QD spectroscopy through the fiber taper, without enhancement through interaction with the high quality factor (Q) microdisk WGMs. The samples were mounted in a continuous-flow liquid He cryostat that has been modified to allow sample probing with optical fiber tapers while being held at cryogenic temperatures (T~14 K), as described in detail in Ref. 13. The cryostat setup provides any combination of free-space and fiber taper pumping and collection [see Fig. 1(a) for details].

The inset of Fig. 1(b) shows the emission spectrum from an ensemble of QDs in one of the microdisks. Here, the device is optically pumped through an objective lens at normal incidence (free-space pumping), with a spot size of 3 μm and wavelength λ_p=830 nm. Clearly present are the ground and excited states (s and p shells) of the ensemble of QDs which, based on the estimated QD density of 300–500 μm^{-2}, consists of ~1000 QDs. To study isolated emission lines from single QDs, we focus on the long-wavelength tail end of the QD distribution (λ=1290–1310 nm). In this range, isolated emission lines from a single QD are seen for a fraction (10%) of the interrogated devices. A typical spectrum as collected through the pump lens (free-space collection) from one such device is shown in the top panel of Fig. 1(b). Under identical pumping conditions, the signal collected through a fiber taper waveguide positioned on top of, and in contact with, the microdisk is shown in the bottom panel of Fig. 1(b). The taper is a single mode optical fiber that has been heated and stretched down to a minimum radius of a=650 nm, and is installed in the customized liquid He cryostat as detailed in Ref. 13. The most stark difference between the free-space and fiber taper collected spectra is the 25 times increase in fiber taper collected power. Similar improvement in collection efficiency was measured over all the QDs studied in this work.

Before further studying the fiber taper as a collection optic, we attempt to identify the different QD lines of Fig. 1(b). Of particular benefit in this assignment is the recent work of Cade et al.,14 who study a DWELL material very similar to that investigated here. In Fig. 2(a), we show taper-collected emission spectra as a function of pump power (free space, λ_p=830 nm) for a fixed taper position. Emission is first seen for incident powers of a few nanowatts (estimated absorbed powers of tens of picowatts), with excitonic...
lines centered at 1291.95, 1300.97, 1301.81, and 1307.75 nm. As we discuss later, spatially resolved measurements clearly indicate that the shortest wavelength emission line is unrelated to the latter three, which we identify as the positively charged exciton $X_b$ (Refs. 14 and 15) and the negatively charged exciton line ($X^-$). As the pump power is increased, additional emission lines appear, including the positively charged exciton ($X^+$) at 1299.87 nm and the biexciton (2X) line at 1305.11 nm. The $X^-X$, $X^+X$, and 2X-X splitting values of 4.6, −1.1, and 3.1 meV values measured in Ref. 14, although the fine structure splitting in the X line is significantly larger (600 versus 300 μeV) for this QD. In Fig. 2(b), we plot the emission level in each QD state against pump power. Below saturation, the emission lines all scale nearly linearly with pump power, except for the 2X line which scales superlinearly. The subquadratic growth rate ($n = 1.54$), consistent with Ref. 14, is related to the reduced QD symmetry that generated the large $X_b - X_b$ splitting. Finally, the temperature (T) dependence of the X lines is shown in Fig. 2(c), where significant broadening is seen for $T > 50$ K. Below this temperature we measure linewidths of 0.1−0.15 nm, roughly corresponding to the spectral resolution of our system (0.1 nm = 75 μeV).

A rough estimate of the absolute collection efficiency of the fiber taper is derived by considering the saturated photon count rates for the X lines in Fig. 2(b). The measured saturated photon count rate into the $X_b$ line is $1.5 \times 10^5$ counts/s, which after considering the detector, taper, and spectrometer grating efficiencies (85%, 80%, and 60%), and including light in the backwards fiber channel, corresponds to a taper-collected photon count rate of $7.4 \times 10^5$ counts/s. Neglecting possible suppression or enhancement of radiation due to the presence of the microdisk, the saturated photon emission rate for InAs QDs is $5\cdots10^5$ counts/s [photon lifetime $\tau = 1\cdots2$ ns (Ref. 1)]. This yields an approximate fiber taper collection efficiency of $\eta = 0.1\%$. It is important to note that this efficiency is for nonresonant collection, and does not correspond to that attainable for QDs resonant with a high-Q microdisk WGM, which one would expect to be much higher due to the Purcell-enhanced emission into a localized cavity mode and the efficient taper-WGM coupling. Finally, our estimate of the saturated photon emission rate neglects fluorescence intermittency due to pumping of dark states of the QD; 0.1% is therefore a minimum bound on $\eta$.

Obtaining a theoretical value for the nonresonant fiber taper collection efficiency is hindered by the complex geometry in which the QD is embedded; however, a coarse estimate can be made by comparison to Refs. 8 and 9. In these works, a spontaneous emission collection efficiency of 20%–50% is estimated for a dipole emitter on the surface of a silica fiber taper of radius $a = 1.4/k_0$ ($k_0$ is the free-space wave number). For our larger fiber taper ($a = 3/k_0$), and for a QD 125 nm away from its surface (corresponding to the middle of the GaAs slab), the theoretical collection efficiency is on the order of 1%. Beyond providing an upper bound on the collection efficiency, the model indicates that we are far from the optimum fiber taper diameter. Comparison with Ref. 9 indicates that an order of magnitude increase in the collection efficiency may be obtained by decreasing the fiber taper radius to $a = 300$ nm, an experimentally realizable value. An additional benefit of using the fiber taper as a near-field collection optic is the potential for spatially resolved measurements. Although the spatial resolution provided by a glass fiber taper is lower than the sub-100 nm level achiev-

(b) log-log plot of the collected emission for the $X_a$ (○), $X_a$ (×), $X^+$ (+), $X^-$ (Δ), 2X (□), and $X^2$ (□) QD states of part (a). The dashed lines are least squares fits to the emission data below saturation, assuming $I = P^n$, where $I$ is the collected photon count rate emitted into a given line and $P$ is the pump power. (c) Linewidth of the QD exciton states $X_a$ and $X_b$ as a function of temperature.](image2)
Spatial selection of QDs may also be realized by resonantly pumping a microdisk WGM. This excites QDs located in the microdisk perimeter, even those that have exciton lines which are significantly detuned spectrally, results in enhanced emission into the microdisk WGMs.

In summary, we have shown that a micron-scale optical fiber taper waveguide, previously demonstrated to be an effective tool for characterization of semiconductor microcavities, can also be used to study single semiconductor quantum dots. As a near-field collection optic, the fiber taper is shown to channel quantum dot light emission directly into a single mode fiber with a high efficiency of 0.1%, and to provide a submicron spatial resolution of QDs. The ability to effectively investigate both microcavities and quantum dots suggests that these fiber tapers can serve as a very versatile tool for studying microphotonic structures, and in particular, for investigations of chip-based cavity QED.

Fig. 3(c) shows the emission spectrum when we pump on resonance with 690 pW of power at the taper input (corresponding to 330 pW of dropped/absorbed power). Emission from the centrally located QD [top scan of Fig. 3(c)] is no longer present, and has been replaced by a pronounced emission peak at $\lambda = 1291.95$ nm, corresponding to the $X'$ line, confirming that this emission is likely due to a QD located in the disk periphery. Another difference in comparison to the nonresonant pumping spectrum is the presence of several broad emission peaks. These peaks are due to emission into relatively low-Q, higher-radial-order WGMs of the microdisk, as confirmed by fiber-taper-based transmission spectroscopy of the cavity with a tunable laser. The source of such background emission into detuned cavity modes is not well understood, but has been observed to occur for even large detunings of 10–20 nm. In this case, it is likely that the preferential excitation of QDs that reside in the microdisk perimeter, even those that have exciton lines which are significantly detuned spectrally, results in enhanced emission into the microdisk WGMs.
