We investigate the propagation of highly nonlinear solitary waves in heterogeneous, periodic granular media using experiments, numerical simulations, and theoretical analysis. We examine periodic arrangements of particles in experiments in which stiffer and heavier beads (stainless steel) are alternated with softer and lighter ones (polytetrafluoroethylene beads). We find good agreement between experiments and numerics in a model with Hertzian interactions between adjacent beads, which in turn agrees very well with a theoretical analysis of the model in the long-wavelength regime that we derive for heterogeneous environments and general bead interactions. Our analysis encompasses previously studied examples as special cases and also provides key insights into the influence of the dimer lattice on the properties (width and propagation speed) of the highly nonlinear wave solutions.

Over the past several years, the highly nonlinear dynamic response of granular materials has drawn increased attention from the scientific community [1–16]. The corresponding theory developed for uniform lattice systems [1] supports the formation of a novel type of wave in materials, setting a paradigm for the design and creation of systems with unprecedented properties. A simple setup for the study of highly nonlinear dynamics in solids is provided by one-dimensional (1D) granular media consisting of chains of interacting spherical particles that deform elastically when they collide. The broad interest in such systems has arisen because they possess qualitatively different features from weakly nonlinear systems. For example, their solitary-wave solutions have a finite support that is independent of their amplitude [1], providing perhaps the most experimentally tractable application of the notion of “compactons” [17]. There have also been several recent studies on the effects of defects (inhomogeneities, particles with different masses, etc.) in such systems, allowing the observation of interesting physical responses such as fragmentation, anomalous reflections, and energy trapping [4–6,8–12,15]. Moreover, chains of granular media have been shown to be highly tunable [1–3] and have the potential to be used in many engineering applications—including shock and energy absorbing layers [9–12], sound focusing devices (tunable acoustic lenses and delay lines), sound absorption layers, and sound scramblers [13,14].

Chains of granular media provide an ideal setting for investigating the interplay between nonlinearities and periodicity. The study of nonlinear oscillator chains has a time-honored history, originating with the Fermi-Pasta-Ulam problem [18–20]. Its applications arise in numerous areas of physics, including coupled waveguide arrays and photorefractive crystals in nonlinear optics [21,22], Bose-Einstein condensates in optical lattices in atomic physics [23], and DNA double-strand dynamics in biophysics [24]. A particular theme that often arises in this context is that of “heterogeneous” versus “uniform” lattices. Here, we focus on the prototypical heterogeneity of “dimers” (i.e., chains of beads made of alternating materials). This topic is of interest to a diverse array of physical settings ranging from ferroelectric perovskites [25,26] and polymers [27] to optical waveguides [28] and cantilever arrays [29]. Chains of beads provide a particularly interesting and versatile setting with which to study such problems because of their strong nonlinearity and the wide range of available material properties (and concomitant tunability) [2,3,10,13,14].

Our aim in the present work is to investigate solitary-wave propagation in chains of granular dimers [30] with experiments, numerical simulations, and theoretical analysis. Some preliminary results on dimer chains are discussed in [1]. In this Rapid Communication, we consider a broad class of configurations consisting of stainless steel–polytetrafluoroethylene (PTFE) [13,14] dimer chains with different periodicities (obtained by varying the number of consecutive steel particles). We report good agreement between experiments and numerics. We also apply a long-wavelength approximation to the nonlinear lattice model to obtain a quasicontinuum nonlinear partial differential equation (PDE) description of the system. Because of the chain lengths and the pulse amplitudes considered in our experimental and numerical analyses, the pulse propagation can be safely assumed to be within the highly nonlinear regime. The effects of gravity in the theoretical analysis have hence been neglected, in accordance with the discussion of [7]. We obtain analytical expressions for wave solutions of the PDE and find good agreement between the widths and propagation speeds of these solutions with those obtained from experiments and numerical simulations.

Young's modulus of the steel striker, and the Poisson ratio 0.3. The steel beads had mass 0.45 g, elastically aligned beads in a delrin guide that contained slots for propagating pulse via force versus time curves and time-of-flight calculations of the pulse speed. Waves were generated by a striker (a 0.45 g stainless steel bead) dropped from various heights. The steel beads had mass 0.45 g, elastic modulus 193 GPa, and Poisson ratio 0.3; and the PTFE beads had mass 0.123 g, elastic modulus 1.46 GPa, and Poisson ratio 0.46. Previous studies of dimer chains considered only materials with similar elastic moduli.

We model a chain of $n$ spherical beads as a 1D lattice with Hertzian interactions between beads [1]:

$$y_j = \frac{A_{j-1,i}}{m_j} \delta_j^{3/2} - \frac{A_{j,i+1}}{m_j} \delta_j^{3/2} + g,$$

$$A_{j,i+1} = \frac{4E_j E_{j+1}(R_j R_{j+1})^{1/2}}{3[E_{j+1}(1 - \nu_j^2) + E_j(1 - \nu_j^{2+1})]},$$

where $y_j$ is the coordinate of the center of the $j$th particle, $j \in \{1, \ldots, n\}$, $\delta_j = \max(y_{j+1} - y_j, 0)$ for $j \in \{1, \ldots, n\}$, $\delta_1 = 0$, $\delta_{n+1} = \max(y_{n+1}, 0)$, $g$ is the gravitational acceleration, $E_j$ is the Young's modulus of the $j$th bead, $y_j$ is its Poisson ratio, $m_j$ is its mass, and $R_j$ is its radius. The particle $j = 1$ represents the steel striker, and the $(n+1)$st particle represents the wall (i.e., an infinite-radius particle that cannot be displaced). The initial velocity of the striker is determined by experiments and all other particles start at rest in their equilibrium positions.

In Fig. 2, we show the good agreement between experimental and numerical results for 1:1 [Figs. 2(a) and 2(b)] and 2:1 [Figs. 2(c) and 2(d)] dimers of steel:PTFE particles. For the 1:1 dimers, the dynamics indicate that the initial excited impulse develops into a solitary wave within the first ten particles of the chain. We also obtain robust pulses for $N$ dimers with $N > 1$ (with $N$ as high as 7 in experiments and as high as 22 in numerics), though the transient dynamics and spatial widths of the developed solitary-like waves are different.

We focus our theoretical analysis on the prototypical 1:1 dimer chain with beads of different masses (denoted $m_1$ and $m_2$). The rescaled equations of motion (without gravity; see the discussion below) can be written [1]

$$m_1u_j = (w_j - u_j)^k - (u_j - w_{j-1})^k,$$

$$m_2w_j = (u_{j+1} - w_j)^k - (w_j - u_j)^k,$$

where $u_j (w_j)$ denotes the displacement of the $j$th sphere of mass $m_1$ ($m_2$). We consider a general power-law interaction to illustrate the comprehensive nature of our approach and use Hertzian contact ($k = 3/2$) to compare our theoretical analysis with our numerical and experimental results.

The distance from $u_j$ to $w_j$ (from $u_j$ to $u_{j+1}$) is $D$ (2D). Using $D$ as a small parameter, we develop a long-wavelength approximation (LWA) by Taylor-expanding Eqs. (2) and (3), for which we express $u_{j+1}$ ($w_{j-1}$) as a function of $u_j$ ($w_j$). The resulting PDEs need to be “homogenized” between the two “species.” To accomplish this, we follow [34], postulating a “consistency condition” between the two fields:

$$w = \lambda(u + b_1Du_x + b_2D^2u_{xx} + b_3D^3u_{xxx} + b_4D^4u_{xxxx} + \cdots).$$

We then self-consistently determine the coefficients $\lambda$ and $b_i$ by demanding that Eqs. (2) and (3) be identical at each
order. The parameter $\lambda$ can take the values 1 (for acoustic excitations) or $-m_1/m_2$ (for optical ones). The nature of our experimental initial conditions generically leads to in-phase waveforms, so we restrict our considerations to $\lambda=1$ hereafter [35]. Considering the ensuing PDE at orders $D^{k3}D^{k+3},$ we find that $b_1=1$, $b_3=m_1/(m_1+m_2)$, $b_3=(2m_1-m_2)/(3(m_1+m_2))$, and $b_3=m_1(m_1-m_2+m_3)/(3(m_1+m_2))$. Observe that these results correctly capture the uniform-chain limit of $m_1=m_2$, for which $w$ should represent the Taylor expansion of radius $D$ around $u$
.

The resulting PDE,

$$u_{\tau\tau}=u_k^{-1}u_{xx}+G_{k3}u^{3}+H_k^{-2}u_{xxx}+I_k^{-1}u_{4x}, \quad (5)$$

has the same form (with different coefficients) as that obtained for uniform chains [1]. In Eq. (5), $\tau=t/(2D^{k+1}/(m_1+m_2)$ is a rescaled time, $G=(2-3k+k^2)m_1^2/[(6(m_1+m_2)^2)]$, $H=2D^2/(k-1)(2m_1^2+m_2/m_3-m_3)/[(6(m_1+m_2)^2)]$, and $l=2D^2/(m_1^2-m_2+m_3^2)/[(6(m_1+m_2)^2)].$ We seek traveling-wave solutions $u=u(\xi)$, with $\xi=x-\nu t$ (and $\nu=dx/d\tau$), and obtain an ordinary differential equation (ODE) for $u_\xi=\nu$. We then change variables with the transformation $\nu=x^2$, where the power $p$ is chosen so that terms proportional to $\nu^p-\nu^2$ disappear in the resulting ODE for $z=z(\xi).$ Finally, we use an integrating factor $\xi^p$, with $a=1-\nu/(p-1)+p/\nu$, to convert the ODE to a tractable form, $z_\xi=\mu x^\nu-\sigma z$, where $\mu=V_s^2/[I(p+a)]$, $\eta=1+p-\nu k$, and $\sigma=1/[I(kp+a)]$. Direct integration then yields

$$u_\xi=\nu=\xi^p=B \cos^{2(k-1)}(\beta \xi), \quad (6)$$

with $B=\mu/[\beta^2(s-1)]^{1/(k-1)}$, $\beta=\sqrt{\sigma}(1-\eta)/2$, and $s=2/(1-\eta)$.

The existence of such a trigonometric solution in the nonlinearly dispersive LWA suggests the possibility of finite-width solutions that consist of a single arc of the profile of Eq. (6), similar to what has been derived for uniform chains [1]. Among the most notable properties of such solutions that are testable both experimentally and numerically are the amplitude-velocity scaling $B=V_s^{2(k-1)}$ (which is similar to the single-species case [1,2]) and the solution width $\pi/\beta$ (which explicitly depends on the mass ratio). We have obtained an analytical expression for the width that is valid for all $k$, but the formula is too lengthy to write explicitly in the general case. The expression for $\beta$ in the case of Hertzian interactions (i.e., $k=3/2$) is

$$\beta=\left((30-8w+8\omega^2)^{-1/2}\sqrt{3(8-5w+5w^2)-\sqrt{4-4w+13\omega^2-18w^3+9w^4}}\right)\times\left\{\left[(1+w)^2(15-4w+4w^2)\right]/(D^2(34-42w+59w^2-34w^3+17w^4+(8-5w-5w^2))\times\left(4-4w+13\omega^2-18w^3+9w^4\right)^{3/2}\right), \right.$$

where $\omega=m_2/m_1$. This result, which is one of the main findings of the present work, generalizes all previously known limiting cases—namely, $m_1=m_2$, for which $\beta=\sqrt{10}/(5D)$ (resulting in pulses extending to $5\pi/\sqrt{10} \approx 5$ sites), and $m_1>m_2$.

FIG. 3. (Color online) Comparison of experiments, numerical simulations, and theory. (a) Scaling of the maximum dynamic (dimensional) force $F_m$ versus (dimensional) propagation speed $V_s$ in a 1:1 stainless steel:PTFE chain. The numerical simulations are shown by the solid curve and the experimental results are shown by points (with error bars). The dashed curve shows the numerical results using the elastic modulus $E=0.6$ GPa for PTFE, the nominal static value reported in most of the literature [13,33]. (b) Evolution of solitary wave width [full width at half maximum (FWHM)] as a function of bead number (also shown as a log-log plot in the inset). The experimental values are shown by solid (green) squares and the numerical values are shown by open (red) circles. (In both cases, we include curves between the points as visual guides.) The theoretical value for the FWHM with $m_1>m_2$ is given by line 1, that for the 1:1 steel:PTFE chain is given by line 2, and that for a homogeneous chain is given by line 3.
wave width (FWHM) as the wave progresses down the chain of beads. As shown in Fig. 3(b), the numerical and experimental results are in good agreement with each other and with the homogenized theory (which should be expected to capture the average of the relevant oscillations). The $F_{\text{num}}$ values in the numerics and experiments alternate from one bead to another because consecutive beads are composed of different materials. As one can see from Fig. 3(b), the average FWHM of the dimer is decidedly different from that of a homogeneous chain ($m_1 = m_2$) even from that of the $m_1 \gg m_2$ limiting case. It is best captured by the theoretical calculation above (for the proper ratio of masses), clearly evincing the relevance of our theoretical approach. As a quantitative measure, the relative error of the theoretical prediction versus the computational-average FWHM is 22.8% for $m_1 = m_2$, 9.2% for $m_1 \gg m_2$, and 2.5% for the relevant mass ratio. In conjunction with the theoretical analysis developed in this paper, our experiments and numerics reveal that the equilibrium conditions (in a horizontal chain) for the wave width are achieved even at very short propagation distances (i.e., with a very small number of beads). For vertical chains of beads that contain a large number of particles (several hundred or more) or are excited by smaller-amplitude pulses, the presence of the nonuniform gravitational precompression should be taken into account. As discussed in [7], this leads to a 1/3 power-law scaling in the wave width as a function of particle number.

In conclusion, we examined the propagation of solitary waves in heterogeneous, periodic chains of granular media with experiments, numerical simulations, and theory. Using different periodicities, we found that such heterogeneous systems robustly support the formation and propagation of highly localized nonlinear solitary waves (with appropriate widths that depend on the periodicity). We used force-velocity scaling (which is the same as for homogeneous chains) and solitary-wave width (which depends on the mass ratio of the dimer materials) as relevant benchmarks for the good agreement among our three approaches. This qualitative and quantitative understanding of the dimer dynamics also paves the way for studies in increasingly heterogeneous media (e.g., trimers) in both one and higher dimensions, as well as of more complex (optical) modes in such systems.

[33] www.dupont.com/teflon/chemical/
[35] To investigate optical excitations, it would be necessary to employ a fundamentally different and more complex framework involving a single precompressed bead and excitations of prescribed frequency in the corresponding linear-spectrum gap of such a setting.
