Abstract

Serpentinization is a weathering process in which ultramafic rocks react with water, generating a range of products, including serpentine and other minerals, in addition to H₂ and low-molecular-weight hydrocarbons that are capable of sustaining microbial life. Lipid biomarker analyses of serpentinite-hosted ecosystems hold promise as tools for investigating microbial activity in ancient Earth environments and other terrestrial planets such as Mars because lipids have the potential for longer term preservation relative to DNA, proteins, and other more labile organic molecules. Here, we report the first lipid biomarker record of microbial activity in the mantle section of the Samail Ophiolite, in the Sultanate of Oman, a site undergoing active serpentinization. We detected isoprenoidal (archaeal) and branched (bacterial) glycerol dialkyl glycerol tetraether (GDGT) lipids, including those with 0–3 cyclopentane moieties, and crenarchaeol, an isoprenoidal GDGT containing four cyclopentane and one cyclohexane moieties, as well as monoether lipids and fatty acids indicative of sulfate-reducing bacteria. Comparison of our geochemical data and 16S rRNA data from the Samail Ophiolite with those from other serpentinite-hosted sites identifies the existence of a common core serpentinization microbiome. In light of these findings, we also discuss the preservation potential of serpentinite lipid biomarker assemblages on Earth and Mars. Continuing investigations of the Samail Ophiolite and other terrestrial analogues will enhance our understanding of microbial habitability and diversity in serpentinite-hosted environments on Earth and elsewhere in the Solar System. Key Words: Lipid biomarkers—Ophiolite—Serpentinization, Biosignatures—Mars. *Astrobiology* 20, 830–845.

1. Introduction

THE SEARCH FOR biosignatures on Mars and other terrestrial planets is aided by investigations of analog environments on Earth. Modern serpentinite-hosted ecosystems include both continental and marine settings, such as the Samail Ophiolite in the Sultanate of Oman (Miller *et al.*, 2016; Canovas *et al.*, 2017; Rempfert *et al.*, 2017), the Tablelands Complex Ophiolite in Canada (Brazelton *et al.*, 2012), and the Lost City Hydrothermal Field (LCHF) near the mid-Atlantic Oceanic Ridge (Kelley *et al.*, 2005; Brazelton *et al.*, 2006). These ecosystems are of significant scientific

interest because serpentinization reactions are capable of supporting microbial metabolisms, and they are proposed to have played an important role in the origin and development of microbial life on Earth (Sleep *et al.*, 2004; Schulte *et al.*, 2006; Martin *et al.*, 2008; Russell *et al.*, 2010; McCollom and Seewald, 2013; Schrenk *et al.*, 2013; Greenberger *et al.*, 2015).

Serpentinization has long been hypothesized to occur on terrestrial planets, moons, and other celestial bodies throughout the Solar System (Holm *et al.*, 2015). Most recently, a suite of minerals, including serpentine, Mg-carbonate, talc, and saponite, was detected on Mars by orbital spectral

imaging, and this suggests the occurrence of ancient serpentinization processes there (Ehlmann *et al.*, 2009, 2010; Amador *et al.*, 2017, 2018). Amador *et al.* (2018) used data from the Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) to investigate the distribution of these minerals and olivine across the martian surface and near surface; several locations in the southern highlands, such as Nili Fossae, Mawrth Vallis, and Leighton Crater, were deemed regions of interest, but relationships between serpentine and ultramafic bedrock were only identified at Nili Fossae (Ehlmann *et al.*, 2010; Amador *et al.*, 2018). Nevertheless, the detection of serpentine exposures in the martian southern highlands suggests that serpentinization was likely a widespread process on early Mars (Ehlmann *et al.*, 2010).

As we continue to explore the martian surface and subsurface with the current rover, Curiosity, and on future missions, it will be critical to determine whether and how serpentinite-hosted sites promote habitability and the preservation of biological signatures. These investigations can also inform decisions regarding the selection of future rover landing sites, as well as samples for return to Earth.

1.1. Life fueled by serpentinization

Serpentinization is a low-temperature, metamorphic process in which mafic and ultramafic rocks undergo hydrous alteration. During this reaction, reduced iron in olivine and pyroxene is oxidized through the reduction of water to produce serpentine and other minerals, as well as high concentrations of H₂ and low-molecular-weight hydrocarbons (Neal and Stanger, 1983; Frost, 1985; Klein and Bach, 2009; Klein *et al.*, 2009; McCollom and Bach, 2009; Miller *et al.*, 2017; Mayhew *et al.*, 2018), as in the following simplified reactions (Eqs. 1 and 2):

Despite the high alkalinity and low inorganic carbon concentrations that are common in serpentinite-hosted ecosystems, the products of serpentinization reactions—H₂ and methane—can provide substrates to sustain aerobic and anaerobic microbial metabolisms (McCollom and Seewald, 2013; Schrenk *et al.*, 2013). Moreover, the reducing conditions that result from serpentinization can facilitate the microbial reduction of sulfate, which, in this case, uses hydrogen as an electron donor (Schrenk *et al.*, 2013).

Metagenomic analyses of samples collected from a suite of modern serpentinite-hosted ecosystems on Earth point to the existence of a common core serpentinization microbiome (Woycheese *et al.*, 2015). Clostridia, Bacteroidetes, and Betaproteobacteria are commonly found in serpentinite-hosted ecosystems (Daae *et al.*, 2013; Suzuki *et al.*, 2013;

Tiago and Veríssimo, 2013; Quéméneur *et al.*, 2015; Woycheese *et al.*, 2015; Brazelton *et al.*, 2017) and *Methanobacterium*, a methane-producing genus of archaea, is also frequently reported (Quéméneur *et al.*, 2015; Woycheese *et al.*, 2015; Brazelton *et al.*, 2017). These findings, taken together with biological and biomolecular evidence, including the determination of isolate physiologies and transcriptomic and/or proteomic data (Canovas *et al.*, 2017), suggest an association of microbial metabolisms such as hydrogen oxidation, sulfur cycling, methanotrophy, and methanogenesis with serpentinization processes (Woycheese *et al.*, 2015).

Lipid biomarkers afford additional information regarding the microbial community composition at serpentinite-hosted sites because they typically reflect organic matter produced over a longer window of time relative to “snapshot” genetic surveys and can, thus, represent a cumulative record of biomass over time (Simoneit *et al.*, 1998). The longevity of bacterial DNA is on the order of a few million years at most (Willerslev *et al.*, 2004). Although the longevity of lipid biomarkers in serpentinite-hosted ecosystems has not been reported, these lipids can be sustained in carbonates (or carbonate-bearing sediments) for hundreds of millions of years or longer (Love *et al.*, 2009; Saito *et al.*, 2015, 2017). To identify the diversity of lipid biomarkers in serpentinite-hosted ecosystems on Earth, several studies have recorded their distribution in marine hydrothermal systems and terrestrial seeps (Table 1) (Simoneit *et al.*, 2004; Bradley *et al.*, 2009a, 2009b; Méhay *et al.*, 2013; Zwicker *et al.*, 2018). For example, at the LCHF, the presence of archaeal glycerol dialkyl glycerol tetraethers (GDGTs) suggests the presence of Thaumarchaeota and Marine Group I–III archaea (Lincoln *et al.*, 2013). The detection of archaeol in both active and inactive vents at the LCHF may suggest the presence of methanogenic archaea (Bradley *et al.*, 2009b). Furthermore, the detection of glycerol mono- and diethers at the LCHF suggests the presence of sulfate-reducing bacteria (Bradley *et al.*, 2009a, 2009b). The microbial community composition of the LCHF, as inferred from lipid assemblages, is largely consistent with DNA-based taxonomy (Kelley *et al.*, 2005; Brazelton *et al.*, 2006, 2012; Bradley *et al.*, 2009a, 2009b; Lincoln *et al.*, 2013).

1.2. The Samail Ophiolite

One of the largest (>10,000 km²), best exposed, and most widely studied serpentinite-hosted ecosystems on Earth is the mantle section of the Samail Ophiolite, located in the Hajar Mountains in the Sultanate of Oman and the United Arab Emirates (Glennie *et al.*, 1974; Coleman and Hopson, 1981; Nicolas *et al.*, 2000). This ophiolite, which formed ~96–93 Ma (Tilton *et al.*, 1991; Rioux *et al.*, 2012, 2013, 2016), and was obducted onto the Arabian continental margin in the late Cretaceous (Coleman, 1981; Hacker, 1994; Rioux *et al.*, 2016), contains a peridotite mantle composed primarily of olivine, orthopyroxene, and serpentine (Boudier and Coleman, 1981; Godard *et al.*, 2000, 2003; Monnier *et al.*, 2006; Tamura and Arai, 2006; Hanghøj *et al.*, 2010). Low-temperature alteration of the peridotite, through interactions with groundwater and/or atmospheric CO₂, has led to the precipitation of carbonate veins within the ophiolite’s bedrock and calcite-rich

TABLE 1. CURRENT RECORD OF LIPIDS IDENTIFIED IN SERPENTINITE-HOSTED ECOSYSTEMS, PROBABLE SOURCE MICROBES, AND ASSOCIATED MICROBIAL METABOLISMS

Lipids recorded in Samail Ophiolite samples	Lipids reported at the LCHF ^a	Lipids reported at the Chimaera Ophiolite ^b	Lipids reported at the Rainbow Field ^c	Probable source microbes for lipids ^d	Associated processes/environmental significance ^d
Isoprenoidal GDGTs 0–4	+			Anaerobic methanotrophic archaea (but also Crenarchaeota, Thaumarchaeota, and methanogenic archaea)	Methanotrophy
Crenarchaeol	+			Thaumarchaeota (e.g., Nitrososphaerales)	Nitrification
Archaeol	+	+		Methanogenic archaea (e.g., <i>Methanobacterium</i>)	Methanogenesis
Branched GDGTs	+			Soil microbes (e.g., Acidobacteria), unknown sources	Unknown
Glycerol monoethers (MAGE)	+	+		Sulfate-reducing bacteria (e.g., Firmicutes, <i>Thermodesulfovibrionaceae</i>)	Sulfate reduction
Fatty acids	+		+	Sulfate-reducing bacteria (e.g., Firmicutes, <i>Thermodesulfovibrionaceae</i>)	Sulfate reduction
1,2-Alkyl diols				Nonmarine alkaliphilic bacteria	Thermal/alkaline environments

(+) denotes lipid is present at serpentinite-hosted ecosystem; blank spaces denote lipid was not measured and/or discussed in the literature.

GDGT, glycerol dialkyl glycerol tetraether; LCHF, Lost City Hydrothermal Field; MAGE, monoalkyl glycerol monoethers.

travertines at its surface (Neal and Stanger, 1983, 1985; Clark and Fontes, 1990; Kelemen and Matter, 2008; Kelemen *et al.*, 2011); ¹⁴C dating and stable C and O isotopic analyses suggest that these alteration products formed within the past 50,000 years (Kelemen and Matter, 2008; Mervine *et al.*, 2014).

At the ophiolite, active serpentinization is inferred from alkaline fluid seeps and wells (pH 11–12, fO₂ < 10^{−75} bar) (Barnes *et al.*, 1978; Neal and Stanger, 1983; Kelemen *et al.*, 2018) containing high concentrations of Ca²⁺, H₂, and CH₄ [≤2.18 mM, ≤321.27 μM, and ≤131.62 μM, respectively, Canovas *et al.* (2017); see also Schrenk *et al.* (2013); Paukert Vankeuren *et al.* (2019)], and low concentrations of dissolved inorganic carbon (≤5.17 mM) (Canovas *et al.*, 2017). Host rocks have gradients in vein area and vein type related to the current erosional surface, indicative of ongoing weathering, and they contain highly reduced Fe–Ni–Cu–S minerals preserving fO₂ < 10^{−70} bar, consistent with the composition of present-day borehole fluids (Lorand, 1988; Eslami *et al.*, 2018; Kelemen *et al.*, 2018). All of these characteristics are consistent with geochemical models of serpentinization (Barnes *et al.*, 1978; Bruni *et al.*, 2002; Paukert *et al.*, 2012), and with the inference that serpentinization is ongoing.

To date, only a few studies have investigated microbial diversity at the Samail Ophiolite (e.g., Bath *et al.*, 1987; Miller *et al.*, 2016; Rempfert *et al.*, 2017; Fones *et al.*, 2019). Miller *et al.* (2016) collected samples from wells drilled into peridotite in the mantle section of the ophiolite and found 16S rDNA evidence for the presence of sulfate reducing taxa (e.g., *Meiothermus* and *Thermodesulfovibrionaceae*), methane-producing archaea (e.g.,

Methanobacterium sp.), and methane oxidizing bacteria (e.g., *Methylococcales*). Despite the utility of molecular biogeochemical research, there has been limited investigation of the lipid biomarker record at terrestrial serpentinite-hosted sites.

In this study, we investigate the lipid biomarker record from the carbonate veins and travertines at the Samail Ophiolite in Oman. Based on lipid biomarker assessments from the LCHF and other serpentinite-hosted ecosystems (Bradley *et al.*, 2009a, 2009b; Zwicker *et al.*, 2018), we expected to find a similarly diverse lipidome at the Samail Ophiolite. Specifically, we report distributions of membrane-spanning isoprenoidal (archaeal) and branched (bacterial) GDGTs, as well as monoalkyl glycerol monoethers (MAGE) and fatty acids, considered to be derived from sulfate-reducing bacteria.

2. Materials and Methods

2.1. Sample collection, preparation, and X-ray diffraction

Samples were collected in 2012 from vein carbonates, travertines, and host rocks in the Samail Ophiolite in the Oman mountains, located in the Sultanate of Oman (Fig. 1, Table 2, and Supplementary Fig. S1). These were broken from outcrops with a hammer, untouched, and double wrapped in aluminum foil at each site of sampling to minimize contamination. In the laboratory, samples were first cleaned with deionized water and ground into a fine powder with a puck and mill. The mineral composition of each sample was evaluated by powdered X-ray diffraction (XRD) analysis on a PANalytical X'Pert Pro XRPD (PANalytical,

FIG. 1. Samail Ophiolite field locations (stars), where samples G2–G14 were collected. Map was generated using ArcGIS Online. Sources: Esri, HERE, Garmin, FAO, NOAA, USGS. HERE, HERE Technologies; FAO, Food and Agriculture Organization; NOAA, National Oceanic and Atmospheric Administration; USGS, United States Geological Survey.

Almelo, the Netherlands) at the Center for Materials Science and Engineering at MIT (Cambridge, MA). XRD spectra were collected from 5° to 90° and analyzed with the computer software program HighScore Plus (Malvern Panalytical, Malvern, United Kingdom). Samples were categorized into subsets A and B, according to mineral composition and biomarker distribution (see Section 3).

2.2. Lipid extraction

Before solvent extraction, powdered samples were spiked with 1 µg of the following quantification standards: 3-methylheicosane and epiandrosterone. All samples were ultrasonically extracted three times with dichloromethane (DCM):methanol (MeOH), 9:1 (v/v). Samples were then

TABLE 2. LIST OF SAMAIL OPHIOLITE SAMPLES COLLECTED AND ANALYZED WITH CORRESPONDING SITE DESCRIPTIONS AND GPS UTM COORDINATES

Sample subset	Sample name	Sample description	Carbonate phase(s) present ^a	GPS coordinates (WGS84, UTM zone 40)	
				Easting	Northing
Subset A	G2	Layered carbonate ~20 cm above ultramafic contact	Aragonite, calcite, dolomite	0608435	2525955
	G3	Carbonate at ultramafic contact	Calcite, dolomite	0608435	2525955

centrifuged at 3,000 rpm for 30 min, and extracts from each sample were combined and concentrated to a small volume (<1 mL) by using N₂. The total lipid extract (TLE) was then passed through filter columns (containing combusted sodium sulfate and sand) to remove particulate impurities. Copper pellets (activated with 12N HCl, neutralized with DCM-washed water, and then washed 3× with MeOH, DCM, and hexane) were added to the TLEs and left overnight to facilitate the removal of elemental sulfur. The TLEs were filtered through a second pipette column packed with quartz wool and transferred to 2 mL GC vials with inserts. Due to limited sample volume and low lipid recovery for some samples, compound-specific isotopic analyses were not performed.

2.3. Gas chromatography–mass spectrometry

An aliquot (33.3%) of each TLE was transferred into a 2-mL vial, dried with N₂, and finally derivatized with 50 µL *N,O*-bis(trimethylsilyl) trifluoro-acetamide (BSTFA +1% trimethylchlorosilane) and 50 µL pyridine at 60°C for 30 min. A total of 1 µL aliquots were injected in splitless mode to an Agilent 7890A gas chromatograph coupled to an Agilent 5975C mass spectrometer (GC–MS). Separation of compounds was achieved by using a DB5-MS capillary column (60 m×0.25 mm, 0.25 µm film thickness; Agilent, Santa Clara, CA). Initial temperature of the column was set to 70°C, followed by a ramp of 10°C/min until a maximum oven temperature of 325°C was reached. Concentrations of fatty acids and alkyl diols were determined by using the internal standard, 3-methylheneicosane; concentrations of MAGE were determined by using the internal standard, epiandrosterone. Additional rock material from samples G11 and G13 was solvent extracted, using the same methods as described in section 2.2, and the positions of fatty acid unsaturations were determined by dimethyl disulfide adduction (see Nichols *et al.*, 1986; O'Reilly *et al.*, 2017, their supporting methods).

2.4. High-performance liquid chromatography

One-third of each TLE sample was analyzed with high-performance liquid chromatography–MS on an Agilent 1260 Infinity series LC coupled to a 6130 quadrupole mass spectrometer via an atmospheric pressure chemical ionization (APCI) interface in positive mode. Samples were measured by selected ion monitoring (SIM) and separated with two Acquity UPLC BEH HILIC Amide columns (2.1×150 mm, 1.7 µm; Waters, Milford, MA) maintained at 50°C. The method was adapted from the work of Becker *et al.* (2013), and the sample injection volume was 10 µL. Using a constant flow rate of 0.5 mL/min, we eluted the samples with a solvent gradient program of a linear change from 3% B to 20% B in 20 min, then a linear increase to 50% B at 35 min, and a linear increase to 100% B at 45 min, holding for 6 min, and then a decrease to 3% B for 9 min to re-equilibrate the column, where A was *n*-hexane and B was *n*-hexane/isopropanol (90:10). APCI source conditions were positive ion mode, drying gas (N₂) temperature 350°C, vaporizer temperature 380°C, drying gas flow rate 6 L/min, nebulizer gas (N₂) pressure 30 psi, capillary voltage 2000 V, and corona current 5 µA. GDGTs were detected by both full scans and SIM, and they were

quantified by [M+H]⁺ (where M is the molecular ion) with an extraction window of individual ion chromatograms. Samples were spiked with C₄₆ GTGT (glycerol trialkyl glycerol tetraether) to determine the concentration of GDGTs (Huguet *et al.*, 2006).

3. Results

3.1. Carbonate mineralogy

XRD analyses were conducted to determine the mineral composition of the Samail Ophiolite samples. Layered carbonate and travertine samples (G2, G3, and G7) were composed of magnesian calcite (Table 2 and Supplementary Fig. S2), and samples G2 and G3 also contained aragonite and/or dolomite. Magnesite was found exclusively in vein samples (G11 and G13), which were also composed of magnesian calcite and aragonite; dolomite was also present in sample G13. Host rock samples (G12 and G14) contained either calcite or dolomite (Table 2). See Supplementary Fig. S2 for a list of all minerals found in Samail Ophiolite samples.

3.2. Isoprenoidal glycerol tetraethers

Isoprenoidal GDGTs (iGDGTs; see Fig. 2 for lipid structures), which include GDGTs 0–4 with 0 to 4 moieties, and crenarchaeol (and its putative regio-isomer) with four cyclopentane moieties and one cyclohexane moiety were found in all solvent extracted samples, with the highest concentrations measured at 2 ng/g of dried rock (Fig. 3 and Supplementary Table S1). We categorize our samples into two main groups, based on ratios of GDGT-0/crenarchaeol: GDGT-0 was the dominant iGDGT in all subset A samples (G2, G3, and G7), which is reflected by high ratios of GDGT-0/crenarchaeol (1.3–5.0; Fig. 3, Supplementary Fig. S3, and Supplementary Table S1). In contrast, crenarchaeol was the dominant iGDGT in all subset B samples (G11, G12, G13, and G14), with comparatively lower ratios of GDGT-0/crenarchaeol (<1, Fig. 3, Supplementary Fig. S3, and Supplementary Table S1).

3.3. Branched glycerol tetraethers

Branched GDGTs (brGDGTs; see Fig. 2 for lipid structures) were present in all samples and included brGDGTs I, II, and III, which contain methyl substituents and no cyclopentane moieties, and brGDGTs Ib–IIb, and Ic–IIc with one or two cyclopentane moieties, respectively, and their methylated substituents. Concentrations of brGDGTs ranged up to 10 ng/g of dried rock, and brGDGT I, II, and III were the most highly concentrated in all samples relative to brGDGTs with cyclopentane substituents (Fig. 3 and Supplementary Table S1).

3.4. Archaeol

Archaeol, an isoprenoidal diether lipid (see Fig. 2 for lipid structure), was also present in all samples with the exception of G14. This lipid had the highest concentrations in subset A samples (40, 1, and 1 ng/g of dried rock in G2, G3, and G7, respectively) relative to subset B samples (<1 ng/g of dried rock in G11, G12, and G13) (Fig. 3 and Supplementary Table S1).

FIG. 2. Structures of lipid biomarkers detected at the Samail Ophiolite and discussed in the text. Isoprenoidal and branched tetra- and diether lipids are shown, as well as representative structures of a derivatized monoether, fatty acid, and alkyl diol.

3.5. Monoalkyl glycerol monoethers

Samples G2 through G13 contained a suite of MAGE lipids (see Fig. 2 for representative lipid structure) with C_{15} through C_{18} straight-chain, branched, and monosaturated hydrocarbons. MAGE were identified based on the characteristic base peak at m/z 205, which is produced from cleavage between C1 and C2 of the glycerol for trimethylsilyl (TMS) ether derivatives. Other characteristic ions include m/z 117, 147, 130, 133, $[M-15]^+$, $[M-90]^+$, and $[M-103]^+$ (Hernandez-Sanchez *et al.*, 2014; Grossi *et al.*, 2015; Wang and Xu, 2016). MAGE isomers were also identified according to the characteristic elution orders for

saturated, monounsaturated, and methyl-branched isomers on nonpolar GC columns. $C_{16:0}$ and $C_{18:0}$ MAGE were most abundant throughout all samples, ranging in mass up to 13 and 11 ng of lipid/g of dried rock, respectively (found in sample G13; Supplementary Table S2).

3.6. Fatty acids

Unesterified fatty acids (see Fig. 2 for representative lipid structure) were present in all samples, and they were identified as TMS derivatives with a characteristic fragment ion at m/z 117, as well as by comparison to the NIST database

FIG. 3. iGDGT, brGDGT, and archaeol concentrations in (A) subset A (G2–G7) and (B) subset B (G11–G14) Samail Ophiolite samples. GDGT, glycerol dialkyl glycerol tetraether; brGDGT, branched GDGT; iGDGT, isoprenoidal GDGT.

(National Institute of Standards and Technology, Gaithersburg, MD). Positions of fatty acid unsaturation were identified for samples G11 and G13 (see Section 2), and the locations of unsaturation for the other samples were determined by comparison of relative retention times. Samples G2 and G13 contained the greatest abundance and most diverse suite of fatty acids per gram of dried rock (*i.e.*, C₁₀

through C₃₀ saturated, unsaturated, branched, and straight-chain fatty acids) relative to the other samples (Supplementary Table S3). Concentrations of fatty acids ranged from below detection to 299 ng/g of dried rock (Supplementary Table S3). Across all samples, C₁₆ and C₁₈ straight-chain saturated fatty acids were the most abundant, ranging up to 222 and 147 ng/g of dried rock, respectively

(for sample G13; Supplementary Table S3). Methyl-branched fatty acids were identified in all samples with the exception of G14, but they were only detected in appreciable amounts in G2, G11, and G13 (Supplementary Table S3). Carbon chain lengths ranged from 10 to 25 and the most commonly identified branching positions were at the iso (ω -1) and anteiso (ω -2) positions. Mono-unsaturated fatty acids were detected in trace amounts in all samples apart from G13. The major monounsaturated fatty acids were C₁₆ and C₁₈ with ω 9 and ω 7 unsaturations (Supplementary Table S3).

3.7. Alkyl diols

A series of 1,2-alkyl diols (see Fig. 2 for representative lipid structure) were detected in the Samail Ophiolite samples and identified by comparison with published spectra (Zeng *et al.*, 1992; Wait *et al.*, 1997) (Supplementary Table S4). Carbon chain lengths ranged from 18 to 20, and hydroxyl moieties were located at positions 1 and 2 on the carbon chain. All 1,2-alkyl diols contained methyl branches that were likely at the 2- and 3-positions (Wait *et al.*, 1997) but, in the absence of authentic standards, could not be established with certainty. The overall highest concentrations of 1,2-alkyl diols were found in samples G11 and G13, with values ranging in each sample from 2 to 12 and 9 to 48 ng/g of dried rock, respectively (Supplementary Table S4). Relatively lower concentrations of 1,2-alkyl diols were present in samples G2 and G12, with values ranging from 1 to 6 and 1 to 3 ng/g of dried rock, respectively (Supplementary Table S4). Only two 1,2-alkyl diols were detected in sample G3 (17-methyloctadecan-1,2-diol and 18-methylnonadecan-1,2-diol), and these were also found in low concentrations (up to 3 ng/g of dried rock); 1,2-alkyl diols were absent from samples G7 and G14 (Supplementary Table S4).

4. Discussion

4.1. Potential sources of lipid biomarkers in the Samail Ophiolite samples

4.1.1. Isoprenoidal glycerol tetraethers. The distribution of iGDGTs in subset A samples (G2, G3, and G7) (Fig. 3 and Supplementary Table S1) is typical of those found in low-temperature marine sediments, which are dominated by both GDGT-0 and crenarchaeol (Schouten *et al.*, 2002) and reflect a substantial contribution from Thaumarchaeota. These ammonia-oxidizing archaea have been shown to fix inorganic carbon in culture (Könneke *et al.*, 2005). Additional sources of iGDGT 0–4 in these samples likely include Crenarchaeota (Thurl and Schäfer, 1988; Trincone *et al.*, 1992; Völkl *et al.*, 1993; Boyd *et al.*, 2011) and methanotrophic Euryarchaeota (Pancost *et al.*, 2001; Zhang *et al.*, 2003; Blumenberg *et al.*, 2004). For all samples in subset B (G11, G12, G13, and G14), crenarchaeol was the dominant iGDGT, and it comprised >65% of all iGDGTs in these carbonates (Fig. 3 and Supplementary Table S1). This distribution is characteristic of alkaline soil environments (Weijers *et al.*, 2006), and iGDGTs found in subset B samples may reflect substantial contributions from soil Thaumarchaeota and/or other terrestrial archaeal species.

At the LCHF (an oceanic setting, devoid of terrestrial soil input), the co-occurrence of crenarchaeol and nucleic acids

of Marine Group I Thaumarchaeota indicates a likely product-source relationship between the two (Lincoln *et al.*, 2013, 2014). Rempfert *et al.* (2017) reported ribosomal DNA sequences for Thaumarchaeota in some Samail Ophiolite well samples, supporting the identification of these archaea as the primary source of crenarchaeol in this study. Cultivated members of the phylum Thaumarchaeota are capable of ammonia oxidation (Könneke *et al.*, 2005), and amoA, the gene that codes for this metabolic process, has been correlated with Thaumarchaeotal abundance and crenarchaeol concentrations (Leininger *et al.*, 2006). Concentrations of total ammonia in Samail Ophiolite hyperalkaline spring waters have been shown to range up to 0.12 mM, but these values may be considerably lower in surface waters (Canovas *et al.*, 2017) [ammonia concentrations in end-member fluids at the LCHF are less than 6 μ M (Lang *et al.*, 2013)]. This may be adequate to support Thaumarchaeota because isolates such as *Nitrosopumilus maritimus* are known to grow under ammonia limitation due to their high substrate affinity for ammonia (Martens-Habben *et al.*, 2009). Moreover, Canovas *et al.* (2017) demonstrated that there is a substantial energy supply from ammonia oxidation in fluids from the Samail Ophiolite.

Differences in the distribution of iGDGTs across samples (Fig. 3 and Supplementary Table S1) can be explained by the environments in which these samples were formed (Table 2 and Supplementary Fig. S2). The travertine and layered carbonates (subset A samples) were composed of calcite, dolomite, and aragonite, which suggests that these may have originated from the surface outflow of serpentinized fluids that were rich in Ca²⁺ and OH⁻ (Kelemen and Matter, 2008; Paukert *et al.*, 2012). In contrast, magnesite was found exclusively in vein samples (G11 and G13), and this mineral was likely formed by interactions between peridotite and meteoric or surface waters in subsurface environments (Neal and Stanger, 1985; Kelemen and Matter, 2008; Paukert *et al.*, 2012). Surface and subsurface habitats differ in composition, water:rock ratios, and state of reaction progress, and this may account for some of the differences observed between sample subsets. Although sample mineral composition may have also played a role in the preservation of iGDGTs, we were unable to identify specific mineralogical effects unrelated to the environment of sample formation (surface vs. subsurface) or type of sample (travertine, vein, host rock, etc.). Moreover, it is likely that the lipid biomarker record presented here reflects contributions from both modern, endolithic microbes and microbial activity at the time of carbonate formation. Microbial communities that were present during early carbonate formation likely depended on fundamentally different metabolic strategies relative to modern endolithic microbes at Oman, and this may also contribute to variations in iGDGT distributions observed in the current study.

4.1.2. Branched glycerol tetraethers. Initially, brGDGTs were considered to be exclusively of nonmarine origin because these lipids are frequently found in soil and peat bogs, and they are associated with the presence of *Acidobacteria* (Weijers *et al.*, 2009). However, brGDGTs have also been found in marine (Peterse *et al.*, 2009) and lacustrine (Sinninghe Damsté *et al.*, 2009; Tierney and Russell, 2009; Tierney *et al.*, 2010) environments, suggesting a more global

distribution for these lipids. In this study, we suggest that brGDGTs in subset A samples are likely derived from non-soil sources, whereas brGDGTs in subset B samples are likely synthesized by soil bacteria (see discussion on iGDGTs and alkyl diols for additional differences between sample subsets). BrGDGTs have also been found in marine hydrothermal systems such as the LCHF (Lincoln *et al.*, 2013), the Southwest Indian Ridge [Eastern Pacific Ocean; Pan *et al.* (2016)], and the southern Mid-Atlantic Ridge (Li *et al.*, 2018), providing additional evidence for the widespread production of these lipids, though their specific sources are not currently known.

4.1.3. Archaeol. The presence of archaeol in six of our seven samples is consistent with a scenario of methanogenesis at the Samail Ophiolite. Indeed, the methane-producing archaeon, *Methanobacterium*, has been reported in subsurface fluids at the ophiolite (Miller *et al.*, 2016; Rempfert *et al.*, 2017) in conjunction with methane concentrations of up to 4.3% volume (Schrenk *et al.*, 2013). Moreover, the elevated ratios of GDGT-0/crenarchaeol in subset A samples may suggest methanogenic activities (Pan *et al.*, 2016). However, archaeol can also be synthesized by a variety of non-methanogenic archaea, including anaerobic methane oxidizers, halophiles, miscellaneous Crenarchaeota (Koga and Morii, 2005; Lipp and Hinrichs, 2009), and Thaumarchaeota (Elling *et al.*, 2017), and abiogenic processes, such as Fischer-Tropsch and Sabatier reactions, can also contribute to methane generation (Etiope and Sherwood Lollar, 2013; Etiope, 2017). Thus, the origin of methane at the Samail Ophiolite, as in other serpentinizing environments, remains poorly constrained.

Isotopic compositions of methane at the ophiolite provide no clear clues to its source. Miller *et al.* (2016) reported methane greatly enriched in ^{13}C in Samail Ophiolite fluids, outside previously defined ranges for biogenic, abiotic, and thermogenic methane. They discuss explanations for extreme carbon isotopic enrichment that do not exclude a biological origin, including carbon limitation. Alternatively, methane may be formed through low-temperature abiogenic processes that use chromitite or ruthenium as a catalyst (Etiope and Sherwood Lollar, 2013). Future work investigating the carbon isotopic composition of archaeol, as well as other lipids not identified in the current set of samples, but associated with both methanogenesis and serpentinization processes [e.g., isoprenoidal diethers; Bradley *et al.* (2009b)], would enhance our understanding of methane production at the Samail Ophiolite and in analog serpentinite-hosted ecosystems.

4.1.4. MAGE and fatty acids. MAGE with varying saturated and unsaturated C_{15} – C_{18} side chains are believed to be primarily derived from sulfate-reducing bacteria (Langworthy *et al.*, 1983; Rütters *et al.*, 2001; Vinçon-Laugier *et al.*, 2016, 2017), even though they have also been recorded in a number of other bacterial taxa (Grossi *et al.*, 2015; Yang *et al.*, 2015). Hernandez-Sanchez *et al.* (2014) demonstrated that branched MAGE are commonly found in suboxic/anoxic marine sediments, whereas water column particulates typically contain lower relative abundances. Iso-, anteiso-, and mid-chain methyl branched fatty acids are also present in our samples, and they are similarly attributed

to sulfate-reducing bacteria. However, numerous other taxa could also contribute to these fatty acids (O'Reilly *et al.*, 2017). Nevertheless, 16S rRNA data have demonstrated the universality of sulfur cycling bacteria, for example, *Desulfonatronum*, *Thiobacillus*, and Firmicutes, at serpentinite-hosted ecosystems (Daae *et al.*, 2013; Woycheese *et al.*, 2015), and lipid evidence for sulfate reduction at other serpentinite-hosted ecosystems has been reported (Bradley *et al.*, 2009b; Klein *et al.*, 2015). The occurrence of *Thermodesulfovibrionaceae*, a family of sulfate-reducing bacteria, at the Samail ophiolite (Miller *et al.*, 2016; Rempfert *et al.*, 2017) may suggest a contribution of sulfate-reducing bacteria to MAGE and fatty acid production in our samples.

4.1.5. Alkyl diols. Relatively high concentrations of 1,2-alkyl diols were restricted to subset B samples (*i.e.*, G11 and G13). 1,2-alkyl diols are rarely reported in environmental samples and based on evidence at present appear to be restricted to thermal and/or alkaline spring environments (Zeng *et al.*, 1992; Pancost *et al.*, 2005) and cultures of thermophilic bacteria (Pond *et al.*, 1986; Wait *et al.*, 1997; Van der Meer *et al.*, 2002). If our interpretation of the iGDGT distribution in our samples is correct, then the high occurrence of 1,2-alkyl diols in subset B samples may originate from nonmarine alkaliphilic bacteria. However, a higher plant signal cannot be ruled out (Buschhaus *et al.*, 2013).

4.1.6. Potentially diagnostic lipids not reported in the current study. Due to the limited sample volume and low recovery of some lipids (see Section 3), we did not screen for bacteriohopanepolyols (BHPs), which can be synthesized by methanotrophic bacteria (Talbot *et al.*, 2001; van Winden *et al.*, 2012), methanogen-derived hydroxyarchaeol (Koga *et al.*, 1993), and intact polar lipids (IPLs). IPLs, in particular, are prone to rapid degradation during early diagenesis, and although these lipids can aid in the characterization of living microbial communities, their utility in the reconstruction of ancient records is, at best, limited (e.g., Logemann *et al.*, 2011). Despite the absence of data on BHPs, hydroxyarchaeol, and IPLs in this study, we do not rule out the possibility of the presence of these lipids in the Samail Ophiolite samples, and the potential for their inclusion in the serpentinization lipidome (Table 1). Moreover, we did not detect steroid biomarkers in the Samail Ophiolite samples, but we suggest that these may also be important lipids at other serpentinite-hosted ecosystems.

4.1.7. Summary of lipid biomarkers and their sources. We categorize the Samail Ophiolite samples into two distinct subsets, as determined by sample mineralogies and lipid biomarker distributions. Subset A samples were likely formed in serpentinite-hosted surface environments and record lipids derived primarily from marine microorganisms; subset B samples were likely formed in subsurface environments due to interactions with surface waters and record lipids derived primarily from soil bacteria and other terrestrial sources. The presence of archaeol in subset A samples, in addition to elevated GDGT-0/crenarchaeol ratios, may suggest active methanogenesis at the Samail Ophiolite. This is

consistent with rRNA evidence of methane-producing archaea there (Miller *et al.*, 2016). The presence of MAGE and fatty acids in these samples likely suggests the occurrence of sulfate-reducing bacteria at the ophiolite.

4.2. Implications for the preservation and detection of lipids in ancient environments on Mars

This study reconstructs microbial activity in a modern serpentinite-hosted ecosystem on Earth as inferred from the lipid biomarker record of recently formed carbonates (<50,000 years) (Kelemen and Matter, 2008; Kelemen *et al.*, 2011; Mervine *et al.*, 2014). Lipids present in the Samail Ophiolite samples that are consistent with rRNA results, such as crenarchaeol (likely derived from Thaumarchaeota), archaeol (possibly derived from archaea of the class Methanobacteria), and fatty acids and monoethers (likely derived from sulfate-reducing bacteria), may have been formed by modern and/or recent microbial activity. Lipid synthesis during early carbonate formation (~50,000 ka) likely also contributed to the total lipid reservoir at Oman, though relative contributions from modern and ancient sources cannot be constrained by the methods used in this study. However, if lipid biomarkers are, indeed, preserved on Mars, they were likely produced billions of years ago, during the Noachian and/or Hesperian Periods (4.1–3.7 and 3.7–3.0 Gyr, respectively) because the warmer and wetter climate during these Periods (Cabrol and Grin, 1999; Moore and Howard, 2005; Fassett and Head, 2008; Warner *et al.*, 2010; Andrews-Hanna and Lewis, 2011; Ehlmann *et al.*, 2011; Halevy and Head, 2014; Goudge *et al.*, 2016) may have supported microbial life (Cabrol and Grin, 1999; Warner *et al.*, 2010; Ehlmann *et al.*, 2011). Thus, the implications of this study for the detection of lipid biomarkers in ancient environments on Earth and Mars are discussed next.

An important consideration in the search for ancient biosignatures is the potential of these molecules for long-term preservation. Although the preservation potential of the serpentinitization lipidome remains poorly constrained, evidence from the sedimentary rock record on Earth suggests that the long-term preservation of lipids is a common occurrence. The earliest reported evidence of ether lipids on Earth, which includes archaeol, non-isoprenoidal monoethers and diethers, and their diagenetic products (biphytanes), is from the early to mid-Triassic (Saito *et al.*, 2015, 2017) and the late Carboniferous (Birgel *et al.*, 2008). However, laboratory studies have demonstrated the ability of these archaeal lipids to tolerate high levels of thermal maturation (Koopmans *et al.*, 1995, 1996; Pease *et al.*, 1998), highlighting their potential for even longer-term preservation than has been previously reported (Saito *et al.*, 2015, 2017). This, combined with the ability of some archaea to tolerate extreme environmental conditions, such as exposure to UV radiation and perchlorates (Oren, 2014; see later discussion in section 4.2), make archaeal lipids excellent candidates for detection on Mars. Moreover, slower weathering rates on Mars relative to Earth and conditions of rapid organic burial (Hays *et al.*, 2017) would likely facilitate the long-term preservation of archaeal lipids if, in fact, they were produced on Mars.

Fatty acids and alkyl diols have comparatively longer records of preservation relative to ether lipids in the rock

record on Earth, and they have been reported in sediments that are hundreds of millions to billions of years old (Han and Calvin, 1969; Van Hoesen *et al.*, 1969). However, these studies were conducted before the widespread prevalence of contamination of ancient sediments from contemporary microbes was appreciated, and thus, further investigation into the longevity of these lipids is warranted. Nevertheless, these studies suggest that fatty acids, alkyl diols, and other bacterially derived lipids have the potential for long-term preservation on timescales consistent with the potential evolution of life on Mars.

Due to inorganic carbon limitation in serpentinitizing systems (McCollom and Seewald, 2013; Schrenk *et al.*, 2013) and the low concentrations of some lipids reported in this study (see Section 3), the successful identification of lipids in these habitats is likely reflective of lipid structural quality, rather than total lipid abundance. On Earth, early diagenetic processes can alter lipids, and they can form molecular fossils with notable patterns of degradation (Van Vleet and Quinn, 1979; Haddad *et al.*, 1992; Reiche *et al.*, 2018). For example, ether lipids are commonly preserved in the fossil record as biphytane hydrocarbons, which are the diagenetic products of GDGTs. The preferential degradation of unsaturated, methylated, and low-molecular-weight fatty acids relative to their higher molecular weight and saturated counterparts can also occur during early diagenesis, and later diagenetic effects can result in an alteration of fatty acid carbon chain length (Johnson and Calder, 1973; Matsuda and Koyama, 1977; Van Vleet and Quinn, 1979; Haddad *et al.*, 1992). This suggests that the ability of lipids to persist through time as molecular fossils in the martian subsurface may be of paramount importance to their successful identification and recovery by future missions to Mars.

Here, we identify the solvent extractable organic compounds present in carbonate samples from the Samail Ophiolite. However, lipids can also be absorbed onto, or entrained within, minerals and/or preserved in recalcitrant macromolecular material (kerogen) during diagenesis due to the replacement of functional and/or other organic groups with cross-linked, insoluble components (Gobé *et al.*, 2000; Pancost *et al.*, 2008; Vandenbroucke and Largeau, 2007). Methods involving the chemical or thermal cleavage of organics from the macromolecular material, such as hydrolysis (Love *et al.*, 1997; Maroto-Valer *et al.*, 1997), have been utilized in the detection of kerogen-bound alkanes, steranes, hopanes (Murray *et al.*, 1998), and archaeal lipids (Pancost *et al.*, 2008) on Earth. These methods may be especially useful in extracting organic material from sediments that would otherwise generate low lipid yields. Thus, future investigations of macromolecular-bound products at the Samail Ophiolite and in other serpentinite-hosted environments on Earth will be critical to inform the planning for future rover missions to Mars with sample return.

A substantial challenge to the preservation of lipids on Mars is its inhospitable surface environment. Lipids may be altered or completely destroyed by chemical oxidation in high-energy environments, due to the prevalence of perchlorates in the martian regolith and exposure to ionizing radiation (Hays *et al.*, 2017). Serpentinite-hosted environments would facilitate better preservation of lipids and other biosignatures than surface sediments because these are below the zone affected by solar and cosmic radiation. Moreover,

these ecosystems efficiently buffer fluids to extremely low-oxygen fugacities, even within millimeters of Earth's oxidizing surface conditions. In addition to lipids, subsurface environments on Mars have the potential to preserve a suite of other biosignatures, including microbial structures and textures, isotopic signatures, and trace elements (Hays *et al.*, 2017).

With the identification of alteration minerals throughout the martian southern highlands, it is likely that serpentinization was a common and widespread process on early Mars (Ehlmann *et al.*, 2009, 2010; Amador *et al.*, 2017, 2018). If, indeed, these regions are determined to have hosted ancient serpentinization processes, we suggest their potential as important locations for the long-term preservation of lipid biomarkers. Based on evidence from this study, we also highlight the diversity of lipids produced in serpentinite-hosted environments.

5. Conclusions

Here, we present one of the first lipid biomarker records of a terrestrial serpentinite-hosted ecosystem, contributing to a growing understanding of the role of serpentinization processes in sustaining microbial life on Earth. The distributions of isoprenoidal and brGDGTs, MAGE, and fatty acids found at the Samail Ophiolite show strong similarities to those of biomarker assemblages identified at the submarine, serpentinite-hosted LCHF, providing evidence for a common core serpentinization lipidome that includes sulfate-reducing and ammonia-oxidizing bacteria, methanogens, and methanotrophs. Continuing investigations of the Samail Ophiolite and similar serpentinite-hosted ecosystems on Earth will help to build a robust molecular toolkit needed to identify and interpret putative biosignatures in serpentinizing systems on Mars and other terrestrial planets.

Abbreviations Used

APCI	= atmospheric pressure chemical ionization
BHP	= bacteriohopanepolyol
DCM	= dichloromethane
GDGT	= glycerol dialkyl glycerol tetraether
iGDGT	= isoprenoidal GDGT
IPL	= intact polar lipid
LCHF	= Lost City Hydrothermal Field
MAGE	= monoalkyl glycerol monoethers
MeOH	= methanol
SIM	= selected ion monitoring
TLE	= total lipid extract
TMS	= trimethylsilyl
XRD	= X-ray diffraction
