Neural-Swarm2: Planning and Control of Heterogeneous Multirotor Swarms using Learned Interactions

Guanya Shi, Wolfgang Hö nig, Xichen Shi, Yisong Yue, and Soon-Jo Chung

Abstract—We present Neural-Swarm2, a learning-based method for motion planning and control that allows heterogeneous multirotors in a swarm to safely fly in close proximity. Such operation for drones is challenging due to complex aerodynamic interaction forces, such as downwash generated by nearby drones and ground effect. Conventional planning and control methods neglect capturing these interaction forces, resulting in sparse swarm configuration during flight. Our approach combines a physics-based nominal dynamics model with learned Deep Neural Networks (DNNs) with strong Lipschitz properties. We evolve two techniques to accurately predict the aerodynamic interactions between heterogeneous multirotors: i) spectral normalization for stability and generalization guarantees of unseen data and ii) heterogeneous deep sets for supporting any number of heterogeneous neighbors in a permutation-invariant manner without reducing expressiveness. The learned residual dynamics benefit both the proposed interaction-aware multi-robot motion planning and the nonlinear tracking control designs because the learned interaction forces reduce the modelling errors. Experimental results demonstrate that Neural-Swarm2 is able to generalize to larger swarms beyond training cases and significantly outperforms a baseline nonlinear tracking controller with up to three times reduction in worst-case tracking errors. Video is available at https://youtu.be/Y02juH6BDxo

I. INTRODUCTION

The ongoing commoditization of unmanned aerial vehicles (UAVs) requires robots to fly in much closer proximity to each other than before, which necessitates advanced planning and control methods for large aerial swarms [1][2]. For example, consider a search-and-rescue mission where an aerial swarm must enter and search a collapsed building in such scenarios, close-proximity flight enables the swarm to navigate the building much faster compared to swarms that must maintain large distances from each other. Other important applications of close-proximity flight include manipulation, search, surveillance, and mapping. In many scenarios, heterogeneous teams with robots of different sizes and sensing or manipulation capabilities are beneficial due to their significantly higher adaptability. For example, in a search-and-rescue mission larger UAVs can be used for manipulation tasks or to transport goods, while smaller ones are more suited for exploration and navigation.

A major challenge of close-proximity control and planning is that small distances between UAVs create complex aerodynamic interactions. For instance, one multirotor flying above another causes the so-called downwash effect on the lower one, which is difficult to model using conventional model-based approaches [3]. Without accurate downwash interaction modeling, a large safety distance between vehicles is necessary, thereby preventing a compact 3-D formation shape, e.g., 60 cm for the small Crazyflie 2.0 quadrotor (9 cm rotor-to-rotor) [4]. Often, a formation is restricted to 2-D planar motions [5]. For heterogeneous teams, even larger and asymmetric safety distances are required [6]. However, the downwash for two small Crazyflie quadrotors hovering 30 cm on top of each other is only ~9 g, which is well within their thrust capabilities, and suggests that proper modeling of downwash and other interaction effects can lead to more precise motion planning and dense formation control.

In this paper, we present a learning-based approach, Neural-Swarm2, which increases the precision, safety, and density of close-proximity motion planning and control of heterogeneous multirotor swarms. In the example shown in Fig. 1, we safely operate with vertical proximities less than half than prior work [4] using the same robots. In particular, we train deep neural networks (DNNs) to predict the residual interaction forces (b,c).
forces that are not captured by the nominal models of free-space aerodynamics. To the best of our knowledge, this is the first model for aerodynamic interactions between two or more multirotors in flight. Our DNN architecture supports heterogeneous inputs in a permutation-invariant manner without reducing the expressiveness. The DNN only requires relative positions and velocities of neighboring multirotors as inputs, similar to the existing collision-avoidance techniques [7], which enables fully-decentralized computation. We use the predicted interaction forces to augment the nominal dynamics and derive novel methods to directly consider them during motion planning and as part of the multirotors’ controller.

From a learning perspective, we leverage and extend two state-of-the-art tools to derive effective DNN models. First, we extend deep sets [8] to the heterogeneous case and prove its representation power. Our novel encoding is used to model interactions between heterogeneous vehicle types in an index-free or permutation-invariant manner, enabling better generalization to new formations and a varying number of vehicles. The second is spectral normalization [9], which ensures the DNN is Lipschitz continuous and helps the DNN generalize well on test examples that lie outside the training set. We demonstrate that the interaction forces can be computationally efficiently and accurately learned such that a small 32-bit microcontroller can predict such forces in real-time.

From a planning and control perspective, we derive novel methods that directly consider the predicted interaction forces. For motion planning we use a two-stage approach. In the first stage, we extend an existing kinodynamic sampling-based planner for a single robot to the interaction-aware multi-robot case. In the second stage, we adopt an optimization-based planner to refine the solutions of the first stage. Empirically, we demonstrate that our interaction-aware motion planner both avoids dangerous robot configurations that would saturate the multirotors’ motors and reduces the tracking error significantly. For the nonlinear control we leverage the Lipschitz continuity of our learned interaction forces to derive stability guarantees similar to our prior work [10]. The controller can be used to reduce the tracking error of arbitrary desired trajectories, including ones that were not planned with an interaction-aware planner.

We validate our approach on different tasks using two to sixteen quadrotors of two different sizes, and we also integrate ground effect and other unmodeled dynamics into our model, by viewing the physical environment as a special “robot”. To our knowledge, our approach is the first that models interactions between two or more multirotor vehicles and demonstrates how to use such a model effectively and efficiently for motion planning and control of aerial teams.

II. RELATED WORK

The aerodynamic interaction force applied to a single UAV flying near the ground (ground effect), has been modeled analytically [12][14]. In many cases, the ground effect is not considered in typical nonlinear multirotor controllers and thus increases the tracking error of a multirotor when operating close to the ground. However, it is possible to use ground effect prediction in real-time to reduce the tracking error [10][14].

The interaction between two rotor blades of a single multirotor has been studied in a lab setting to optimize the placement of rotors on the vehicle [15]. However, it remains an open question how this influences the flight of two or more multirotors in close proximity. Interactions between two multirotors can be estimated using a propeller velocity field model [3]. Unfortunately, this method is hard to generalize to the multi-robot or heterogeneous case and this method only considers the stationary case, which is inaccurate for real flights.

The use of DNNs to learn higher-order residual dynamics or control actions is gaining attention across a range of control and reinforcement learning settings [10][16][21]. For swarms, a common encoding approach is to discretize the whole space and employ convolutional neural networks (CNNs), which yields a permutation-invariant encoding. Another common encoding for robot swarms is a Graphic Neural Network (GNN) [22][23]. GNNs have been extended to heterogeneous graphs [24], but it remains an open research question how such a structure would apply to heterogeneous robot teams. We extend a different architecture, which is less frequently used in robotics applications, called deep sets [8]. Deep sets enable distributed computation without communication requirements. Compared to CNNs, our approach: i) requires less training data and computation; ii) is not restricted to a pre-determined resolution and input domain; and iii) directly supports the heterogeneous swarm. Compared to GNNs, we do not require any direct communication between robots. Deep sets have been used in robotics for homogeneous [11] and heterogeneous [25] teams. Compared to the latter, our heterogeneous deep set extension has a more compact encoding and we prove its representation power.

For motion planning, empirical models have been used to avoid harmful interactions [2][4][6][26][27]. Typical safe boundaries along multi-vehicle motions form ellipsoids [2] or cylinders [6] along the motion trajectories. Estimating such shapes experimentally would potentially lead to many collisions and dangerous flight tests and those collision-free regions are in general conservative. In contrast, we use deep learning to estimate the interaction forces accurately in heterogeneous multi-robot teams. This model allows us to directly control the magnitude of the interaction forces to accurately and explicitly control the risk, removing the necessity of conservative collision shapes.

We generalize and extend our prior conference paper [11] significantly: i) we develop heterogeneous deep sets to extend to the heterogeneous case, which also unifies the approach with respect to our prior work that considers the ground effect for improved multirotor landing [10], ii) we introduce a novel method to use the learned interaction forces for multi-robot motion planning, and iii) we explicitly compensate for the delay in motor speed commands in our position and attitude controllers, resulting in stronger experimental results for both our baseline and Neural-Swarm2.
Neural-Swarm2 can generally apply to any robotic system and we will focus on multirotors in this paper. We first present single multirotor dynamics including interaction forces modeled as disturbances. Then, we generalize these dynamics for a swarm of multirotors. Finally, we formulate our objective as a variant of an optimal control problem and introduce our performance metric.

### A. Single Multirotor Dynamics

A single multirotor’s state comprises of the global position \( \mathbf{p} \in \mathbb{R}^3 \), global velocity \( \mathbf{v} \in \mathbb{R}^3 \), attitude rotation matrix \( \mathbf{R} \in \text{SO}(3) \), and body angular velocity \( \omega \in \mathbb{R}^3 \). Its dynamics are:

\[
\begin{align*}
\dot{\mathbf{p}} &= \mathbf{v}, \\
\dot{\mathbf{v}} &= m\mathbf{g} + \mathbf{Rf}_u + \mathbf{f}_a, \\
\dot{\mathbf{R}} &= \mathbf{RS}(\omega), \\
\dot{\omega} &= \mathbf{J}\omega \times \omega + \tau_u + \tau_a,
\end{align*}
\]

where \( m \) and \( \mathbf{J} \) denote the mass and inertia matrix of the system, respectively; \( \mathbf{S}(\cdot) \) is a skew-symmetric mapping; \( \mathbf{g} = [0; 0; -g] \) is the gravity vector; and \( \mathbf{f}_u = [0; 0; T] \) and \( \tau_u = [\tau_x; \tau_y; \tau_z] \) denote the total thrust and body torques from the rotors, respectively. The output wrench \( \eta = [\tau_x; \tau_y; \tau_z] \) is linearly related to the control input \( \eta = \mathbf{B}_0u, \) where \( u = [u_a; z; f_a; f_{a,z}] \) is the squared motor speeds for a vehicle with \( M \) rotors and \( \mathbf{B}_0 \) is the actuation matrix. A multirotor is subject to additional disturbance force \( \mathbf{f}_a = [f_{a,z}; f_{a,y}; f_{a,z}] \) and disturbance torque \( \tau_a = [\tau_{a,z}; \tau_{a,y}; \tau_{a,z}] \). We also consider a first order delay model in [1c], where \( u_t \) is the actual command signal we can directly control, and \( \lambda \) is the scalar time constant of the delay model.

Our model creates additional challenges compared to other existing multicopter dynamics models (e.g., [27]). The first challenge stems from the effect of delay in [1c]. The second challenge stems from disturbance forces \( \mathbf{f}_a \) in [1a] and disturbance torques \( \tau_a \) in [1b], generated by the interaction between other multicopters and the environment.

### B. Heterogeneous Swarm Dynamics

We now consider \( N \) multirotor robots. We use \( \mathbf{x}^{(i)} = [\mathbf{p}^{(i)}; \mathbf{v}^{(i)}; \mathbf{R}^{(i)}; \omega^{(i)}] \) to denote the state of the \( i \)th multirotor. We use \( \mathbf{x}^{(ij)} \) to denote the relative state component between robot \( i \) and \( j \), e.g., \( \mathbf{x}^{(ij)} = [\mathbf{p}^{(j)} - \mathbf{p}^{(i)}; \mathbf{v}^{(j)} - \mathbf{v}^{(i)}; \mathbf{R}^{(j)}\mathbf{R}^{(j)\text{T}}]. \)

We use \( \mathcal{I}^{(i)} \) to denote the type of the \( i \)th robot, where robots with identical physical parameters such as \( m, \mathbf{J}, \) and \( \mathbf{B}_0 \) are considered to be of the same type. We assume there are \( K \leq N \) types of robots, i.e., \( \mathcal{I}^{(i)} \) is a surjective mapping from \( \{1, \ldots, N\} \) to \{\text{type}_1, \ldots, \text{type}_K\}. Let \( r_{\text{type}_k}^{(i)} \) be the set of the relative states of the \( \text{type}_k \) neighbors of robot \( i \):

\[
r_{\text{type}_k}^{(i)} = \{\mathbf{x}^{(ij)} | j \in \text{neighbor}(i) \text{ and } \mathcal{I}(j) = \text{type}_k\}.
\]

The ordered sequence of all relative states grouped by robot type is

\[
r^{(i)}_2 = (r_{\text{type}_1}^{(i)}; r_{\text{type}_2}^{(i)}; \ldots; r_{\text{type}_K}^{(i)}).
\]

The dynamics of the \( i \)th multirotor can be written in compact form:

\[
\dot{\mathbf{x}}^{(i)} = \Phi^{(i)}(\mathbf{x}^{(i)}, \mathbf{u}^{(i)}) + \begin{bmatrix} 0 \\ \tau_u^{(i)}(r^{(i)}_2) \\ 0 \\ \tau_a^{(i)}(r^{(i)}_2) \end{bmatrix},
\]

where \( \Phi^{(i)}(\mathbf{x}^{(i)}, \mathbf{u}^{(i)}) \) denotes the nominal dynamics of robot \( i \), and \( \tau_u^{(i)}(\cdot) \) and \( \tau_a^{(i)}(\cdot) \) are the unmodeled force and torque of the \( i \)th robot that are caused by interactions with neighboring robots or the environment (e.g., ground effect and air drag).

Robots with the same type have the same nominal dynamics and unmodeled force and torque:

\[
\Phi^{(i)}(\cdot) = \Phi^{(i)}(\cdot), \quad \tau_u^{(i)}(\cdot) = \tau_u^{(i)}(\cdot), \quad \tau_a^{(i)}(\cdot) = \tau_a^{(i)}(\cdot) \forall i.
\]

Our system is heterogeneous in three ways: i) different robot types have heterogeneous nominal dynamics \( \Phi^{(i)}(\cdot) \); ii) different robot types have different unmodeled \( \tau_u^{(i)}(\cdot) \) and \( \tau_a^{(i)}(\cdot) \); and iii) the neighbors of each robot belong to \( K \) different sets.

We highlight that our heterogeneous model not only captures different types of robot, but also different types of environmental interactions, e.g., ground effect and air drag. This is achieved in a straightforward manner by viewing the physical environment as a special robot type. We illustrate this generalization in the following example.

**Example 1** (small and large robots, and the environment). We consider a heterogeneous system as depicted in Fig. 2a. Robot 3 (large robot) has three neighbors: robot 1 (small), robot 2 (small) and environment 4. Therefore, for robot 3, we have

\[
r_{\text{large}}^{(3)} = r_{\text{large}}(r^{(3)}_2) = r_{\text{large}}(r^{(3)}_2, r^{(3)}_{\text{small}}, r^{(3)}_{\text{env}}),
\]

\[
r_{\text{small}}^{(3)} = \{\mathbf{x}^{(31)}, \mathbf{x}^{(32)}\}, \quad r_{\text{large}}^{(3)} = \emptyset, \quad r_{\text{env}}^{(3)} = \{\mathbf{x}^{(34)}\}
\]

and a similar expression for \( \tau_{\text{a}}^{(3)} \).

### C. Interaction-Aware Motion Planning & Control

Our goal is to move the heterogeneous team of robots from their start states to goal states, which can be framed as the following optimal control problem:

\[
\min_{\mathbf{u}^{(i)}, \mathbf{x}^{(i)}, t} \sum_{i=1}^{N} \int_0^{t_f} \|\mathbf{u}^{(i)}(t)\| \, dt
\]

subject to:

\[
\begin{align*}
\mathbf{x}^{(i)}(0) &= \mathbf{x}^{(i)}(0); \\
\mathbf{x}^{(i)}(t) &\in \Xi^{(i)}; \\
\|\mathbf{p}^{(j)}(t)\| &\geq r^{(i)}(r^{(i)}_2(t)) \quad i < j, \quad j \in [2, N] \\
\|\mathbf{f}_a^{(i)}(t)\| &\leq f_{a,\text{max}}^{(i)}; \\
\|\tau_a^{(i)}(t)\| &\leq \tau_{a,\text{max}}^{(i)} \quad i \in [1, N] \\
\mathbf{x}^{(i)}(0) &= \mathbf{x}^{(i)}(0); \\
\mathbf{x}^{(i)}(t_f) &= \mathbf{x}^{(i)}(t_f)
\end{align*}
\]

where \( U^{(k)} \) is the control space for \( \text{type}_k \) robots, \( \lambda^{(k)} \) is the free space for \( \text{type}_k \) robots, \( r^{(k)} \) is the minimum safety distance between \( \text{type}_1 \) and \( \text{type}_k \) robots, \( f_{a,\text{max}}^{(i)} \) is the
maximum endurable interaction force for type\( k \) robots, \( f_a^{(i)} \) is the maximum endurable interaction torque for type\( k \) robots, \( x_s^{(i)} \) is the start state of robot \( i \), and \( x_f^{(i)} \) is the desired state of robot \( i \). In contrast to existing literature [6], we assume a tight spherical collision model and bound the interaction forces directly, eliminating the need of manually defining virtual collision shapes. For instance, larger \( f_a^{(i)} \) and \( \tau_a^{(i)} \) will yield denser and more aggressive trajectories. Also note that the time horizon \( t_f \) is a decision variable.

Solving (6) in real-time in a distributed fashion is intractable due to the exponential growth of the decision space with respect to the number of robots. Thus, we focus on solving two common subproblems instead. First, we approximately solve (6) offline as an interaction-aware motion planning problem. Second, we formulate an interaction-aware controller that minimizes the tracking error online. This controller can use both predefined trajectories and planned trajectories from the interaction-aware motion planner.

Since interaction between robots might only occur for a short time period with respect to the overall flight duration but can cause significant deviation from the nominal trajectory, we need to guarantee that the learned DNNs maintain stability. In general, approximated solutions \( \tilde{f}_a \) to (6) using DNNs, we need to guarantee that the learned DNN is permutation-invariant. Therefore, we consider the following “deep sets” [8] architecture to approximate homogeneous \( f_a \) and \( \tau_a \):

\[
\begin{align*}
\tilde{f}_a(r_{type1}^{(i)}) &= \rho \left( \sum_{x^{(i)} \in r_{type1}^{(i)}} \phi(x^{(i)}) \right) := \hat{f}_a^{(i)}(r_{type1}^{(i)}),
\end{align*}
\]

where \( \phi(\cdot) \) and \( \rho(\cdot) \) are two DNNs. The output of \( \phi(\cdot) \) is a hidden state to represent “contributions” from each neighbor, and \( \rho(\cdot) \) is a nonlinear mapping from the summation of these hidden states to the total effect.

Obviously the network architecture in (8) is permutation-invariant due to the inner sum operation. We now show that this architecture is able to approximate any continuous permutation-invariant function. The following Lemma 1 and Theorem 2 are adopted from [8] and will be used and extended in the next section for the heterogeneous case.

**Lemma 1.** Define \( \bar{\phi}(z) = [1; z; \cdots; z^M] \in \mathbb{R}^{M+1} \) as a mapping from \( \mathcal{R} \) to \( \mathbb{R}^{M+1} \), and \( \mathcal{X} = \{x_1; \cdots; x_M\} \in [0, 1]^M \) as a subset of \([0, 1]^M\). For \( x = [x_1; \cdots; x_M] \in \mathcal{X} \), define \( q(x) = \sum_{m=1}^M \phi(x_m) \). Then \( q(x) : \mathcal{X} \rightarrow \mathbb{R}^{M+1} \) is a homeomorphism.

**Proof.** The problem boils down to the Newton-Girard formulae, which connect the moments of a sample set (sum-of-power) to the elementary symmetric polynomials (see [8]).

**Theorem 2.** Suppose \( h(x) : [0, 1]^M \rightarrow \mathbb{R} \) is a permutation-invariant continuous function, i.e., \( h(x) = h(\pi(x_1, \cdots, x_M)) \) for any permutation \( \pi \). Then there exist continuous functions \( \hat{\rho} \) such that

\[
\bar{\rho}(\hat{\rho}(x)) = h(x), \quad \forall x \in [0, 1]^M.
\]

**Proof.** We choose \( \phi(z) = [1; z; \cdots; z^M] \) and \( \hat{\rho}(\cdot) = h(q^{-1}(\cdot)) \), where \( q(\cdot) \) is defined in Lemma 1. Note that since \( q(\cdot) \) is a homeomorphism, \( q^{-1}(\cdot) \) exists and it is a continuous function from \( \mathbb{R}^{M+1} \) to \( \mathcal{X} \). Therefore, \( \hat{\rho} \) is also a continuous function from \( \mathbb{R}^{M+1} \) to \( \mathbb{R} \), and \( \hat{\rho}(\sum_{m=1}^M \phi(x_m)) = \bar{\rho}(q(x)) = h(q^{-1}(q(x))) = h(x) \) for \( x \in \mathcal{X} \). Finally, note that for any \( x \in [0, 1]^M \), there exists some permutation \( \pi(\cdot) \) such that \( \pi(x) \in \mathcal{X} \). Then both \( \hat{\rho}(q(x)) \) and \( h(x) \) are permutation-invariant, have \( \hat{\rho}(q(x)) = \hat{\rho}(\pi(q(x))) = h(\pi(x)) = h(x) \) for all \( x \in [0, 1]^M \).

**2. Learning of Swarm Aerodynamic Interaction**

We employ state-of-the-art deep learning methods to capture the unknown (or residual) dynamics caused by interactions of heterogeneous robot teams. In order to use the learned functions effectively for motion planning and control, we require that the DNNs have strong Lipschitz properties (for stability analysis), can generalize well to new test cases, and use compact encodings to achieve high computational and statistical efficiency. To that end, we introduce heterogeneous deep sets, a generalization of regular deep sets [8], and employ spectral normalization [9] for strong Lipschitz properties.

In this section, we will first recap the homogeneous learning architecture covered in prior work [8, 11]. Then we will generalize them to the heterogeneous case with representation guarantees. Finally, we will introduce spectral normalization and our data collection procedures.

**A. Homogeneous Permutation-Invariant Neural Networks**

Recall that in the homogeneous case, all robots are with the same type (type\( 1 \)). Therefore, the input to functions \( f_a \) or \( \tau_a \) is a single set. The permutation-invariant aspect of \( f_a \) or \( \tau_a \) can be characterized as:

\[
\begin{align*}
f_a(r_{type1}^{(i)}) &= f_a(\pi(r_{type1}^{(i)})),
\tau_a(r_{type1}^{(i)}) &= \tau_a(\pi(r_{type1}^{(i)}))
\end{align*}
\]

for any permutation \( \pi \). Since the aim is to learn the function \( f_a \) and \( \tau_a \) using DNNs, we need to guarantee that the learned DNN is permutation-invariant. Therefore, we consider the
\( h(x^{(1)}, \ldots, x^{(M)}) = h(x^{\pi(1)}, \ldots, x^{\pi(M)}) \) for any permutation \( \pi \). Then \( h(x^{(1)}, \ldots, x^{(M)}) \) can be approximated arbitrarily close in the proposed architecture in (8).

**Proof.** First, there exists a bijection from the bounded vector space in \( \mathbb{R}^{D_1} \) to \([0,1]\) after discretization, with finite but arbitrary precision. Thus, Theorem 2 is applicable. Second, we apply Theorem 2 \( D_2 \) times and stack \( D_2 \) scalar-valued functions to represent the vector-valued function with output space \( \mathbb{R}^{D_2} \). Finally, because DNNs are universal approximators for continuous functions [22], the proposed architecture in (8) can approximate any \( h(x^{(1)}, \ldots, x^{(M)}) \) arbitrarily close. \( \square \)

**B. Heterogeneous \( K \)-Group Permutation-Invariant DNN**

Different from the homogeneous setting, the inputs to functions \( f_a^{x(i)} \) and \( \tau_a^{z(i)} \) in (5) are \( K \) different sets. First, we define permutation-invariance in the heterogeneous case. Intuitively, we expect that the following equality holds:

\[
\begin{align*}
&f_a^{x(i)}(r_{type_1}^{(i)}, \ldots, r_{type_K}^{(i)}) \\
&= f_a^{x(i)}(\pi_1(r_{type_1}^{(i)}), \ldots, \pi_K(r_{type_K}^{(i)}))
\end{align*}
\]

for any permutations \( \pi_1, \ldots, \pi_K \) (similarly for \( \tau_a^{z(i)} \)). Formally, we define \( K \)-group permutation invariance as follows.

**Definition 1 (\( K \)-group permutation invariance).** Let \( x^{(k)} = [x^{(k)}_1; \ldots; x^{(k)}_L] \in [0,1]^{M_k} \) for \( 1 \leq k \leq K \), and \( x = [x^{(1)}; \ldots; x^{(K)}] \in [0,1]^{M_K} \) where \( M_K = \sum_{k=1}^{K} M_k \). \( h(x): \mathbb{R}^{M_K} \rightarrow \mathbb{R} \) is \( K \)-group permutation-invariant if

\[
h([x^{(1)}; \ldots; x^{(K)}]) = h([\pi_1(x^{(1)}); \ldots; \pi_K(x^{(K)})])
\]

for any permutations \( \pi_1, \pi_2, \ldots, \pi_K \).

For example, \( h(x_1, x_2, y_1, y_2) = \max\{x_1, x_2\} + 2 \cdot \max\{y_1, y_2\} \) is a \( 2 \)-group permutation-invariant function, because we can swap \( x_1 \) and \( x_2 \) or swap \( y_1 \) and \( y_2 \), but if we interchanged \( x_1 \) and \( y_1 \) the function value may vary. In addition, the \( f_{large} \) function in Example 1 is a \( 3 \)-group permutation-invariant function.

Similarly to Lemma 1 in order to handle ambiguity due to permutation, we define \( X_{M_k} = \{[x_1; \ldots; x_{M_k}] \in [0,1]^{M_k} | x_1 \leq \cdots \leq x_{M_k}\} \) and

\[
X_K = \{[x^{(1)}; \ldots; x^{(K)}] \in [0,1]^{M_K} | x^{(k)} \in X_{M_k} , \forall k\}.
\]

Finally, we show how a \( K \)-group permutation-invariant function can be approximated with the following representation theorem.

**Theorem 4.** \( h(x): [0,1]^{M_K} \rightarrow \mathbb{R} \) is a \( K \)-group permutation-invariant continuous function if and only if it has the representation

\[
h(x) = \bar{\rho} \left( \sum_{m=1}^{M_1} \bar{\phi}_1(x^{(1)}_m) + \cdots + \sum_{m=1}^{M_K} \bar{\phi}_K(x^{(K)}_m) \right)
\]

for some continuous outer and inner functions \( \bar{\rho}: \mathbb{R}^{K+M_K} \rightarrow \mathbb{R} \) and \( \bar{\phi}_k: \mathbb{R} \rightarrow \mathbb{R}^{K+M_K} \) for \( 1 \leq k \leq K \).
applying the same argument as in Corollary 3. We propose the following heterogeneous deep set structure to model the heterogeneous functions $f_a^{Z(i)}$ and $\tau_a^{Z(i)}$:

$$
\begin{bmatrix}
f_a^{Z(i)}(r_{\text{type}_1}, \ldots, r_{\text{type}_K}) \\
\tau_a^{Z(i)}(r_{\text{type}_1}, \ldots, r_{\text{type}_K})
\end{bmatrix}
\approx \rho_{Z(i)} \left( \sum_{k=1}^{K} \sum_{i \in I_{\text{type}_k}} \phi_{Z(j)}(x^{(ij)}) \right)
$$

(10)

Example 3 (Use of 3-group permutation-invariant function for multirotors). For example, in the heterogeneous system provided by Example 2 (as depicted in Fig. 7(a)), we have

$$
\begin{bmatrix}
f_a^{(3)} \\
\tau_a^{(3)}
\end{bmatrix}
= \begin{bmatrix}
f_a^{\text{large}}(r^{(3)}_{\text{small}}, r^{(3)}_{\text{large}}, r_{\text{env}}) \\
\tau_a^{\text{large}}(r^{(3)}_{\text{small}}, r^{(3)}_{\text{large}}, r_{\text{env}})
\end{bmatrix}
\approx \rho_{\text{large}} \left( \phi_{\text{small}}(x^{(31)}) + \phi_{\text{large}}(x^{(32)}) + \phi_{\text{env}}(x^{(34)}) \right),
$$

for the large robot 3, where $\phi_{\text{small}}$ captures the interaction with the small robot 1 and 2, and $\phi_{\text{env}}$ captures the interaction with the environment 4, e.g., ground effect and air drag.

The structure in (10) has many valuable properties:

- **Representation ability.** Since Theorem 4 is necessary and sufficient, we do not lose approximation power by using this constrained framework, i.e., any $K$-group permutation-invariant function can be learned by (10). We demonstrate strong empirical performance using relatively compact DNNs for $\rho_{Z(i)}$ and $\phi_{Z(j)}$.

- **Computational and sampling efficiency and scalability.** Since the input dimension of $\phi_{Z(j)}$ is always the same as the single vehicle case, the feed-forward computational complexity of (10) grows linearly with the number of neighboring vehicles. Moreover, the number of neural networks ($\rho_{Z(i)}$ and $\phi_{Z(j)}$) we need is $2K$, which grows linearly as the number of different robot types increases. In practice, we found that one hour flight data is sufficient to accurately learn interactions between two to five multirotors.

- **Generalization to varying swarm size.** Given learned $\phi_{Z(j)}$ and $\rho_{Z(i)}$ functions, (10) can be used to predict interactions for any swarm size. In other words, a model trained on swarms of a certain size may also accurately model (slightly) larger swarms. In practice, we found that trained with data from one to three multirotor swarms, our model can give good predictions for five multirotor swarms.

C. **Spectral Normalization for Robustness and Generalization**

To improve a property of robustness and generalizability of DNNs, we use spectral normalization [9] for training optimization. Spectral normalization stabilizes a DNN training by constraining its Lipschitz constant. Spectrally normalized DNNs have been shown to generalize well, which is an indication of stability in machine learning. Spectrally normalized DNNs have also been shown to be robust, which can be used to provide control-theoretic stability guarantees [10 29]. The bounded approximation error assumption (Assumption 1) in our control stability and robustness analysis (Sec. VI-B) also relies on spectral normalization of DNNs.

Mathematically, the Lipschitz constant $\|g\|_{\text{Lip}}$ of a function $g(\cdot)$ is defined as the smallest value such that:

$$
\forall x, x': \|g(x) - g(x')\|_2 / \|x - x'\|_2 \leq \|g\|_{\text{Lip}}.
$$

Let $g(x, \theta)$ denote a ReLU DNN parameterized by the DNN weights $\theta = W_1, \ldots, W_{L+1}$:

$$
g(x, \theta) = W_{L+1} \sigma(W_L \sigma(\cdots \sigma(W_1 x) \cdots)),
$$

(11)

where the activation function $\sigma(\cdot) = \max(\cdot, 0)$ is called the element-wise ReLU function. In practice, we apply the spectral normalization to the weight matrices in each layer after each batch gradient descent as follows:

$$
W_i \leftarrow W_i / \|W_i\|_2 \cdot \gamma^{1/\alpha}, \ i \in [1, L + 1],
$$

(12)

where $\|W_i\|_2$ is the maximum singular value of $W_i$ and $\gamma$ is a hyperparameter. With (12), $\|g\|_{\text{Lip}}$ will be upper bounded by $\gamma$. Since spectrally-normalized $g$ is $\gamma$-Lipschitz continuous, it is robust with respect to noise $\Delta x$, i.e., $\|g(x + \Delta x) - g(x)\|_2$ is always bounded by $\gamma \|\Delta x\|_2$. In this paper, we apply the spectral normalization on both the $\phi_{Z(j)}(\cdot)$ and $\rho_{Z(i)}(\cdot)$ DNNs in (10).

D. **Curriculum Learning**

Training DNNs in (10) to approximate $f_a^{Z(i)}$ and $\tau_a^{Z(i)}$ requires collecting close formation flight data. However, the downwash effect causes the nominally controlled multirotors (without compensation for the interaction forces) to move apart from each other. Thus, we use a curriculum/cumulative learning approach: first, we collect data for two multirotors without a DNN and learn a model. Second, we repeat the data collection using our learned model as a feed-forward term in our controller, which allows closer-proximity flight of the two vehicle. Third, we repeat the procedure with increasing numbers of vehicles, using the current best model.

Note that our data collection and learning are independent of the controller used and independent of the $f_a^{Z(i)}$ or $\tau_a^{Z(i)}$ compensation. In particular, if we actively compensate for a learned $f_a^{Z(i)}$ or $\tau_a^{Z(i)}$, this will only affect $\eta$ in (1a) and not the observed $f_a^{Z(i)}$ or $\tau_a^{Z(i)}$.

V. **INTERACTION-AWARE MULTI-ROBOT PLANNING**

We approximately solve (6) offline by using two simplifications: i) we plan sequentially for each robot, treating other robots as dynamic obstacles with known trajectories, and ii) we use double-integrator dynamics plus learned interactions. Both simplifications are common for multi-robot motion planning with applications to multirotors [2 50]. Such a motion planning approach can be easily distributed and is complete for planning instances that fulfill the well-formed infrastructure property [31]. However, the interaction forces (10) complicate planning significantly, because the interactions are highly nonlinear and robot dynamics are not independent from each other anymore.
For example, consider a three robot team with two small and one large robot as in Fig. 1(a). Assume that we already have valid trajectories for the two small robots and now plan a motion for the large robot. The resulting trajectory might result in a significant downwash force for the small robots if the large robot flies directly above the small ones. This strong interaction might invalidate the previous trajectories of the small robots or even violate their interaction force limits $f_{\text{small}}^{\text{max}}$ and $\tau_{\text{small}}^{\text{max}}$. Furthermore, the interaction force is asymmetric and thus it is not sufficient to only consider the interaction force placed on the large robot. We solve this challenge by directly limiting the change of the interaction forces placed on all neighbors when we plan for a robot. This concept is similar to trust regions in sequential optimization [32].

The simplified state is $\mathbf{x}^{(i)} = \{\mathbf{p}^{(i)}; \mathbf{v}^{(i)}; \mathbf{f}^{(i)}\}$ and the simplified dynamics [4] become:

$$\mathbf{x}^{(i)} = \mathbf{f}^{(i)}(\mathbf{x}^{(i)}, \mathbf{u}^{(i)}) = \left[ \begin{array}{c} \mathbf{v}^{(i)} \\ \mathbf{u}^{(i)} + \mathbf{f}^{(i)} \\ \mathbf{f}^{(i)} \end{array} \right].$$  (13)

These dynamics are still complex and nonlinear because of $\mathbf{f}^{(i)}$, which is the learned interaction force represented by DNNs in (10). We include $\mathbf{f}^{(i)}$ in our state space to simplify the enforcement of the bound on the interaction force in (6).

We propose a novel hybrid two-stage planning algorithm, see Algorithm 1 leveraging the existing approaches while still highlighting the importance of considering interacting forces/torques in the planning. The portions of the pseudocode in Algorithm 1 that significantly differ from the existing methods and add interaction-awareness to our approach are highlighted. In Stage 1, we find initial feasible trajectories using a kinodynamic sampling-based motion planner. Note that any kinodynamic planner can be used for Stage 1. In Stage 2, we use sequential convex programming (SCP) [2, 32, 33] to reﬁne the initial solution to reach the desired states exactly and to minimize our energy objective defined in (6). Intuitively, Stage 1 identiﬁes the homeomorphism class of the solution trajectories and ﬁxes $\tilde{f}_j$, while Stage 2 ﬁnds the optimal trajectories to the goal within that homeomorphism class. Both stages differ from similar methods in the literature [2], because they need to reason over the coupling of the robots caused by interaction forces $\tilde{f}_j$.

A. Stage 1: Sampling-Based Planning using Interaction Forces

For Stage 1, any kinodynamic single-robot motion planner can be extended. For the coupled multi-robot setting in the present paper, we modify AO-RRT [34], which is a meta-algorithm that uses the rapidly-exploring random tree (RRT) algorithm as a subroutine.

**Sampling-Based Planner:** Our adaption of RRT (Lines 2 to 15) in Algorithm 1 works as follows. First, a random state $\mathbf{x}_{\text{rand}}$ is uniformly sampled from the state space (Line 5) and the closest state $\mathbf{x}_{\text{near}}$ that is already in the search tree $\mathcal{T}$ is found (Line 7). This search can be done efﬁciently in logarithmic time by employing a specialized data structure such as a kd-tree [35] and requires the user to deﬁne a distance function on the state space. Second, an action is uniformly sampled from the action space (Line 8) and the dynamics [4] are forward propagated for a ﬁxed time period $\Delta t$ using $\mathbf{x}_{\text{near}}$ as initial condition, e.g., by using the Runge-Kutta method (Line 9). Note that this forward propagation directly considers the learned dynamics $\mathbf{f}^{(i)}$. Third, the new state $\mathbf{x}_{\text{new}}$ is checked for validity with respect to i) the state space (which includes $\mathbf{f}^{(i)}$), ii) collisions with other robots, and iii) change and bound of the neighbor’s interaction forces (Line 10). The ﬁrst validity check ensures that the interaction force of the robot itself is bounded, while the third check is a trust region and upper bound for the neighbor’s interaction forces.

If $\mathbf{x}_{\text{new}}$ is valid, it is added as a child node of $\mathbf{x}_{\text{near}}$ in the search tree $\mathcal{T}$ (Line 11). Finally, if $\mathbf{x}_{\text{new}}$ is within an $\varepsilon$-distance to the goal $\mathbf{x}_{f}$, the solution can be extracted by following the parent pointers of each tree node starting from $\mathbf{x}_{\text{new}}$ until the root node $\mathbf{x}_{0}$ is reached (Line 15). We note that our RRT variant departs from ones in the literature which either sample $\mathbf{x}_{\text{near}}$, or use a combination of both [34]. We are interested in a constant $\Delta t$ for our optimization formulation in Stage 2. In this case, a best-control approximation would lead to a probabilistic incomplete planner [36].

While RRT is probabilistically complete, it also almost surely converges to a suboptimal solution [37]. AO-RRT remedies

---

**Algorithm 1: Interaction-aware motion planning**

**Input:** $\mathbf{x}^{(i)}_0, \mathbf{x}^{(j)}_f, \Delta t$

**Result:** $\mathbf{x}^{(i)}_{\text{sol}} = (\mathbf{x}^{(i)}_0, \mathbf{x}^{(i)}_1, \mathbf{x}^{(i)}_2, \ldots, \mathbf{x}^{(i)}_{\text{sol}})$, $U^{(i)}_{\text{sol}} = (u^{(i)}_0, u^{(i)}_1, u^{(i)}_2, \ldots, u^{(i)}_{\text{sol}})_{t_{\text{sol}} - 1}$

> Stage 1: Find duration $t_f$ and initial trajectories that are close to the goal state

1. $c^{(i)} \leftarrow \infty$, $\mathbf{x}^{(i)}_{\text{sol}} \leftarrow ()$, $U^{(i)}_{\text{sol}} \leftarrow () \forall i \in \{1, \ldots, N\}$

2. repeat

   foreach $i \in \text{RandomShuffle}([1, \ldots, N])$ do

   3. $T = ((\mathbf{x}^{(i)}_0), \emptyset)$

   4. repeat

      5. $\mathbf{x}_{\text{rand}} \leftarrow \text{UniformSample}(\mathbf{x}^{(i)}_0)$

      6. $\mathbf{x}_{\text{near}} \leftarrow \text{FindClosest}(T, \mathbf{x}_{\text{rand}})$

      7. $\mathbf{u}_{\text{rand}} \leftarrow \text{UniformSample}(U^{(i)}_t)$

      8. $\mathbf{x}_{\text{new}}, c \leftarrow \text{Propagate}((\mathbf{x}_{\text{near}}, \mathbf{u}_{\text{rand}}, \Delta t), \{\mathbf{x}^{(j)}_t | j \neq i\})$

      9. if $\text{StateValid}(\mathbf{x}_{\text{new}}, \{\mathbf{x}^{(j)}_t | j \neq i\})$ and $c \leq c^{(i)}$ then

         10. $\text{Add}(T, \mathbf{x}_{\text{near}} \rightarrow \mathbf{x}_{\text{new}})$

         11. if $\|\mathbf{x}_{\text{new}} - \mathbf{x}^{(i)}_f\| \leq \varepsilon$ then

            12. $c^{(i)} \leftarrow c$

            13. $\mathbf{x}^{(i)}_{\text{sol}}, U^{(i)}_{\text{sol}} \leftarrow \text{ExtractSolution}(T, \mathbf{x}_{\text{new}})$

            14. break

   15. until $\text{TerminationCondition}()$

   16. $\mathbf{x}^{(i)}_{\text{sol}}, U^{(i)}_{\text{sol}} \leftarrow \text{PostProcess}(\mathbf{x}^{(i)}_{\text{sol}}, U^{(i)}_{\text{sol}})$

> Stage 2: Refine trajectories sequentially; Based on SCP

17. repeat

   foreach $i \in \text{RandomShuffle}([1, \ldots, N])$ do

   18. $\mathbf{x}^{(i)}_0, U^{(i)}_t \leftarrow \text{SolveCP}(\text{Eq. (17)}, \{\mathbf{x}^{(i)}_t | \forall i\}, \{U^{(i)}_t | \forall i\})$

21. until Converged()
Fig. 3. Example for Stage 1 of our motion planning with learned dynamics. Here, we have an initial solution for a small (blue) robot and plan for a large (orange) robot. The created search tree of the large robot is color-coded by the magnitude of the interaction force on the orange robot. During the search, we reject states that would cause a significant change in the interaction force for the blue robot (edges in blue).

Modification of Sampling-Based Planner: We extend AO-RRT to a sequential interaction-aware multi-robot planner by adding \( \dot{f}_a^{(i)} \) and time to our state space and treating the other robots as dynamic obstacles. As cost, we use a discrete approximation of the objective in (6). For each AO-RRT outer-loop iteration with a fixed cost bound, we compute trajectories sequentially using a random permutation of the robots (Line 3). When we check the state for validity (Line 10), we also enforce that the new state is not in collision with the trajectories of the other robots and that their interaction forces are bounded and within a trust region compared to their previous value, see Fig. 3 for visualization. Here, the red edges show motions that cause large (\( \approx 10 \text{ g} \)) but admissible interaction forces on the orange robot, because the blue robot flies directly above it. The blue edges are candidate edges as computed in Line 9 and are not added to the search tree, because their motion would cause a violation of the interaction force trust region of the blue robot (condition in Line 10). Once the search tree contains a path to the goal region, a solution is returned (orange path).

The output of the sequential planner (Line 15) is a sequence of states \( X_{\text{sol}}^{(i)} \) and actions \( U_{\text{sol}}^{(i)} \), each to be applied for a duration of \( \Delta t \). Note that the sequences might have different lengths for each robot. Implicitly, the sequences also defines \( t_f \). Furthermore, the first element of each sequence is the robots’ start state and the last element is within a \( \epsilon \)-distance of the robots’ goal state. We postprocess this sequence of states to make it an appropriate input for the optimization, where the sequences have a uniform length (Line 17). In practice, we found that that repeating the last state and adding null actions, or (virtual) tracking of the computed trajectories using a controller are efficient and effective postprocessing techniques.

Other sampling-based methods can be used as foundation of the first stage as well, with similar changes in sequential planning, state-augmentation to include the interaction forces, state-validity checking, and postprocessing.

B. Stage 2: Optimization-Based Motion Planning

We employ sequential convex programming (SCP) for our optimization. SCP is a local optimization method for non-convex problems that leverages convex optimization. The key concept is to convexify the nonconvex portions of the optimization problem by linearizing around a prior solution. The resulting convex problem instance is solved and a new solution obtained. The procedure can be repeated until convergence criteria are met. Because of the local nature of this procedure, a good initial guess is crucial in particular for high-dimensional and highly nonlinear system dynamics. In our case, we use the searched trajectories from Stage 1 in Sec. V-A as the initial guess.

We use the following approach. First, we adopt a simple zero-order hold temporal discretization of the dynamics (13) using Euler integration:

\[
\dot{x}_k^{(i)} = x_k^{(i)} + \dot{x}_k^{(i)} \Delta t.
\]  

Second, we linearize \( \dot{x}_k^{(i)} \) around our prior states \( \dot{x}_k^{(i)} \) and actions \( \ddot{u}_k^{(i)} \):

\[
x_k^{(i)} \approx A_k(x_k^{(i)} - \dot{x}_k^{(i)}) + B_k(u_k^{(i)} - \ddot{u}_k^{(i)}) + f(i)(\dot{x}_k^{(i)}, \ddot{u}_k^{(i)}),
\]  

where \( A_k \) and \( B_k \) are the partial derivative matrices of \( f(i) \) with respect to \( x_k^{(i)} \) and \( u_k^{(i)} \) evaluated at \( \dot{x}_k^{(i)}, \ddot{u}_k^{(i)} \). Because we encode \( f_a^{(i)} \) using fully-differentiable DNNs, the partial derivatives can be efficiently computed analytically, e.g., by using autograd in PyTorch [38].

Third, we linearize \( f_a^{(j)} \) around our prior states \( x_k^{(i)} \) for all neighboring robots \( j \in \text{neighbor}(i) \):

\[
f_a^{(j)} \approx C_k^{(j)}(x_k^{(i)} - \dot{x}_k^{(i)}) + f_a^{(j)}(x_k^{(i)}),
\]  

where \( C_k^{(j)} \) is the derivative matrix of \( f_a^{(j)} \) (the learned interaction function of robot \( j \), represented by DNNs) with respect to \( x_k^{(i)} \) evaluated at \( x_k^{(i)} \) and \( r_f^{(j)}(\dot{x}_k^{(i)}) \) is the ordered sequence of relative states as defined in (3) but using the fixed prior state \( \dot{x}_k^{(i)} \) rather than decision variable \( x_k^{(i)} \) in (2).
we can formulate the following convex programs, one per robot:

$$\min_{x_k(0), u_k} \sum_{i=0}^{T} \|u_k(i)\|^2 + \lambda_1 \|x_T - x_f(i)\|_\infty + \lambda_2 \delta$$  \hspace{1cm} (17)

subject to:

$$x_k(i) \in X_{\delta}(i), \quad i \in [1, N]$$

$$u_k(i) \in U(i), \quad i \in [1, N]$$

$$x_k(i) - \tilde{x}_k(i) \geq \gamma_{\tau}(i) \|p_k(i)\|_2, \quad i \in [1, N], \delta \geq 0$$

$$\gamma_{u}(i) = \gamma_{\tau}(i)^\tau \tilde{p}_k(i), \quad i \in [1, N]$$

$$|C_k(i) (x_k(i) - \tilde{x}_k(i))| \leq b_{fa}, \quad i < j, j \in [2, N]$$

$$|x_k(i) - \tilde{x}_k(i)| \leq b_x, \quad |u_k(i) - \tilde{u}_k(i)| \leq b_u, \quad i \in [1, N]$$

where $X_{\delta}(i)$ is the state space increased by $\delta$ in each direction, the linearized robot dynamics are similar to [22], and the convexified inter-robot collision constraint is from [2]. We use soft constraints for reaching the goal (with weight $\lambda_2$) and the state space (with weight $\lambda_2$), and trust regions around the solution of the previous iteration (Lines 18 to 21 in Algorithm 1). It is possible to implement Algorithm 1 in a distributed fashion similar to prior work [2].

VI. INTERACTION-AWARE TRACKING CONTROLLER

Given arbitrary desired trajectories, including ones that have not been computed using the method presented in Sec. V, we augment existing nonlinear position and attitude controllers for multicopters [39] [40] that account for interaction force and torques and compensate motor delays.

A. Tracking Control Law with Delay Compensation

We use a typical hierarchical structure as shown in Fig. 4 for controlling multicopter robots. Given the desired 3-dimensional position trajectory $p_d(i)(t)$ for robot $i$, we define a reference velocity

$$v_r(i) = \dot{p}_d(i) - A_p(i) \tilde{p}_d(i),$$  \hspace{1cm} (18)

with position error $\tilde{p}_d(i) = p_d(i) - \tilde{p}_d(i)$ and gain matrix $A_p(i) > 0$. The position controller is defined by the desired thrust vector

$$f_d(i) = -m(i) g + m(i) \dot{v}_r(i) - \dot{\tilde{f}}_d(i)$$

$$- (K_v(i) + m(i) \Gamma_v(i)) \ddot{v}_r(i) - K_v(i) \Gamma_v(i) \int \dot{v}_r(i),$$  \hspace{1cm} (19)

where $\dot{v}_r(i) = v_r(i) - \dot{\tilde{v}}_r(i)$ is the velocity error, and $K_v(i)$, $\Gamma_v(i)$ are positive definite gain matrices. From (1a), by setting $R(i) f_d(i) = \tilde{f}_d(i)$, we compute the total desired thrust $T_d(i) = f_d(i)$. \hat{k} and the desired attitude $\tilde{R}_a(i)$ [10]. We convert the error rotation matrix $\tilde{R}_d(i) = \tilde{R}_a(i)^T \tilde{R}_a(i)$ to a constrained quaternion error $\tilde{q}_e(i) = \frac{1}{2} (\tilde{q}_e(i))$, and define the reference angular rate as

$$\omega_r(i) = \tilde{R}_d(i)^T \omega_d(i) - \Lambda_q(i) \omega_d(i).$$  \hspace{1cm} (20)

We use the following nonlinear attitude controller from [39] with interaction torque compensation:

$$\tau_d(i) = J(i) \omega_r(i) - J(i) \omega(i) \times \omega_r(i) - \tau_a(i)$$

$$- K_\omega(i) \dot{\omega}(i) - \Gamma_\omega(i) \int \dot{\omega}(i).$$  \hspace{1cm} (21)

$K_\omega(i)$ and $\Gamma_\omega(i)$ are positive definite gain matrices on angular rate error $\dot{\omega}(i) = \omega(i) - \dot{\tilde{\omega}}(i)$ and its integral, respectively.

From (19) and (21), the desired output wrench for the $i$-th robot $\eta_d(i) = [T_d(i) \tau_d(i)]$ must be realized through a delayed motor signal $u_c(i)$ from (1c). Here, we implement a simple yet effective method to compensate for motor delay [41]:

$$u_c(i) = B_0(i)^T \left[ (\eta_d(i) + \frac{\eta_d(i)}{\lambda(i)}) \right],$$  \hspace{1cm} (22)

where the actuation matrix $B_0(i)$ and delay constant $\lambda(i)$ are determined apriori. We consider the multicopter to be fully motorized and delay constant $\lambda(i)$ to be realized through a delayed motor signal $u_c(i)$ from (1c).

B. Analysis of Stability and Robustness

The robust position and attitude controllers (19) and (21) can handle bounded model disturbance [10] [39]. Here, we make the same assumption as in [10] [17], that the learning errors and their rates of change are upper bounded.

Assumption 1 (Bounded approximation error of DNNs). We denote the approximation errors between the learned model in [10] and the true unmodeled dynamics for interaction force and torque as $\epsilon_f = f_d(i) - \tilde{f}_d(i)$ and $\epsilon_r = \tau_d(i) - \tilde{\tau}_d(i)$, respectively. For each robot, we assume $\epsilon_f$ and $\epsilon_r$ are
uniformly upper bounded. Formally, \( \sup_{x(t) \in X(t)} \| e_f \| = \varepsilon_f^{(i)} \) and \( \sup_{x(t) \in X(t)} \| e_r \| = \varepsilon_r^{(i)} \). Furthermore, we assume the time derivative of errors are upper bounded as well, i.e \( \sup_{x(t) \in X(t)} \| \dot{e}_f \| = \dot{\varepsilon}_f^{(i)} \) and \( \sup_{x(t) \in X(t)} \| \dot{e}_r \| = \dot{\varepsilon}_r^{(i)} \).

Note that the \( \varepsilon_f^{(i)} \), \( \varepsilon_r^{(i)} \), \( \dot{\varepsilon}_f^{(i)} \) and \( \dot{\varepsilon}_r^{(i)} \) can all be derived from Lipschitz of DNNs in [10] if spectrally normalized [9, 29]. Under Assumption 1, we can show the stability of the position and attitude controllers using results from [11, 39].

**Theorem 5.** For the position controller defined in (18) and (21) under Assumption 1, the attitude tracking error \( \| p^{(i)} \| \) converges exponentially to an error ball:

\[
\lim_{t \to \infty} \| \tilde{p}^{(i)} \| = \frac{\dot{\varepsilon}_f^{(i)}}{\lambda_{\min} (\Lambda_p^{(i)}) \lambda_{\min} (\Gamma_v^{(i)}) \lambda_{\min} (K_v^{(i)})} \quad (23)
\]

**Proof.** Select sliding variables: \( s_1 = \tilde{p}^{(i)} + \Lambda_p^{(i)} \tilde{p}^{(i)} \) and \( s_2 = m \tilde{s}_1 + K_v s_1 \). Then, (19) can be written as

\[
f_d^{(i)} = -m \dot{p}^{(i)} + m \dot{v}^{(i)} - \dot{\tilde{f}}_a - K_v^{(i)} s_1 - \Gamma_v^{(i)} \int s_2.
\]

Applying to (1a), we get closed-loop dynamics \( \dot{s}_2 + \Gamma_v^{(i)} \dot{s}_2 = \dot{\varepsilon}_f \). Thus combining hierarchical linear systems of \( \dot{s}_1 \) and \( \dot{s}_2 \), we can easily arrive at (23).

**Theorem 6.** For the attitude controller defined in (21) and (22) under Assumption 1, the attitude tracking error \( \| q_v^{(i)} \| \) converges exponentially to an error ball determined by \( d_v^{(i)} \).

**Proof.** Applying (21) to (1b), we get closed-loop dynamics

\[
J^{(i)} \dot{\omega}^{(i)} - J^{(i)} \omega^{(i)} \times \hat{\omega}^{(i)} - K_v^{(i)} \omega^{(i)} - \Gamma_v^{(i)} \int \hat{\omega}^{(i)} = \varepsilon_r^{(i)}
\]

Following the proof structure for Theorem 2 in [39], we can derive an ultimate bound for \( \| q_v^{(i)} \| \) determined by \( d_v^{(i)} \).

With motor delay, we can state the following result for stabilizing the output wrench error \( \tilde{\eta}^{(i)} = \eta^{(i)} - \eta^{(i)} \) with (22), assuming the motor delay constant is obtained from testing.

**Theorem 7.** For robot \( i \), the controllers (19), (21) and (22) will exponentially stabilize the augmented states of position, attitude and output wrench error: \( \| p^{(i)} \|, \| v^{(i)} \|, \| q_v^{(i)} \|, \| \hat{\omega}^{(i)} \|, \| \dot{\eta}^{(i)} \| \).

**Proof.** (19) and (21) stabilizes \( \| p^{(i)} \|, \| v^{(i)} \|, \| q_v^{(i)} \|, \| \hat{\omega}^{(i)} \|, \| \dot{\eta}^{(i)} \| \) exponentially from Theorems 5 and 6. Thus by Theorem 3.1 from [41], it follows that the augmented states is also exponentially stabilized by (22).

Even with small modeling error on \( \lambda^{(i)} \), controller (22) can robustly cancel out some effects from delays and improve tracking performance in practice. Furthermore, it can handle not only first-order motor delay [13], but also signal transport delays as discussed in [41]. In case of the small quadrotors used in our experiments, such delays exist on similar order of magnitude, thus making (22) essential for improving the control performance.

**VII. EXPERIMENTS**

We use quadrotors based on Bitcraze Crazyflie 2.0/2.1 (CF). Our small quadrotors are Crazyflie 2.X, which are small (9 cm rotor-to-rotor) and lightweight (34 g) products that are commercially available. Our large quadrotors use the Crazyflie 2.1 as control board on a larger frame with brushed motors (model: Parrot Mini Drone), see Table 1 for a summary of physical parameters. We use the Crazyswarm [42] package to control multiple Crazyflies simultaneously. Each quadrotor is equipped with a single reflective marker for position tracking at 100 Hz using a motion capture system. The nonlinear controller, extended Kalman filter, and neural network evaluation are running on-board the STM32 microcontroller.

For the controller, we implement the delay compensation (22) in the following way: i) we numerically estimate \( \hat{\tau}^{(i)} \) as part of the position controller (19), and ii) we approximate \( \hat{\tau}^{(i)} \) by adding the additional term \( -K_v^{(i)} \hat{\omega}^{(i)} \) to the attitude controller (21), where \( \hat{\omega}^{(i)} \) is numerically estimated and \( K_v^{(i)} \) is a positive definite gain matrix. We found that the other terms of \( \hat{\tau}^{(i)} \), i.e. the time-derivative of (21), are negligible for our use-case. Our baseline controller is identical (including the chosen gains) to our proposed controller with the exception that the interaction force is set to zero. Note that our baseline controller is more robust than the default controller in the Crazyswarm package, which cannot safely execute the close-proximity flight shown in Fig. 1(c).

For data collection, we use the uSD card extension board and store binary encoded data roughly every 10 ms. Each dataset is timestamped using the on-board microsecond timer and the clocks are synchronized before takeoff using broadcast radio packets. The drift of the clocks of different Crazyflies can be ignored for our short flight times (less than 2 min).

**A. Calibration and System Identification of Different Robots**

Prior to learning the residual terms \( f_a^{(i)} \) and \( \tau_a^{(i)} \), we first calibrate the nominal dynamics model \( \Phi^{(i)}(x, u) \). We found that existing motor thrust models [43, 44] are not very accurate, because they only consider a single motor and ignore the effect of the battery state of charge. We
callibrate each Crazyflie by mounting the whole quadrotor upside-down on a load cell (model TAL221) which is directly connected to the Crazyflie via a custom extension board using a 24-bit ADC (model HX711). The upside-down mounting avoids contamination of our measurements with downwash-related forces. We use a 100 g capacity load cell for the small quadrotor and a 500 g capacity load cell for the large quadrotor. We randomly generate desired PWM motor signals (identical for all 4 motors) and collect the current battery voltage, PWM signals, and measured force. We use this data to find three polynomial functions: $\psi_1$, $\psi_2$, and $\psi_3$. The first function $f = \psi_1(\hat{p}, \hat{v})$ computes the force of a single rotor given the normalized PWM signal $\hat{p}$ and the normalized battery voltage $\hat{v}$. This function is only required for the data collection preparation in order to compute $\hat{f}_a^{(i)}$. The second function $\hat{p} = \psi_2(f, \hat{v})$ computes the required PWM signal $\hat{p}$ given the desired force $\hat{f}$ and current battery voltage $\hat{v}$. Finally, $\hat{f}_{\max} = \psi_3(\hat{p}, \hat{v})$ computes the maximum achievable force $\hat{f}_{\max}$, given the current PWM signal $\hat{p}$ and battery voltage $\hat{v}$. The last two functions are important at runtime for outputting the correct force as well as for thrust mixing when motors are saturated [45].

We use the same measurement setup with the load cell to establish the delay model of $T_d^{(i)}$ with a square wave PWM signal. While the delay model is slightly asymmetric in practice, we found that our symmetric model (1c) is a good approximation. All results are summarized in Table I. We use the remaining parameters (J, thrust-to-torque ratio) from the existing literature [44].

### B. Data Collection

Recall that in [10], we need to learn $2K$ neural networks if we have $K$ types of robots. In our experiments, we consider two types of quadrotors (small and large) and also the environment (mainly ground effect and air drag), as shown in Example 1. Therefore, we have 5 neural networks to be learned:

$$\rho_{\text{small}}, \rho_{\text{large}}, \phi_{\text{small}}, \phi_{\text{large}}, \phi_{\text{env}},$$

where we do not have $\rho_{\text{env}}$ because aerodynamical force acting on the environment is not interesting for our purpose. To learn these 5 neural networks, we fly the heterogeneous swarm in 12 different scenarios (see Table III) to collect labeled $\hat{f}_a^{(i)}$ and $\tau_a^{(i)}$ data for each robot. For instance, Example 1 (as depicted in Fig. 1a) corresponds to the “{S,S} → L” scenario in Table III where the large robot has two small robots and the environment as its neighbors.

We utilize two types of data collection tasks: random walk and swapping. For random walk, we implement a simple reactive collision avoidance approach based on artificial potentials on-board each Crazyflie [45]. The host computer randomly selects new goal points within a small cube for each vehicle at a fixed frequency. These goal points are used as an attractive force, while neighboring drones contribute a repulsive force. For swapping, the drones are placed in different horizontal planes on a cylinder and tasked to move to the opposite side. All the drones are vertically aligned for one time instance, causing a large interaction force. The random walk data helps us to explore the whole space quickly, while the swapping data ensures that we have data for a specific task of interest. Note that for both random walk and swapping, the drones also move close to the ground, to collect sufficient data for learning the ground effect. For both task types, we varied the scenarios listed in Table III.

To learn the 5 DNNs in (24), for each robot in each scenario, we collect the timestamped states $x^{(i)} = [p^{(i)}, v^{(i)}, R^{(i)}, a^{(i)}]$ for each robot $i$. Then we compute $y^{(i)}$ as the observed value of $f_a^{(i)}$ and $\tau_a^{(i)}$. We compute $\hat{f}_a^{(i)}$ and $\hat{\tau}_a^{(i)}$ using (4), where the nominal dynamics $\Phi^{(i)}$ is calculated based on our system identification in Sec. VII-A. Note that the control delay is also considered when we compute $\hat{f}_a^{(i)}$ and $\hat{\tau}_a^{(i)}$. Our training data consists of sequences of $(\{r_{\text{type}_j}^{(i)}, \ldots, r_{\text{type}_K}^{(i)}\}, y^{(i)})$ pairs, where $r_{\text{type}_j}^{(i)} = \{x^{(ij)} | j \in \text{neighbor}(i) \}$ and $I(j) = \text{type}_j$ is the set of the relative states of the type-$j$ neighbors of $i$. We have the following loss function for robot $i$ in each scenario (see Table III for the detailed model structure in each scenario):

$$\left\| \rho_T^{(i)} \left( \sum_{k=1}^{K} \sum_{x^{(ij)} \in I^{(i)}_{\text{type}_j}} \phi_{\text{type}_j}(x^{(ij)}) \right) - y^{(i)} \right\|_2^2,$$

and we stack all the robots’ data in all scenarios and train on them together.

In practice, we found the unmodeled torque $\|\tau_a^{(i)}\|$ is very small in magnitude and almost like white noise, so we only learn $f_a^{(i)}$. We compute the relative states from our collected data as $x^{(ij)} = [p^{(j)} - p^{(i)}, v^{(j)} - v^{(i)}] \in \mathbb{R}^6$ (i.e., relative position and relative velocity both in the world frame), since the attitude information $R$ and $\omega$ are not dominant for $f_a^{(i)}$. If the type of neighbor $j$ is “environment”, we set $p^{(j)} = 0$ and $v^{(j)} = 0$. In this work, we only learn the $z$ component of $f_a^{(i)}$ since we found the other two components, $x$ and $y$, are very small, and do not significantly alter the nominal dynamics. Therefore, the output of our learning model in (10) is a scalar to approximate the $z$ component of the unmodeled force function $\hat{f}_a^{(i)}$.

### C. Learning Results and Ablation Analysis

Each scenario uses a trajectory with a duration around 1000 seconds. For each scenario, we equally split the total trajectory into 50 shorter pieces, where each one is about 20 seconds. For each scenario, we equally split the total trajectory into 50 shorter pieces, where each one is about 20 seconds. Then we randomly choose 80% of these 50 trajectories for training and 20% for validation.

Our DNN functions of $\phi$ ($\phi_{\text{small}}, \phi_{\text{large}}, \phi_{\text{env}}$) have four layers with architecture $6 \rightarrow 25 \rightarrow 40 \rightarrow 40 \rightarrow H$, and our $\rho$ DNNs ($\rho_{\text{small}}, \rho_{\text{large}}$) also have $L = 4$ layers, with architecture $H \rightarrow 40 \rightarrow 40 \rightarrow 40 \rightarrow 1$. We use the ReLU function as the activation operator, and we use PyTorch for training and implementation of spectral normalization (see Sec. IV-C) of all these five DNNs. In training, we iterate all the data 20 times for error convergence.

Note that $H$ is the dimension of the hidden state. To study the effect of $H$ on learning performance, we use three different values of $H$ and the mean validation errors for each $H$ are
(mean validation error) is not sensitive to three times to get mean and standard deviation. As depicted and in Fig. 5(a) the small multirotor only has the environment indicated by the red color in that part of the heatmap. Similarly, the magnitude of \( \hat{f}_{a,z} \) for a single small multirotor positioned \( \{\phi_{\text{env}}, \phi_{\text{small}}\} \) networks. Each heatmap gives the prediction of \( f_{a,z} \) of a vehicle in different horizontal and vertical (global) positions, and the (global) position of neighboring drones are represented by drone icons. A more detailed explanation is in Sec. VII-C.

As shown in Table III. Meanwhile, we also study the influence of the number of layers by fixing \( H = 20 \) and changing \( L \), which is the number of layers of all \( \rho \) nets and \( \phi \) nets. For \( L = 3 \) or \( L = 5 \), we delete or add a \( 40 \rightarrow 40 \) layer for all \( \rho \) nets and \( \phi \) nets, before their last layers. We repeat all experiments three times to get mean and standard deviation. As depicted in Table III, we found that the average learning performance (mean validation error) is not sensitive to \( H \), but larger \( H \) results in higher variance. In terms of the number of layers, four layers are significantly better than five (which tends to overfit data), and slightly better than three. To optimize performance, we finally choose \( H = 20 \) and use four-layer neural networks, which can be efficiently evaluated on-board.

Figure 5 depicts the prediction of \( f_{a,z} \), trained with flying data from 12 scenarios listed in Table II. The color encodes the magnitude of \( f_{a,z} \) for a single small multirotor positioned at different global \((y, z)\) coordinates. The big/small black drone icons indicate the (global) coordinates of neighboring big/small multirotors, and the dashed line located at \( z = 0 \) represents the ground. All quadrotors are in the same \( x \)-plane. For example, in Fig. 5(e) one large quadrotor is hovering at \((y = -0.1, z = 0.5)\) and one small quadrotor is hovering at \((y = 0.1, z = 0.5)\). If we place a third small quadrotor at \((y = 0, z = 0.3)\), it would estimate \( \hat{f}_{a,z} = -10 g \) as indicated by the red color in that part of the heatmap. Similarly, in Fig. 5(a) the small multirotor only has the environment as a special neighbor. If the small multirotor is hovering at \((y = 0, z = 0.05)\), it would estimate \( \hat{f}_{a,z} = 5 g \), which is mainly from the ground effect. All quadrotors are assumed to be stationary except for Fig. 5(d), where the one neighbor is moving at \( 0.8 \text{ m/s} \).

We observe that the interaction between quadrotors is non-stationary and sensitive to relative velocity, as well as not a simple superposition between pairs. In Fig. 5(d), the vehicle’s neighbor is moving, and the prediction becomes significantly different from Fig. 5(c), where the neighbor is just hovering. We can also observe that the interactions are not a simple superposition of different pairs. For instance, Fig. 5(g) is significantly more complex than a simple superposition between pairs. In Fig. 5(d), the vehicle’s neighbor is moving, and the prediction becomes significantly different from Fig. 5(c), where the neighbor is just hovering. We can also observe that the interactions are not a simple superposition of different pairs. For instance, Fig. 5(g) is significantly more complex than a simple superposition of three repeated Fig. 5(b). Moreover, we find that the ground effect and the downwash effect from neighboring multirotor interact in an interesting way. For instance, in Fig. 5(b), the downwash effect is “mitigated” as the vehicle gets closer to the ground. Finally, we observe that the large quadrotors cause significantly higher interaction forces than the small ones (see Fig. 3(e)), which further emphasizes the importance of our heterogeneous modeling.

Note that in training we only have data from 1-3 vehicles (see Table II). Our approach can generalize well to a larger system. In Fig. 5 predictions for a 4-vehicle team (as shown in Fig. 5(g,h)) are still reasonable. Moreover, our models work well in real flight tests with 5 vehicles (see Fig. 9) and even

D. Motion Planning with Aerodynamics Coupling

We implement Algorithm 1 in Python using PyTorch 1.5 [38] for automatic gradient computation, CVXPY 1.0 [47]
for convex optimization, and GUROBI 9.0 [48] as underlying solver. To simulate the tracking performance of the planned trajectories, we also implement a PID controller, which uses the planned controls as feed-forward term. We compare trajectories that were planned with a learned model of \( f_{a,z} \) with trajectories without such a model (i.e., \( f_{a,z} = 0 \)) using Algorithm 1 with identical parameters. At testing time, we track the planned trajectories with our controller, and forward propagate the dynamics with our leaned model of \( f_{a,z} \) in all cases.

We visualize an example in Fig 6 where two small and one large robots are tasked with exchanging positions. We focus on the 2D case in the \( yz \)-plane to create significant interaction forces between the robots. The first stage of Algorithm 1 uses sampling-based motion planning to identify the best homeomorphism class where the small multirotors fly on top of the large multirotor (the interaction forces would require more total energy the other way around). However, the robots do not reach their goal state exactly and motions are jerky (Fig. 6 left). The second stage uses SCP to refine the motion plan such that robots reach their goal and minimize the total control effort (Fig. 6 middle). The planned trajectory can be tracked without significant error and the interaction forces are very small for the two small quadrotors and within the chosen bound of \( 10 g \) for the large quadrotor. We compare this solution to one where we do not consider the interaction forces between robots by setting \( f_{a,z} = 0 \) in Algorithm 1. The planned trajectories tend to be shorter (Fig. 6 right, dashed lines) in that case. However, when tracking those trajectories, significant tracking errors occur and the interaction forces are outside their chosen bounds of \( 5 g \) for the small multirotors.

We empirically evaluated the effect of planning with and without considering interaction forces in several scenarios, see Fig. 7. We found that ignoring the interaction forces leads to significant tracking errors consistently in all cases (top row). While this tracking error could be reduced when using our interaction-aware control law, the interaction forces are in some cases significantly over their desired limit. For example, in the small/large, small/small/large, and large/large cases, the worst-case interaction forces were consistently nearly double of their limit (red line, bottom row). In practice, such large disturbances might cause instabilities or even total loss of control, justifying the use of an interaction-aware motion planner.

E. Control Performance in Flight Tests

We study the flight performance improvements on swapping tasks with varying number of quadrotors. For each case, robots are initially arranged in a circle when viewed from above but at different \( z \)-planes and are tasked with moving linearly to the opposite side of the circle in their plane. During the swap, all vehicles align vertically at one point in time with vertical distances of 0.2 m to 0.3 m between neighbors. The tasks are similar, but not identical, to the randomized swapping tasks used in Sec. VII-B because different parameters (locations, transition times) are used.

Our results are summarized in Fig. 8 for various combinations of two and three multirotors. Here, we compute a box plot with median (green line) and first/third quartile (box) of the maximum \( z \)-error (repeated over 6 swaps). In some cases, the downwash force was so large that we upgraded the motors of the small quadrotor to more powerful ones to improve the best-case thrust-to-weight ratio to 2.6. Such modified quadrotors are indicated as “S*”. We also verified that the \( x \)- and \( y \)-error distributions are similar across the different controllers and do not report those numbers for brevity.

Our controller improves the median \( z \)-error in all cases and in most cases this improvement is statistically significant. For example, in the “L2S” case, where a large multirotor is on top of a small multirotor for a short period of time, the median \( z \)-error is reduced from 17 cm to 7 cm.

To estimate the limits of our learning generalization, we test our approach on larger teams. First, we consider a team of five robots, where two large robots move on a circle in the horizontal plane and three small robots move on three vertical planes such that the two circles form intertwined rings. In this case, the \( f_{a,z} \) prediction is accurate and the maximum \( z \)-error can be reduced significantly using our neural network prediction, see Fig. 9 for an example. Second, we consider a team of 16 robots moving on three intertwined rings as shown in Fig. 11(b,c). Here, two large and four small robots move on an ellipsoid in the horizontal plane, and five robots move on circles in different vertical planes. In this case, robots can have significantly more neighbors (up to 15) compared to the training data (up to 2), making the prediction of \( f_{a,z} \) relatively less accurate. However, the maximum \( z \)-error of a small multirotor in one of the vertical rings with powerful motors is still reduced from 15 cm to 10 cm.

VIII. Conclusion

In this paper, we present Neural-Swarm2, a learning-based approach that enables close-proximity flight of heterogeneous multirotor teams. Compared to previous work, robots can fly much closer to each other safely, because we accurately predict the interaction forces caused by previously unmodeled aerodynamic vehicle interactions. To this end, we introduce heterogeneous deep sets as an efficient and effective deep neural network architecture to learn the interaction forces between
multiple quadrotors and only relies on relative positions and velocities of neighboring vehicles. Our architecture also allows to model the ground effect and other unmodeled dynamics by viewing the physical environment as a special neighboring to model the ground effect and other unmodeled dynamics. Our architecture also allows to model the ground effect and other unmodeled dynamics.

We demonstrate that the learned interactions are crucial in two applications of close-proximity flight. First, they can be used effectively in multi-robot motion planning to compute trajectories that have bounded disturbances caused by neighboring robots and that consider platform limitations such as maximum thrust capabilities directly. The resulting trajectories allow a higher robot density compared to existing work that relies on conservatively enlarged collision shapes. Second, we can compute the interaction forces in real-time on a small 32-bit microcontroller and apply them as additional feed-forward term in a novel delay-compensated nonlinear stable tracking controller. Such an approach enables to reduce the tracking error significantly, if the maximum thrust capabilities of the robots are sufficient.

We validate our approach on different tasks using two to sixteen quadrotors of two different sizes and demonstrate that our training method generalizes well to a varying number of
