Euclid: impact of nonlinear prescriptions on cosmological parameter estimation from weak lensing cosmic shear

(Affiliations can be found after the references)

ABSTRACT

Upcoming surveys will map the growth of large-scale structure with unprecedented precision, improving our understanding of the dark sector of the Universe. Unfortunately, much of the cosmological information is encoded by the small scales, where the clustering of dark matter and the effects of astrophysical feedback processes are not fully understood. This can bias the estimates of cosmological parameters, which we study here for a joint analysis of mock Euclid cosmic shear and Planck cosmic microwave background data. We use different implementations for the modelling of the signal on small scales and find that they result in significantly different predictions. Moreover, the different nonlinear corrections lead to biased parameter estimates, especially when the analysis is extended into the highly nonlinear regime, with both the Hubble constant, H0, and the clustering amplitude, σ8, affected the most. Improvements in the modelling of nonlinear scales will therefore be needed if we are to resolve the current tension with more and better data. For a given prescription for the nonlinear power spectrum, using different corrections for baryon physics does not significantly impact the precision of Euclid, but neglecting these correction does lead to large biases in the cosmological parameters. In order to extract precise and unbiased constraints on cosmological parameters from Euclid cosmic shear data, it is therefore essential to improve the accuracy of the recipes that account for nonlinear structure formation, as well as the modelling of the impact of astrophysical processes that redistribute the baryons.

Key words. Gravitational lensing: weak – large scale structure of Universe – cosmological parameters

1. Introduction

The next generation surveys (stage IV) of the cosmic large-scale structure will greatly improve both the amount and quality of data for cosmological investigations. For instance, in the coming decade the surveys carried out by Euclid,3 the Vera Rubin C. Observatory,4 and the Nancy Grace Roman Space Telescope5 will probe scales and redshifts that were previously inaccessible. The correct interpretation of such a large amount of high-quality data, however, also poses a challenge for our theoretical modelling.

In this paper we explore the current modelling limitations for one of the most promising probes: cosmic shear, the measurement of the apparent distortions of galaxy shapes caused by the weak lensing (WL) effect of intervening matter between us and the distant sources (see Kilbinger2015 for a recent review). It provides a direct way to trace the distribution of matter, and as a result it can be used to infer the total matter power spectrum, Pδδ(k,z). In contrast, the galaxy power spectrum, Pgg(k,z), estimated from the clustering of galaxies, depends on the galaxy bias and how galaxies occupy nonlinear structures.

A complication is that much of the constraining power of the cosmic shear signal relies on being able to interpret scales far into the nonlinear regime, corresponding to wavenumbers k ≈ 7 h Mpc−1 (e.g. Huterer & Takada2005 Semboloni et al.2011 Taylor et al.2018b). On those scales, perturbations of the matter density field are no longer

3 https://roman.gsfc.nasa.gov/
There are theoretical approaches to predict clustering beyond the limit of linear theory, such as: standard perturbation theory [Blas et al. 2014; see also (Bernaldeau et al. 2002) for a detailed review] that includes higher-order terms; renormalised perturbation theory (Croce & Scoccimarro 2006; Croce et al. 2012; Blas et al. 2016); response functions (Nishimichi et al. 2016): effective field theory (Baumann et al. 2012); or the reaction method (Cataneo et al. 2019). These methods are able to achieve accuracies on power spectrum predictions of ≈1% with respect to numerical simulations, up to scales $k \lesssim 0.3 \, h \, \text{Mpc}^{-1}$ (see e.g. [Foreman & Senatore 2016; Beutler et al. 2017; D’Amico et al. 2019]). This is sufficient for modelling the mildly non-linear regime, where the baryonic acoustic oscillation peak is located, but these techniques cannot be used to predict the signal in the highly non-linear regime that WL analyses will probe.

The common approach to model the nonlinear part of the power spectrum instead relies on fitting formulae determined from comparisons to $N$-body simulations of cold dark matter particles (e.g. Halofit: Smith et al. 2003). While very economical in terms of CPU time, these fitting formulae have a limited range of applicability, because the simulations they are based on assume a specific model – usually ΛCDM or minimal extensions with a constant dark energy equation of state parameter allowed to be different from −1. Thus, applying these corrections to models outside the range constrained by the simulations, e.g. a more general dark energy fluid, may lead to biased results (see e.g. Casarini et al. 2011a; Seo et al. 2012).

Recently, so-called ‘emulators’ – based on a large suite of simulations, such as the Coyote Universe (Heitmann et al. 2010, 2009; Lawrence et al. 2010; Heitmann et al. 2014), the Mira Universe (Heitmann et al. 2016; Lawrence et al. 2017), and the Euclid Emulator Project (Knabenhans et al. 2019) – have been proposed as an alternative to fitting formulae. Emulators interpolate between high-resolution simulation runs at key points (nodes) in the cosmological parameter space. The main advantage of an emulator with respect to a fitting formula is that it does not degrade the accuracy of the corrections over the parameter space sampled by the simulations, such as the range in redshift and scales.

Another way to predict the matter power spectrum on small scales is provided by HMCode [5] (Mead et al. 2015), which is based on the analytical halo model (Peacock & Smith 2000; Seljak 2000; Cooray & Sheth 2002), and tuned to match the Coyote Extended Emulator (Heitmann et al. 2014) results. It has subsequently been improved to include effects of neutrinos, chameleon and Vainshtein screened models, and dynamical dark energy [Mead et al. 2016] 4.

All these methods, besides the declared quality of the method itself (for example the accuracy of the fitting formula, or the accuracy of the interpolation of the emulators), also depend on the quality of the simulations on which they are based. Restricting ourselves to just the nonlinear clustering, the agreement between purely dark matter simulations is limited by the size of the simulated volume, the number of particles employed in the simulation and the choice of initial conditions (see e.g. Casarini et al. 2015; Schneider & Teyssier 2015). Hence, part of the differences between the methods described above may be attributed to the simulation parameters on which they are based (e.g. when dimension and resolution are insufficient) rather than the methods themselves.

Moreover, our ability to extract cosmological information from WL measurements on small scales is limited further by baryonic feedback processes (Sembolini et al. 2011), because gas cooling, star formation, galactic winds, supernova explosions, and feedback from active galactic nuclei modify the expected distribution of matter on small scales (Jing et al. 2006; Rudd et al. 2008; Casarini et al. 2011b; van Daalen et al. 2011; Casarini et al. 2012; Castro et al. 2016; Debackere et al. 2020). Accurate predictions of the matter power spectrum on those scales require hydrodynamical simulations that not only need to reproduce the nonlinear clustering of cold dark matter particles, but also should reliably describe the baryonic component. Such hydrodynamical simulations are much more demanding in terms of computational resources, and the impact of baryonic feedback extracted from hydrodynamical runs has to be modelled and incorporated in the reconstruction of the cosmic shear signal (see e.g. Schneider & Teyssier 2015; Schneider et al. 2016) for a method to include the impact of feedback in the data analysis pipeline).

Given the cost of simulating large volumes with high-resolution for every necessary point in the parameter space for each specific cosmological model, we are particularly interested in techniques that can drastically reduce the number of simulations (see Linder & White 2005; Francis et al. 2007; Casarini et al. 2009). As an example, in this work we use the PKequal [6] method that allows us to determine the nonlinear power spectrum of a dynamical dark energy model at a particular redshift with an ensemble of nonlinear spectra of simpler constant $w$ models (Casarini et al. 2009, 2016).

In this paper, we investigate the impact of different implementations of the nonlinear corrections and baryonic feedback prescriptions on cosmological parameter estimation, adopting cosmic shear measurements from Euclid (Laureijs et al. 2011) as our baseline. Notice that we do not investigate here other effects that might affect the parameter estimation pipeline, such as the common assumption of a Gaussian likelihood, which is only an approximation. The paper is organised as follows. After describing the various nonlinear recipes in Sect. 2, in Sect. 3 we summarise the Euclid specifications relevant for our analysis. As a first example of the impact of nonlinear prescriptions, we assess in Sect. 4 the constraining power of the Euclid survey on the dark energy parameters, here assumed to be described by the so-called CPL parameterisation (Chevallier & Polarski 2001; Linder 2003). In Sect. 5 we quantify the shifts in cosmological parameters when a wrong correction pipeline is used, focusing on the combination of Planck and mock Euclid data. In Sect. 6 we examine the impact of baryonic feedback.

5. During the preparation of this work an update of HMCode was published, as described in Mead et al. (2020).

2. Available nonlinear prescriptions

In this section we describe the techniques that we use in this study to compute the matter power spectrum in the deeply nonlinear regime.

2.1. Halofit

One of the first widely used prescriptions to model the nonlinear part of the power spectrum, called Halofit, was developed by [Smith et al. (2003)]. The authors measured the nonlinear evolution of the matter power spectra using a large library of cosmological N-body simulations with power-law initial spectra [Jenkins et al. (1998)].

The Halofit approach is based on the halo model [Peacock & Smith (2000); Seljak (2000); Ma & Fry (2000)], in which the density field is described in terms of the distribution of isolated dark matter haloes. The correlations in the field are assumed to arise from the clustering of haloes with respect to each other on large scales, and through the clustering of dark matter particles within the same halo on small scales. The total nonlinear power spectrum, \( P_{NL}(k) \), can then be decomposed into

\[
P_{NL}(k) = P_Q(k) + P_H(k),
\]

where \( P_Q(k) \) is the quasi-linear term related to the large-scale contribution to the power spectrum, and \( P_H(k) \) describes the contribution from the self-correlation of haloes. These terms are also known as the 2-halo and the 1-halo term, respectively, and we discuss them in this order below.

[Seljak (2000); Ma & Fry (2000); Scoccimarro et al. (2001)] proposed to use linear theory filtered by the effective window that corresponds to the distribution of haloes as a function of mass, \( n(M) \), convolved with their density profiles, \( \bar{\rho}(k, M) \), and a prescription for their bias with respect to the underlying mass field, \( b_H(M) \). The quasi-linear term can then be expressed as

\[
P_Q(k) = P_L(k) \left[ \frac{1}{\bar{\rho}} \int dM b_H(M) n(M) \bar{\rho}(k, M) \right]^2,
\]

with \( \bar{\rho} \) the homogeneous background matter density, and \( P_L(k) \) the linear power spectrum.

A simpler approach was proposed by [Peacock & Smith (2000)], who assumed that the quasi-linear term corresponds to pure linear theory. \( P_Q(k) = P_L(k) \). However, quasi-linear effects must modify the relative correlations of haloes away from linear theory, irrespective of the allowance made for the finite size of the haloes (see [Smith et al. 2003] and references therein). Halofit takes then an empirical approach, allowing the quasi-linear term to depend on \( n(M) \), and truncating its effects at small scales. If we define the dimensionless power spectrum as

\[
\Delta^2(k) \equiv \frac{P(k)}{2\pi^2 k^3},
\]

the quasi-linear term in Halofit is given by

\[
\Delta^2_Q(k) = \Delta^2_L(k) \left[ \frac{1 + \Delta^2_L(k)}{1 + \alpha_n \Delta^2_L(k)} \right] e^{-f(y)},
\]

where \( y \equiv k/k_{sr} \), \( k_{sr} \) is a nonlinear wavenumber related to the spherical collapse model [Press & Schechter (1974); Sheth & Tormen (1999); Jenkins et al. (2001)], \( \alpha_n \) and \( \beta_n \) are coefficients sensitive to the input linear spectrum, and \( f(y) = y^4/4 + y^2/8 \) governs the decay rate at small scales.

To describe the clustering of matter on small scales, we need a description for \( P_H \), which is given by

\[
P_H(k) = \frac{1}{\rho^2(2\pi)^3} \int dM n(M) |\bar{\rho}(k, M)|^2.
\]

In order to model this term, we can use an expression that looks like a shot-noise spectrum on large scales, but progressively vanishes on small scales by the filtering effects of halo profiles and the mass function. A good candidate is

\[
\Delta^2_H(k) = \frac{a_n y^3}{1 + b_n y + c_n y^{3-\gamma_n}},
\]

where \( a_n, b_n, c_n \), and \( \gamma_n \) are dimensionless numbers that depend on the input spectrum.

[Cooray & Sheth (2002)], however, showed that with this expression the halo model disagrees with low-order perturbation theory in some cases. To solve this, Halofit modifies [Eq. (6)] to obtain a spectrum steeper than Poisson on the largest scales

\[
\Delta^2_H(k) = \frac{\Delta^2_H(k)}{1 + \mu_n y^{-1} + \nu_n y^{-7}},
\]

where \( \mu_n \) and \( \nu_n \) are, again, coefficients that depend on the input spectrum. [Smith et al. (2003)] showed that Halofit is able to reproduce the measurements from simulations more accurately, and down to smaller scales, than the halo model.

2.2. Halofit with Bird and Takahashi corrections

All the coefficients used in the Halofit recipe were determined by [Smith et al. (2003)] from a fit to cold dark matter simulations in boxes of lengths of 256 h\(^{-1}\) Mpc containing 256\(^3\) particles [Jenkins et al. (1998)]. As a consequence of the relatively large particle mass, Halofit may not be suitable if we want to test cosmologies with massive neutrinos, or go down to very small scales, where the impact of baryonic interactions is non-negligible. Moreover, the limited simulation volume results in large sample variance (see [Casarini et al. (2015); Schneider & Teyssier (2015)]), and thus may lead to inaccurate results even for a LCDM cosmology [White & Vale (2004); Casarini et al. (2009); Hilbert et al. (2009); Heitmann et al. (2010); Casarini et al. (2012)]. Finally, as the simulations were performed for the standard cosmological model, using Halofit with a dark energy equation of state \( w \neq -1 \) may yield an incorrect estimate of the power spectrum [Casarini et al. (2011a); See et al. (2012)].

To address these limitations, [Bird et al. (2012)] investigated the impact of massive neutrinos, and performed several N-body simulations of the matter power spectrum incorporating massive neutrinos with masses between 0.15 and 0.6 eV. They focussed on nonlinear scales below 10 h Mpc\(^{-1}\) at \( z < 3 \), and extended the Halofit approximation to account for massive neutrinos. They found that in the strongly nonlinear regime Halofit over-predicts the suppression due to the free-streaming of the neutrinos. In particular, the asymptotic behaviour of the nonlinear term in Halofit is given by \( \Delta^2_H \sim y^{\gamma_n} \), and therefore [Bird et al. (2012)] adjusted \( \gamma_n \) to their LCDM simulations with massive neutrinos. Moreover, they modified the nonlinear power spectrum with the ansatz

\[
(\Delta^2_{NL})^2 = \Delta^2_H (1 + Q_v),
\]

Article number, page 3 of 18
with
\[ Q_\nu = \frac{f_\nu}{1 + k^2/m^2}, \]
where \( f_\nu = \Omega_\nu/\Omega_m \) is the ratio between the neutrino and total matter energy densities, and \( l \) and \( m \) are fitted to the simulations. They also modified Eq. (4) to
\[ \Delta^2_Q(k) = \Delta^2_L(k) \left( 1 + \frac{\Delta^2_L(k)}{1 + \alpha_n \Delta^2_L(k)} e^{-f(w)} \right), \]
with
\[ \Delta^2_L = \frac{p_s k^2}{1 + 1.5k^2}, \]
\[ \beta_n = \beta_n + f_s(r + n^2 s), \]
where \( p, r, s \) and \( \nu \) are fit to the simulations.

Another important improvement to the original Halofit was introduced in [Takahashi et al. 2012], who updated the fitting parameters using high-resolution N-body simulations with box sizes of \( L = 300 - 2000 \) h^{-1} Mpc with \( n_p = 1024^3 \) particles each, for 16 cosmological models around the best fitted cosmological parameters from WMAP data [hinshaw et al. 2013], including dark energy models with a constant equation of state. This revised version of Halofit provides an accurate prediction of the nonlinear matter power spectrum down to \( k \sim 30 \) h Mpc^{-1} and up to \( z \geq 3 \) with an accuracy \( \sim 5 - 10 \% \). In the remainder of this paper we refer to the nonlinear prescription that includes the improvements from [Takahashi et al. 2012] and [Bird et al. 2012] as Halofit, for simplicity.

2.3. Halofit with PKequal

One of the limitations of the standard Halofit approach, even after the corrections by [Bird et al. 2012] and [Takahashi et al. 2012] are considered, is that it is based on a fit to N-body simulations with a constant value for the dark energy equation of state. However, given the precision of stage IV surveys, we are particularly interested in determining whether the data prefer an evolving dark energy equation of state. To avoid biases in our nonlinear predictions one could run N-body simulations that include a time dependence for \( w \), such as the CPL parameterisation [Chevallier & Polarski 2001; Linder 2003] given by
\[ w(a) = w_0 + w_a (1 - a). \]

This approach implies the need for significant computational resources. Another option, however, is to map the nonlinear power spectra of dark energy models with a constant equation of state to those with a time varying one. In this work we consider the PKequal code [Casarini et al. 2010], that implements the spectral equivalence from [Casarini et al. 2009]. [Francis et al. 2007] showed how predictions for constant \( w \) models at \( z = 0 \) can be related to the power spectra of cosmologies with an evolving equation of state \( w(a) \) given by Eq. (13) with an accuracy \( \sim 0.5 \% \) up to \( k \sim 1 \) h Mpc^{-1}. The PKequal technique achieves this precision also at \( z > 0 \) for a general equation of state \( w = w(a) \) by imposing the equivalence of the distance to the last scattering surface and requiring that the amplitudes of the density fluctuations at the redshift of interest are the same. For a given set of values of \( w_0 \) and \( w_a \) these two conditions yield at each \( z \) a unique value of \( w_{eq} \) and \( \sigma_8_{eq} \) for the constant \( w \) model.

The performance of this method has been tested for several dark energy models [Casarini et al. 2009; Casarini 2010], and also in the presence of gas cooling, star formation and SN feedback [Casarini et al. 2011b]. These studies find differences in power spectra between the mapped dynamical dark energy models and the ensemble of equivalent constant \( w \) models that are within 1\% up to \( k \sim 2 - 3 \) h Mpc^{-1}. With this method it is possible to extend both emulators (see Casarini et al. 2016) and fitting formulae (as in this work) to dynamical dark energy models if they are valid for constant \( w \) models.

2.4. HMCode

An alternative approach to predict the nonlinear matter power spectrum, called HMCode, was proposed by [Mead et al. 2015]. It introduces physically motivated free parameters into the halo model formalism, instead of using empirical fitting functions. [Mead et al. 2015] fit these to N-body simulations with box sizes \( L = 90 - 1300 \) h^{-1} Mpc and \( n_p = 512^3 - 1024^3 \) particles for a variety of \( \Lambda \)CDM and \( w \)CDM models [Heitmann et al. 2010]. HMCode also accounts for the effects of baryonic feedback on the power spectrum by fitting the halo model to hydrodynamical simulations that include gas cooling, star formation, as well as supernova and AGN feedback [Schaye et al. 2010; van Daalen et al. 2011].

In [Mead et al. 2016] HMCode was updated to account for massive neutrinos, chameleon and Vainshtein screening mechanisms, as well as evolving dark energy equations of state described by the CPL parameterisation. Throughout the rest of the paper we will consider this latest version when referring to HMCode. We note, however, that the PKequal approach can also be used with the original HMCode by applying it to the equivalent \( \{ w_{eq}, 0 \} \) constant \( w \) model at any redshift \( z \), and imposing the same \( \sigma_8(z) \). This yields the prediction for a given \( \{ w_0, w_a \} \) CPL model, with an accuracy similar to that of the fit and the simulations on which HMCode itself is based.

2.5. Comparison

Before we study how the different methods affect the inference of cosmological parameters and related confidence regions, we show by how much the power spectra differ as a function of the wavenumber \( k \) for the prescriptions described above. We note that theoretical approaches based on perturbation theory or the effective field theory of large-scale structure do not yet provide accurate power spectra for the small scales we consider here.

In Fig. 1 we show the relative difference between the various predictions and the one from Halofit. The power spectra were computed using CAMB [Lewis et al. 2000] at redshift 0, where discrepancies are most pronounced. Hence, these represent a worst case scenario, as WL probes mostly intermediate redshifts. The upper-left panel shows the relative differences between the linear power spectrum (orange), Halofit with PKequal (blue), and HMCode (red) for the \( \Lambda \)CDM model using the Planck TT+TE+EE+lowlE+lensing+BAO 2018 mean values for the
various cosmological parameters (Aghanim et al. 2018). The linear power spectrum diverges from Halofit for \( k > 0.1 \, h \, {\text{Mpc}}^{-1} \), while the disagreement between Halofit and HMCode is below 7.5% for \( k < 10 \, h \, {\text{Mpc}}^{-1} \).

The upper-right panel shows the variation on small scales when we consider parameters around the mean values of ACMD. For this comparison we generated 100 power spectra with cosmological parameters drawn from a 5-dimensional Gaussian distribution with the diagonal given by 5 times the 1σ uncertainty quoted by Planck TT-TENE+lowE+lensing+BAO 2018. These results highlight that the discrepancy between Halofit and HMCode can be larger than 10% for \( k > 3 \, h \, {\text{Mpc}}^{-1} \).

The bottom-left panel considers models beyond ACMD, allowing for a constant equation of state parameter, \( w \), that can differ from \(-1\). The different lines correspond to power spectra when we draw parameters from a 6-dimensional Gaussian distribution where we adopt a dispersion of 0.3 for \( w \) (but we do require \( w < -1/3 \)). The bands showing the discrepancy between the different nonlinear corrections increase slightly (a 10% discrepancy is reached at scales of \( k = 1 - 2 \, h \, {\text{Mpc}}^{-1} \)), but the overall shape remains the same.

Finally, in the bottom-right panel we consider dynamical dark energy models with a dark energy equation of state given by \( \omega(z) \). In this case we add \( w_0 \), so that we draw parameters from a 7-dimensional Gaussian with a dispersion of 1.0 and we require the dark energy equation of state to be always smaller than \(-1/3 \), i.e. \( w_0 + w > -1/3 \). The overall shape for the bands is the same for HMCode and the linear spectra, although the discrepancies are significantly larger (already 10% at scales of \( k = 0.6 \, h \, {\text{Mpc}}^{-1} \)). We also note that, since we allow \( w_0 \) to vary, there is a difference between Halofit and Halofit+PKequal.

Lawrence et al. (2017) presented an updated version of COSMIC EMU that includes massive neutrinos. Their high-resolution simulations are interpolated with an accuracy of \( \sim 4\% \). Lawrence et al. (2017) compared their COSMIC EMU predictions with Halofit, and HMCode. When massive neutrinos are considered, the different approaches show differences of \( \sim 20\% \) and \( \sim 15\% \) respectively in the power spectra for scales above \( k = 0.1 \, h \, {\text{Mpc}}^{-1} \), indicating the need for further improvements.

### 3. The Euclid Cosmic Shear survey

Our aim is to investigate how the expected constraints on cosmological parameters from Euclid data depend on the recipe that is used to predict the matter power spectrum on nonlinear scales, although we note that our findings are also relevant for other stage IV experiments. Euclid is an M-class mission of the European Space Agency (Laureijs et al. 2011) that will carry out a spectroscopic and a photometric survey of galaxies over an area of 15,000 deg². The cosmic shear measurements use high-quality imaging at optical wavelengths, supported by multi-band optical ground-based photometry and near-infrared observations by Euclid. The telescope is designed so that (residual) instrumental sources of bias in the observed cosmic shear signal are subdominant compared to the statistical uncertainties (e.g. Cropper et al. 2013; Euclid Collaboration: Paykari et al. 2020). However, to achieve its objectives, it is essential that the signal can be accurately predicted in the nonlinear regime. Although this is also relevant to fully exploit the data from the clustering of galaxies and the cross-correlations with the lensing signal, we focus on the cosmic shear case in this paper and defer a more comprehensive study to future work.

We adopt the baseline specifications for the Euclid data, which are described in Euclid Collaboration: Blanchard et al. (2019) hereafter EC19. The redshift distribution of the sources is given by

\[
n(z) \sim \frac{1}{z_0} \exp \left[ -\frac{1}{2} \frac{(z - z_0)^{3/2}}{z_0} \right],
\]

with \( z_0 = 0.9/\sqrt{2} \), resulting in a mean redshift of \( z = 0.96 \). The sample is divided into 10 equi-populated redshift bins \( n_i(z) \) (with the index \( i \) indicating the tomographic bin). We assume an average number density of galaxies with precise shape measurements of \( n_g = 30 \, \text{arcmin}^{-2} \). To capture the noise arising from the intrinsic galaxy ellipticities we adopt a dispersion of \( \sigma_r = 0.21 \) for each of the two ellipticity components. We also use the same approach as EC19 to model the data covariances and to compute the WL power spectrum, defined as

\[
C_{\delta \delta}^{\text{corr}}(\ell) = c \int \frac{dz}{W(z)} W(z) P_{\delta S} \left[ \ell + 1/2, r(z), z \right],
\]

where \( P_{\delta S} \) is the nonlinear matter power spectrum, \( r(z) \) is the comoving distance to redshift \( z \), and the window function \( W(z) \) is defined as

\[
W_i(z) = W(z) = \frac{A_{1A} G_1 \Omega_{m,0} \theta_{1A}(z) H(z) n_i(z)}{D(z) c},
\]

where \( n_i(z) \) normalised such that \( \int dz n_i(z) = 1 \). In Eq. (16) the first term corresponds to the usual lensing kernel,

\[
W_i(z) = \frac{3}{2} \Omega_{m,0} \left( \frac{H_0}{c} \right)^2 (1 + z) r(z) \times \int_z^{z_{\max}} dz' n_i(z') \left[ 1 - \frac{r(z)}{r(z')} \right],
\]

whilst the second term models the effect of intrinsic alignments (IA). Here \( D(z) \) is the growth factor, \( G_1 \) is a constant so that the normalisation of the model \( A_{1A} \) can be compared to the literature. To describe the dependence of the IA signal as a function of scale, redshift and galaxy luminosity, we adopt the extended nonlinear alignment model (Joachimi et al. 2015), and the function \( F_{1A}(z) \) is given by

\[
F_{1A}(z) = (1 + z)^{\eta_1} \left[ (L(z)/L_s(z))^{\beta_1} \right],
\]

where \( (L(z)/L_s(z)) \) are the redshift-dependent mean and a characteristic luminosity of source galaxies as computed from the luminosity function, respectively. The parameters \( \eta_1, \beta_1, A_{1A} \) are free parameters that can be determined observationally. We use \( \{ A_{1A}, \eta_1, \beta_1 \} = \{ 1.72, -0.41, 2.17 \} \) as fiducial values, as was done in EC19 while they are allowed to vary in the parameter estimation.

Our approach for the modelling of IA is phenomenological, but we note that more physically motivated models have been proposed. For instance, Fortuna et al. (2020)
Fig. 1. Relative difference between the various predicted matter power spectra and the Halofit prediction at $z = 0$ for different cosmologies. Top-left panel: Using the mean values of the $\Lambda$CDM parameters given by Planck 2018 (Aghanim et al. 2018). Top-right panel: Differences when the $\Lambda$CDM parameters are drawn from a 5-dimensional Gaussian distribution with the diagonal given by 5 times the $1\sigma$ uncertainty quoted by Planck TTTEEE+lowE+lensing+BAO 2018. Bottom-left panel: Differences when also the constant dark energy equation of state is drawn from a Gaussian distribution with a dispersion of 0.3. Bottom-right panel: Difference for evolving dark energy models where, alongside $w_0$, also $w_a$ is Gaussian distributed with a dispersion of 1.0. In the bottom panels $w_0$ and $w_a$ (if present) are always chosen in such a way that $w(z) < -1/3$.

4. Impact of nonlinear corrections on forecasted constraints

Given our desire to use measurements on small scales to estimate cosmological parameters, it is essential to assess how the different methods to model the power spectrum on highly nonlinear scales affect the results. In the following, we limit ourselves to a simple extension of the $\Lambda$CDM model: we assume that dark energy is dynamical with its equation of state parameterised according to Eq. (13), and that density perturbations for this component are well described by the parameterised post-Friedmann approach, which assumes that the dark energy field remains smooth with respect to matter at the scales of interest (Hu & Sawicki 2007; Hu 2008; Fang et al. 2008).

To evaluate the impact of the different recipes for the nonlinear power spectrum on the final parameter estimation from *Euclid*, we use the Fisher matrix approach (see EC19 for an extensive review of the methodology). For the different methods we compute the ‘figure of merit’ (FoM) for the parameters $w_0$ and $w_a$, where the FoM is defined as

$$\text{FoM} = \sqrt{\det\tilde{F}_{w_0w_a}},$$

and $\tilde{F}_{w_0w_a}$ is the Fisher matrix marginalised over all the cosmological parameters except for $w_0$ and $w_a$. This allows us to examine whether degeneracies between cosmological parameters differ when switching from one method to the other. We can also quantify the biases in dark energy parameters and changes in the FoM, which captures the performance of *Euclid*.

The free parameters for this analysis are: the matter and baryon density parameters $\Omega_{m,0}$ and $\Omega_{b,0}$; the dark energy parameters, $w_0$ and $w_a$; the spectral index of primordial perturbations, $n_s$; the dimensionless Hubble parameter, $h$; and $\sigma_8$, i.e. the root mean square of present-day linearly
evolved density fluctuations in spheres of 8 h  \(^{-1}\) Mpc radius. The fiducial values of these parameters are listed in Table 1.

**Table 1.** Fiducial values for the cosmological parameters considered in the Fisher matrix analysis.

We use the specification of Euclid for WL observations that were detailed in Sect. 3 and compute the FoM from the WL power spectra \(C_{\ell}^{gg}\) for different values of the maximum multipole, \(\ell_{\text{max}}\). We consider two different values for \(\ell_{\text{max}}\), namely 1500 and 5000, with the latter probing deeper into the nonlinear regime. Notice that here the same \(\ell_{\text{max}}\) applies to all redshift bins, thus leading to a different cut in scales (\(k_{\text{max}}\)) for each bin. We investigate the difference between this analysis and one considering a \(k_{\text{max}}\) rather than a multipole cut in Appendix A. In both cases the minimum multipole is fixed to \(\ell_{\text{min}} = 10\) following [EC19]. We note that the cuts we use here should be considered an approximation; in general there is no direct mapping between \(\ell_{\text{max}}\) and \(k_{\text{max}}\), and a more refined approach would be needed to convert a cut multipoles into a cut in wavenumber (Taylor et al. 2018b).

Table 2 lists the resulting FoM values for our baseline \(w_0w_a\) CDM cosmology for the three different nonlinear recipes. The variation in the predicted FoMs is substantial, which is not that surprising given the differences we see in Fig. 1 at large \(k\) the differences exceed 10% when the parameters are allowed to vary with respect to the fiducial model.

The large variation is caused by two separate effects. Firstly, the fiducial \(C_{\ell}^{gg}\) is obtained by integrating up to \(k \approx 30 \, h\) Mpc\(^{-1}\) and then inverted when computing the covariance matrix that enters the Fisher matrix forecast. Small differences can become large in the inversion process. Secondly, what is important is not so much the fiducial model itself, but rather the derivatives of the power spectrum with respect to the model parameters. Different nonlinear corrections predict different derivatives, thus leading to different Fisher matrix elements. This is supported by the fact that the FoM for HMCode and Halofit+PKequal are very similar. These two prescriptions explicitly take deviations of \(w_0\) and \(w_a\) from the fiducial CDM values into account, while this is not the case for the standard Halofit, which is designed to describe CDM cosmologies and extended to cases where dark energy is described by a constant equation of state. As a consequence, the amplitude of the derivatives of the matter power spectrum with respect to \(\{w_0, w_a\}\) are similar between HMCode and Halofit+PKequal, but different for Halofit. This explains why the FoM values in the third and fourth columns are so similar.

It is also worth noting that the FoM is highest for Halofit, because in that case \(w_a\) impacts the power spectra at nonlinear scales through its effect on the linear matter power spectrum, while in the other two methods the nonlinear corrections are affected by this parameter as well. Overall, the nonlinear corrections dampen the derivatives with respect to \(w_a\), leading to weaker constraints on this parameter and to a lower FoM. These results demonstrate that the FoM depends critically on the nonlinear model that is used, highlighting the need for (more) accurate prescriptions.

### 5. Bias on cosmological parameter estimates

A major concern is that inaccuracies in the theoretical predictions on nonlinear scales translate into shifts in the inferred cosmological parameters. To quantify the impact of such biases, we create a mock data set of Euclid WL observations, using the specifications listed in Sect. 3. The fiducial cosmology that we use to generate these mock data is summarised in Table 3 where \(A_s\) is the amplitude of the primordial power spectrum, \(\omega_{b,0} = \Omega_{b,0}h^2\) and \(\omega_{c,0} = \Omega_{c,0}h^2\). Here \(\omega_c\) is the present time density parameter for cold dark matter. In contrast to what was done in Sect. 4 we assume here that the expansion history is provided by a dynamical dark energy, assuming \(w_0 = -0.9\) and \(w_a = 0.1\). This allows us to assess the impact of the different nonlinear recipes when a non-standard model is the true underlying cosmology. This is motivated by the fact that the recipes in Sect. 2 differ in how they account for such extensions of the standard cosmological model.

We adopt the nonlinear correction provided by Halofit+PKequal as the reference to which we compare the parameter estimates for the other recipes. We stress that we do not advocate the use of a particular prescription, but rather wish to quantify the shifts in the estimated cosmological parameters that may arise from using a different prediction.

**Table 3.** Fiducial values for the free cosmological parameters in the MCMC analysis. We model neutrinos assuming 2.0328 ultra-relativistic species, and 1 mass eigenstate with \(m_\nu = 0.06\) eV. The MCMC fiducial model implies \(\sigma_8 = 0.786\), which corresponds to the value of the Fisher matrix analysis rescaled according to the new cosmology, i.e. replacing the cosmological constant with a dynamical dark energy with \(w_0 = -0.9\) and \(w_a = 0.1\).

We analyse this mock data set with a Markov Chain Monte Carlo method (MCMC), using the MontePython suite [Audren et al. 2013] Brinckmann & Lesgourgues 2019, with a Euclid lensing mock likelihood as presented in [8](https://github.com/brinckmann/monetepython_public).
Sprenger et al. (2019) With this setting we sample the cosmological parameters listed in Table 3 using either Halofit (switching off $P_{\text{Kequal}}$) or HMCode. When using HMCode, the baryonic feedback parameters are fixed to the values fitting the COSMIC EMU dark-matter-only simulations (Heitmann et al. 2014).

As done in Sect. 3 we perform the analysis for $\ell_{\text{max}} = 1500$ and 5000, in order to explore the impact of the nonlinear corrections on the results when including high multipoles. Also in this case, we explore the difference with a scales cut in Appendix A. We complement the WL mock data set with TT, TE, EE, and lensing data from a mock Planck likelihood, thus reproducing the sensitivity of the data set with TT, TE, EE, and lensing data from a mock Planck likelihood, thus reproducing the sensitivity of the full mission. Note that we do not use real Planck data to avoid a mismatch between the fiducial Euclid cosmology and the actual best fitted Planck values.

This approach enables us to determine the "bias" ($B$) on cosmological parameters with respect to our fiducial cosmology, i.e. the offset of the mean of the estimated posterior distribution from the true value, which in turn allows us to quantify the impact of using a different prescription for the nonlinear evolution of density perturbations. To assess the significance of a particular bias, it is useful to compare it to the expected statistical uncertainty. We therefore consider the (relative) bias on all the cosmological parameters given by

$$B(\theta) = \frac{\langle \theta \rangle - \theta^{\text{fid}}}{\sigma},$$

where $\langle \theta \rangle$ is the mean value of the parameter found with the MCMC analysis, $\sigma$ is the 68% uncertainty estimated from the chains, and $\theta^{\text{fid}}$ is its fiducial value. We note that this estimate implicitly assumes that the posterior distribution can be approximated by a Gaussian, which is indeed valid for constraints based on the combination of Planck and Euclid data.

The statistical uncertainties of Euclid are determined by the survey design (see Sect. 3). To draw reliable conclusions from these data, it is essential that systematic uncertainties are sufficiently small. Ideally biases should vanish, but generally it is too costly to achieve this. A reasonable compromise, however, is to adopt $B_T < 0.1$ (see e.g. Sect. 4.1 in Massey et al. 2013), which is what we do here. We note that the intrinsic variance of the mean estimated by the MCMC also contributes to our estimate of $B(\theta)$. We quantified this contribution by computing the scatter of the mean value by bootstrapping the chains. We find that it is always within 1% of the final error on cosmological parameters.

The results are reported in Table 4 and the posteriors are presented in Fig. 2. Although the optical depth $\tau$ is a free parameter in the model, it is effectively constrained by the Planck measurements alone. We therefore do not report its value here. As expected, the biases are larger for HMCode compared to Halofit without $P_{\text{Kequal}}$. We also find that for Halofit, increasing the range from $\ell_{\text{max}} = 1500$ to $\ell_{\text{max}} = 5000$ does not increase the bias significantly, whereas the bias strongly depends on the $\ell$-range for HMCode, both in amplitude and in sign. This can be explained by looking at Fig. 1 at scales larger than a few $h\,\text{Mpc}^{-1}$, HMCode systematically over-predicts the power with respect to Halofit.
We find that in the Halofit case, the biases in the cosmological parameters approximately satisfy $B(\theta) \lesssim B_T$ when $\ell_{\text{max}} = 1500$, while for HMCode the biases for almost all the parameters exceed this threshold. When setting $\ell_{\text{max}} = 5000$, the parameters estimated in the HMCode case are all biased significantly more than the acceptable threshold (except for $\omega_{m,0}$), and now also the Halofit case exhibits biases larger than $B_T$ for $h$, $\Omega_{m,0}$ and $\sigma_8$.

In order to correct for the significant mismatch in the nonlinear prescriptions, HMCode increases $\omega_{m,0}$, $h$, $\ln(10^{10}\Lambda_5)$, and $w_a$, while at the same time the values for $n_s$ and $w_0$ are decreased. This tweaking of parameters increases the amplitude of the linear matter power spectrum quantities and the linear growth.

Overall, the $\Delta\chi^2 \lesssim 1$ indicates that replacing Halofit+PKequal with Halofit-only does not have a strong impact on the results, as it is well within the range of the statistical uncertainties. On the other hand, using HMCode leads to a significantly higher $\Delta\chi^2$, highlighting how the difference between the two nonlinear prescriptions cannot be fully compensated by modifying the background quantities and the linear growth.

It is worth noting that for both Halofit and HMCode the parameters that are most significantly biased are $H_0$ and $\sigma_8$. These are the parameters that currently show tension between high- and low-redshift measurements (e.g., Riess et al. 2019, Hildebrandt et al. 2020, Spurio Mancini et al. 2019). Our results imply that the Euclid cosmic shear measurements have the statistical power to resolve this, but only if we can accurately model the nonlinear scales.

6. Impact of baryons

Up to this point, we have limited our study to the impact of changing the recipe that is used to compute the nonlinear evolution of cold dark matter perturbations. On the small scales of interest, however, baryons collapse into the dark matter haloes to form stars, or are heated up, or even expelled into the intergalactic medium. These processes modify the matter distribution, and it is therefore important to account for baryonic physics when computing the matter power spectrum $P_{\delta}(k, z)$ (e.g., van Daalen et al. 2011, Casarin et al. 2012, Castro et al. 2018, Debattre et al. 2020). This can be done by multiplying the nonlinear power spectrum, $P_{\delta}(k, z)$, computed using one of the nonlinear prescriptions discussed above – with $B(k, z)$, a ‘baryon correction model’ (BCM) that captures the baryonic effects (e.g., Semboloni et al. 2011), so that

$$P_{c+b}(k, z) = P_{\delta}(k, z)B(k, z),$$

where $P_{c+b}(k, z)$ is the corrected power spectrum. The functional form of $B(k, z)$ is given by

$$B(k, z) = 1 - A_{\text{HD15}}(z) \exp \left\{ \frac{[B_{\delta}(k, z) - C_{\text{HD15}}(z)]^2}{2} \right\} + D_{\text{HD15}}(z) x(k) \exp \left\{ E_{\text{HD15}}(z) x(k) \right\},$$

with $x(k) = \log_{10} (k/[h \text{ Mpc}^{-1}])$ and $X_{\text{HD15}}$ are polynomial functions of redshift given in Harnois-Déraps et al. (2015).

As a second model, we consider the results obtained by Schneider & Teyssier (2015 ST15 hereafter), who accounted for the effects of baryons following a different approach. They start from a suite of DM only N-body simulations, and modify the density field in such a way that it mimics the effects of a particular feedback recipe. They achieve this by explicitly modelling the main constituents of the halos, which are dark matter, hot gas in hydrostatic equilibrium, ejected gas and stars. The model parameters are set to resemble SZ and X-ray observations. The resulting modifications to the power spectrum are shown to be well reproduced by defining $B(k, z)$ as

$$B(k, z) = \frac{1 + \left( k/k_{s}(z) \right)^{2}}{1 + k/k_{s}(z)} g(z) + \left[ 1 + \left( k/k_{b}(z) \right)^{2} \right] \left[ 1 - g(z) \right],$$

with $k_{s}(z)$ and $g(z)$ auxiliary functions provided in Schneider & Teyssier (2015). We set the model parameters to the following fiducial values

$$\{ k_s, \log M_{c+2h}, \eta_b \} = \{ 67 h \text{ Mpc}^{-1}, 13.8, 2.3, 0.17 \}. \quad (23)$$

Note that these are different from those of Schneider & Teyssier (2015), since we have updated them to the best fitting values obtained using the more recent Horizon-AGN simulations (as done in Chisari et al. 2018).

Chisari et al. (2018 Ch18 hereafter) found that the ST15 model performs well at low redshift, but its accuracy degrades for larger $z$. Fitting the Horizon-AGN simulations, they therefore proposed the third model we will consider here, with

$$B(k, z) = \frac{1 + \left( k/k_{s}(z) \right)^{2}}{1 + k/k_{s}(z)} \left[ 1 - 0.39 \right],$$

where $k_s$ is no longer a constant, but a function of $z$ instead. The detailed form is given in Chisari et al. (2018).

We can now quantify the impact of the choice of BCM on the FoM by comparing it to the results for the dark-matter-only forecasts. To this end, we use Halofit as our benchmark model to compute $P_{\delta}(k, z)$, which is consistent with what is done in the quoted papers. Our results are presented in Table 5.

The more recent Ch18 model yields the smallest change in the FoM, but the differences are never larger than ~15%, even in the scenario with the largest change, i.e. the HD15.
model with $\ell_{\text{max}} = 5000$. This is the consequence of two opposite effects that partially cancel.

On the one hand, at $k \approx 3 - 13 \, h \, \text{Mpc}^{-1}$, gas ejection due to AGN feedback suppresses the power spectrum, while for larger $k$ the effect of stars is to increase it. These very small scales ($k > 15 \, h \, \text{Mpc}^{-1}$) are, however, weighted down by the lensing kernel so that the overall effect is to reduce the signal in the $C_{\ell}^{w}(\ell)$, which tends to reduce the FoM. However, reducing $C_{\ell}^{w}$ also decreases the Gaussian covariance that is used to estimate the uncertainty in the WL signal, as the baryonic effects also change the power spectra used to compute the covariance matrix. As a result, the inverse covariance boosts the FoM. By moving the FoM in opposite directions, these two effects roughly compensate each other, so that the choice of the BCM model impacts the constraining power of the WL signal on dark energy parameters only marginally. Qualitatively similar results are obtained when we compare the marginalised uncertainties for individual parameters. In general, we find that the parameter bounds are less affected than the FoM, in accordance with the argument given above.

Although the detailed implementation of the BCM does not affect the constraining power much, it is nonetheless necessary to investigate whether an incorrect choice biases the cosmological parameter estimates. To this end, we adopt a procedure similar to that of Sect. 3: we generate three simulated Euclid WL data sets assuming that the BCM describing the true effect of baryons is CH18, ST15 or HD15, respectively. We then analyze these data sets, together with simulated Planck CMB data, with theoretical predictions that neglect baryonic effects.

As done in the previous sections, we perform the MCMC analysis for both $\ell_{\text{max}}$ values, 1500 (pessimistic) and 5000 (optimistic), which allows us to assess the relevance of the BCM for high multipoles. Our results are reported in Table 6 and shown in Fig. 3. For $\ell_{\text{max}} = 1500$ we notice that the bias exceeds the threshold $B_{\ell}$ for all parameters except for $\omega_{b,0}$ and $\omega_{c,0}$ in the CH18, while in ST15 also the bias on $\ln(10^{10} A_{s})$ is lower than $B_{\ell}$. HD15 instead only has this

Table 4. Mean values, marginalised 68% errors, and biases in cosmological parameters. The values are obtained by fitting mock Planck and Euclid WL data to either HMCode without baryonic feedback or Halofit without $P_{\text{eq}}$ nonlinear corrections. The last row shows $\Delta \chi^2$. By construction $\chi^2 = 0$, unless the configuration of the MCMC sampling does not match the one used to create the fiducial synthetic data set. The number of degrees of freedom in this case is 11 (the number of free parameters in the model; $\Omega_{m,0}$ and $\sigma_8$ are derived parameters), which enables one to compare $\Delta \chi^2$ to the corresponding confidence interval.

latter parameter within our acceptable threshold, a result confirmed by the highest $\Delta \chi^2$ among the three cases. The most significantly biased parameters in all three analyses are $h$, $w_0$ and $w_a$. Overall however, all three cases produce very similar results, as it can be seen in the left panel of Fig. 3.

For $\ell_{\max} = 5000$, we find that the biases are very large when BCM effects are neglected; $B(\theta) > B_{\ell}$ for all parameters, with $B \gtrsim 5$ for the dark energy parameters $w_0$ and $w_a$, $B \gtrsim 3$ for $h$, and $B \gtrsim 4.5$ for $n_s$. As expected, the biases in the power spectrum amplitude, the baryon density and the cold dark matter density are the least significant, because these are all well constrained by the Planck measurements.

Ignoring BCM effects could lead to a false detection of a time-varying dark energy equation of state. Moreover, with the current tension between $H_0$ measurements between CMB and late-time probes, an unbiased measurement of $H_0$ will also be crucial. Our results confirm earlier work (e.g. Semboloni et al. 2011) that correctly modelling the impact of baryonic feedback on the power spectrum is essential for the analysis of Euclid data.

7. Conclusions

Forthcoming surveys of the large-scale structure will deliver data sets of exquisite quality that will allow us to pursue what is usually referred to as precision cosmology. To correctly interpret these measurements significant improvements in the underlying theoretical predictions are needed: we need to ensure that errors in the modelling of density fluctuations on nonlinear scales do not introduce biases in the inferred cosmological parameters that are larger than the expected statistical uncertainties. This is a particular concern for cosmic shear tomography, given that one has to integrate the matter power spectrum $P_{\delta\delta}(k,z)$ deep into the nonlinear regime, where baryonic physics complicates matters even further. Motivated by these concerns, we have investigated how different popular prescriptions that account for these effects influence both the accuracy and the precision with which Euclid can infer cosmological parameters using cosmic shear alone.

We used Fisher matrix forecasts to quantify the impact of three different nonlinear recipes on the dark energy figure of merit (FoM). The recipes that we considered are the revised implementation of Halofit, Halofit+PKequal, and the HMCode prescription. These differ significantly from one another when the cosmological parameters are left free to take values other than the fiducial ones. As a consequence, the derivatives of $P_{\delta\delta}(k,z)$ that enter the determination of the Fisher matrix are changed, leading to quite discrepant FoM values. In particular, we find that the Halofit case provides the higher FoM because of the different role played by $w_a$ in the nonlinear corrections. Although we have explicitly considered the case of Euclid, this result is generic for cosmic shear tomography analyses, although the size of this effect will depend on the details of the survey of interest. Hence our findings highlight the importance of choosing the most reliable nonlinear model, in order to compute realistic estimates of the expected performance of a particular weak lensing survey.

While it is important to quantify the precision, i.e. how tight the constraints will be, it is perhaps even more important to establish the accuracy of the results: we need to be confident that an incorrect choice of theoretical ingredients does not introduce an unacceptably large bias, i.e. a deviation from the (unknown) true value. Whether or not the bias is too large, also depends on the precision with which that parameter can be measured. We therefore define $B = (\theta - \theta^0)/\sigma$, and adopt a threshold of $B < B_T = 0.1$.

To study the accuracy with which cosmological parameters can be determined, we created mock data sets with a given prescription for nonlinearities and/or baryon physics, and fitting these with a different model. This allowed us to address the issues of the choice of the nonlinear recipe and the baryon correction model separately. To examine the impact of the recipe used to compute the power spectra on nonlinear scales, we created a mock data set using Halofit+PKequal that comprises Euclid cosmic shear and Planck CMB data. We emphasize that the choice of Halofit+PKequal is arbitrary, as we do not know which of the nonlinear corrections better describes the true small scale evolution. We fitted these with Halofit or HMCode.

We find that $B \lesssim B_T$ if Halofit is used for $\ell_{\max} = 1500$, while for $\ell_{\max} = 5000$, some cosmological parameters, namely $h$, $\Omega_{m,0}$ and $\sigma_8$, exceed the threshold. This is not surprising given the similarities of the two models when one only looks at $P_{\delta\delta}$ rather than at its derivatives. In contrast, the use of HMCode leads to strong biases, with almost all parameters already biased by more than $B_T$ if we restrict the analysis to $\ell_{\max} = 1500$. Including the very nonlinear regime scales($\ell_{\max} = 5000$), we find that $B > 1$ for all parameters, except for $\omega_{b,0}$, which is actually tightly constrained by Planck. In particular, the estimate of $w_a$ shifts towards its CDM value even if the mock data were created using $[w_0, w_a] = [-0.9, 0.1]$. What is even more interesting is that the most biased parameters are $h (B = 3.02)$ and $\sigma_8 (B = 4.62)$; the values of both of these are currently debated. The sensitivity of these parameters to the adopted prescription for the nonlinear power spectrum highlights the need for further improvements, which may already be needed to correctly interpret current data.

It is also essential that the changes to the power spectrum caused by baryon physics have to be taken into account. For a fixed nonlinear recipe and baryon correction model prescription, severe biases are found when fitting the mock data with the right nonlinear correction, but not accounting for the presence of baryons, in line with earlier work (e.g. Semboloni et al. 2011). In the most constraining setting ($\ell_{\max} = 5000$), for all the three cases we considered, we find significant biases for all the cosmological parameters, except for $\{\omega_{b,0}, \ln(10^{10}A_s)\}$, which are actually constrained by the Planck data rather than by cosmic shear. While this work was near to completion, Schneider et al. (2020) presented a similar analysis, but their method to account for baryons is very different from the one we adopted here. They use instead a model for the baryonification of dark matter only simulations to determine the matter power spectrum (Schneider et al. 2019). Notwithstanding these differences, which make a straightforward comparison impossible, their conclusions are in agreement with what we found here.

As a final remark, we remind the reader that our results refer to the case where cosmic shear is used as the only probe. This is, however, only part of the information that future surveys will provide. Indeed, the same data used to do cosmic shear tomography (WL) can and will be used to compute the photometric galaxy clustering (GCph) and
Table 6. Mean values, marginalised 68% errors, and bias. The values are obtained by fitting mock Planck and Euclid cosmic shear data with Halofit without baryonic corrections, to nonlinear corrections with either CH18, ST15 or HD15 methods nonlinear corrections. The number of degrees of freedom in this case is 11 (the number of free parameters), which enables one to compare $\Delta \chi^2$ to the corresponding confidence interval.

$\Delta \chi^2$

- $\ell_{\text{max}} = 1500$
  - $\ell_{\text{max}} = 5000$

Fig. 3. One dimensional posterior distributions, and 68% and 95% marginalised joint two-parameter contours for $w_0$ and $w_a$, and the parameters $h$, $n_s$ and $\sigma_8$ from the MCMC analysis. The results are obtained by neglecting baryon effects when fitting mock data sets created without baryonic effects (green) and with baryonic effects (orange for CH18, blue for ST15 and purple for HD15). The left panel refers to the $\ell_{\text{max}} = 1500$ case, while the right panel goes deeper into the nonlinear regime, with $\ell_{\text{max}} = 5000$.

to cross correlate the shear and density fields (XC). As was shown in [EC19] and further investigated in [Tutusaus et al. 2020], it is the joint use of WL+GCph+XC that is needed to achieve $\sim \{1,10\}$% errors on $\{w_0,w_a\}$, rather than any single probe by itself. It is therefore worth considering whether, and to which extent, the results we have obtained here change if all the three probes are considered.

For instance, [EC19] limited the GCph and XC to smaller multipoles compared to what was used for WL, reducing their sensitivity to the small scales corrections. This diminishes the impact of errors in the prediction of $P_\delta(k,z)$ in the large $k$ regime, but at the expense of larger statistical uncertainties. This motivates extending our work to quantify the impact of modelling the small scale power spectra for the joint probes. Such a study, which is beyond the scope of our initial exploration, would provide guidance how to proceed in order to exploit the high-quality data that stage IV surveys will provide.
Appendix A: Comparison between scales and multipoles cuts

In the analyses performed in this paper, we considered two cases, with different cuts in multipoles used; the optimistic $\ell_{\text{max}} = 5000$ cut represents the situation in which data for all scales are included in the analysis, while the $\ell_{\text{max}} = 1500$ mimics the removal of nonlinear scales that could be performed in the data analysis in order to reduce the impact of small scales modelling.

However, our approach can be seen as a first approximation, as a constant multipole cut corresponds to different scales for different redshifts. In this subsection we investigate a less simplistic approach, implementing a $k_{\text{max}}$ scale cut, rather than a multipole one, with the purpose of removing part of the nonlinear scales.

We assume $k_{\text{max}} = 0.25 \, \text{h Mpc}^{-1}$ and, using the Limber approximation considered to express the $C(\ell)$ in [Eq. (15)] we convert this cut in a maximum multipole for each redshift bin:

$$\ell_{\text{max}}(z_i) = k_{\text{max}} r(z_i) - \frac{1}{2}, \quad \text{(A.1)}$$

where $z_i$ is the mean redshift of each redshift bin.

We apply this approach to our MCMC analysis, and compare the results we obtain with those of the $\ell_{\text{max}} = 1500$ case. In [Fig. A.1] we show the comparison in the results for the analysis performed using Halofit (left panel) and HMCode (right panel). In both cases we find that the $k_{\text{max}}$ analysis leads to broader constraints with respect to the $\ell_{\text{max}}$ case; this is due to the fact that the chosen $k_{\text{max}}$ translates into a much more aggressive cut in multipoles, specially at low redshift. Therefore, a significative amount of information is lost with respect to the $\ell_{\text{max}} = 1500$ case.

Concerning the bias found on cosmological parameters, $B(\theta)$ does not change significantly in the Halofit analysis, while for HMCode the biases are slightly enhanced with respect to the $\ell_{\text{max}} = 1500$ case, with $w_0$, $w_a$, $h$ and $\sigma_8$ now reaching $B \approx 1$. This apparent increase however is mostly due to the loss of constraining power when the scale cut is implemented; as it can be seen in [Fig. A.1] the marginalized posterior distributions for the cosmological parameters now exhibit non-Gaussian features while Eq. (20) implicitly assumes Gaussian distributions. In [Fig. A.1] it is shown how the scale cut case produces contours closer to the expected fiducial values, a result supported also by the change in $\Delta \chi^2$ moving from the $\ell_{\text{max}}$ to the scale cut, which changes from 32 to 14 in the HMCode case.

We have performed the same analysis at the Fisher matrix level finding a still significant dependence of the results on the adopted nonlinear recipe. We indeed get FoM = $(2.93, 3.59, 1.59)$ for Halofit, HMCode, Halofit+PKequl, respectively. While the severe decrease of the FoM is expected given that we are removing a large part of the data, it is somewhat surprising to still find such a variety of values. This is, however, a consequence of the integrated nature of the WL $C_{ij}(\ell)$. To understand what is going on, let us focus on the case $i = j = 5$ giving $\ell_{\text{max}} \simeq 500$. Because of the photo-$z$ broadening of the lensing kernel, the integral giving $C_{55}(\ell_{\text{max}})$ gets contributions from the redshift range $(0.1, 2.6)$. Over this range, the argument $k_{\text{LS}}(z)$ of the matter power spectrum $P_{\text{LS}}(k, z)$ feeding the integral is larger than $k_{\text{max}}$ for $z < 0.84$ so that which nonlinear recipe is adopted still matters. Such an argument can be repeated for all the bins combinations and the multipoles thus explaining why the FoM is still dependent on the nonlinear recipe even with these very conservative scale cuts, a result in agreement with what was discussed in Taylor et al. (2018a). Therefore, in order to remove completely the dependence on the nonlinear description from the analysis, different approaches are needed, e.g. using band powers rather than a $C_{ij}$ analysis (Joachimi et al. 2020).

Appendix B: MCMC results validation

The results of this paper have been obtained using both Fisher matrix and MCMC codes. The Fisher analysis relies on one of the codes used in EC19 which has passed through a careful validation procedure that included intensive comparisons between different Fisher matrix codes. Our MCMC analysis relies on a public MontePython likelihood for Euclid WL (Brinckmann & Lesgourgues 2019) adapted to the Euclid specifications of EC19. It has been further modified to include different models of baryonic feedback effects. This likelihood code was first used in Springer et al. (2019).

In contrast to the Fisher code, it has not been validated against other codes. In this Appendix, we therefore present a comparison between validated Fisher forecasts and the MCMC ones.

In the Euclid-only case, our analysis reveals some deviations that are attributed to the intrinsic limitation of any Fisher analysis, due to the non-Gaussianity of the posterior distribution, as well as some important parameter degeneracies. Nevertheless, the impact on the forecasts becomes negligible when Planck constraints are included in the analysis. In this case, we find that the forecasts on cosmological parameters obtained with the Fisher and MCMC methods agree very well. This therefore validates our MCMC approach against the Fisher codes used in EC19.

The Euclid forecasts for WL in EC19 are accompanied by a series of public Fisher matrices, corresponding to different setups and cosmologies. In order to validate our MontePython likelihood and MCMC analysis, we have compared forecasts obtained for both the pessimistic and optimistic setups, and using the same cosmological parameters (in particular, $\Omega_{\text{m0}}$ and $\Omega_{\text{b0}}$ instead of $\omega_{\text{m}}$ and $\omega_{\text{b}}$). We have performed these comparisons for Euclid only, and in combination with Planck. In the latter case, we used the mock Planck likelihood available in Montepython that accurately reproduces the Planck limits on cosmological parameters. We construct a covariance matrix from the MCMC chains in the Planck-only case. Its inverse provides a Fisher matrix that can be added to the validated Euclid Fisher matrices.

We have checked that the Planck-only case constrains the standard cosmological parameters well, with close-to-Gaussian two-dimensional posterior distributions. This is a good indication that one can safely use the Planck covariance matrix for the Fisher analysis. In contrast to the standard cosmological parameters, most of the constraining power for the dark energy parameters $w_0$ and $w_a$ comes from Euclid, not Planck. As a consequence, the corresponding entries in the Planck Fisher matrix are not relevant and do not significantly impact the Euclid + Planck forecasts for these parameters.

For Euclid only, the marginalized two-dimensional posterior distributions and the Fisher contours obtained in the case $\ell_{\text{max}} = 1500$ for five varying cosmological parameters
Fig. A.1. One dimensional posterior distributions, and 68% and 95% confidence level marginalised contours for the dark energy parameters ($w_0$ and $w_a$) and the parameters $h$ and $\sigma_8$. Here we compare results obtained with a multipole cut at $l_{\text{max}} = 1500$ (green contours) with those related to the analysis with the scales cut $k_{\text{max}} = 0.25$ h Mpc$^{-1}$ (red contours). The mock data of Euclid cosmic shear assume Halofit+PKequal nonlinear corrections as reference, while the parameter estimation is performed with either HMcode (right panel), or Halofit (left panel). Black dashed lines mark the fiducial model.

$(\Omega_{m,0}, \Omega_{b,0}, h, n_s$ and $\sigma_8)$, with DE and IA parameters fixed to their fiducial values, are shown in Fig. B.1. We find that the directions and widths of all the Fisher ellipses are well recovered by the MCMC approach. However, we also find two significant differences. First, the MCMC contours in the plane $(\Omega_{b,0}, h)$ display a banana shape, leading to a more stringent constraint on $\Omega_{b,0}$ compared to the Fisher method. In turn, this affects two-dimensional contours between $\Omega_{b,0}$ and other parameters. Second, the marginalized posterior distribution for $h$ has a significant non-Gaussian shape, falling more rapidly at lower values than at higher values. Consequently, some of the contours are less extended on one side compared to the Fisher ellipses. This also arises from the degeneracy between $h$ and $\Omega_{b,0}$, with these parameters being poorly constrained with Euclid WL only. These features cannot be recovered by the Fisher analysis that relies on the assumption that the posterior distribution is Gaussian, which is not the case for strong variations of $h$ and $\Omega_{b,0}$. Nonetheless, these results show that both the MCMC and Fisher methods provide consistent results, even if the agreement between them is limited by the intrinsic limitation of the Fisher analysis. Adding dark energy parameters in the analysis further degrades the agreement between the Fisher and MCMC forecasts, for similar reasons. Here, we have only shown the case in which $w_0$ and $w_a$ remain fixed, for a better illustration of the effect of parameter degeneracies on the two method comparison.

For Planck+Euclid WL, we find a very good agreement between Fisher and MCMC forecasts, even when the DE and IA parameters are varying. This is shown in Fig. B.2, representing the MCMC marginalized two-dimensional posterior distributions, which fit well to all the Fisher ellipses. We find that the differences in the forecasts are less than 10% for all the cosmological parameters. This therefore validates the approach we have used throughout the paper. It also illustrates the importance of adding CMB data to break parameter degeneracies. Compared to the Euclid WL only case, the differences between the Fisher and MCMC methods are suppressed. The few remaining differences can be either due to a limited convergence of the MCMC chains, to uncertainties induced by the binning method, or to a slightly non-Gaussian likelihood function for Planck-only that induces small differences between MCMC posteriors and the corresponding Planck Fisher ellipses extracted from the covariance matrix of the MCMC chains. Similar results have been obtained for the optimistic setup with $l_{\text{max}} = 5000$.
