Non-random (skewed) X chromosome inactivation (XCI) in the female brain can ameliorate X-linked phenotypes, though clinical studies typically consider 80-90% skewing favoring the healthy allele as necessary for this effect[1-10]. Here we quantify for the first time whole-brain XCI at single-cell resolution and discover a preferential inactivation of paternal to maternal X at ~60:40 ratio, which surprisingly impacts disease penetrance. In Fragile-X-syndrome mouse model, Fmr1-KO allele transmitted maternally in ~60% brain cells causes phenotypes, but paternal transmission in ~40% cells is unexpectedly tolerated. In the affected maternal Fmr1-KO(m)/+ mice, local XCI variability within distinct brain networks further determines sensory versus social manifestations, revealing a stochastic source of X-linked phenotypic diversity. Taken together, our data show that a modest ~60% bias favoring the healthy allele is sufficient to ameliorate X-linked phenotypic penetrance, suggesting that conclusions of many clinical XCI studies using the 80-90% threshold should be re-evaluated. Furthermore, the paternal origin of the XCI bias points to a novel evolutionary mechanism acting to counter the higher rate of *de novo* mutations in male germiline[11-16]. Finally, the brain capacity to tolerate a major genetic lesion in ~40% cells is also relevant for interpreting other neurodevelopmental genetic conditions, such as brain somatic mosaicism.

The X chromosome expresses more brain-specific genes than any other chromosome[17] and X-linked gene mutations give rise to a high number of neurodevelopmental disorders, including Rett syndrome (RTT), Fragile X syndrome (FXS) and more than one hundred thirty X gene-linked intellectual disability and developmental disability disorders[17-23].

In female eutherian mammals, X chromosome inactivation (XCI) is thought to be a random process by which either maternally inherited X (Xm) or paternally inherited X (Xp) is chosen for epigenetic silencing, ensuring X dosage compensation compared to males[24-27]. However, a non-random (skewed or biased) XCI pattern favoring one Xm or Xp chromosome can occur as a consequence of a stochastic XCI fluctuation or developmental selection against an X chromosome carrying a deleterious mutation. Such selection bias favoring the healthy X chromosome has been proposed to occur in unaffected or only mildly affected female carriers of X-linked brain disorders, with the degree of skewing needed to reduce phenotypic penetrance typically defined as ≥80:20 selection ratio favoring the healthy X[1-10]. The evidence for this model of XCI clinical significance, however, remains inconclusive, as some studies reported correlations between neurodevelopmental disease manifestations and XCI skewing measured in peripheral blood cells, for example, in RTT and FXS[28-35], while others failed to identify consistent evidence to support this[6,9,36-41], including three studies that directly examined XCI in postmortem brains of RTT patients instead of relying on the indirect measure of XCI in blood[6,9,36]. Therefore, the extent to which XCI skewing exists in normal female brain and, even more importantly, the degree of skewing necessary to influence phenotypes in heterozygous X-linked neurodevelopmental disorders remain unclear.

In the current study, we determined the degree to which X chromosome inactivation (XCI) varies between individual female mice under normal conditions and the level of XCI skewing that is necessary and sufficient to alter penetrance of X-linked neurodevelopmental phenotypes in a mouse model of FXS. We applied our sensitive methods of whole-brain imaging and computational data analyses[42-44] to reveal a novel XCI pattern of ~60:40 bias favoring silencing of the paternal versus maternal X chromosome, alongside a stochastic ~20% variability across all brain regions in each individual mouse. Strikingly, this rather modest parent-of-origin bias and regional variability had clear effects on phenotypic penetrance in the FXS mouse model. First, the overall paternal bias in XCI

99   protected offspring from the effects of the Fmr1-KO allele inherited from the father—a

100   finding that may represent a novel evolutionary mechanism countering the damaging

101   neurodevelopmental effects of a higher mutation rate in male germline line[11-16]. Second,

102   the local XCI fluctuations influenced the type of behavioral phenotype observed in mice

103   with Fmr1-KO allele inherited maternally—a result that suggests a novel stochastic source

104   of the broad phenotypic variability seen in X-linked neurodevelopmental disorders in

105   female patients and which can also help to localize different disease symptoms to candidate

106   affected brain regions, which may be useful in developing therapeutic strategies.

107

108   **Systematic parent-of-origin effect on brain XCI**

109   To obtain unbiased and complete survey of brain XCI we applied our serial two-photon

110   tomography (STPT)-based imaging and computational methods[42-44] to quantify maternal

111   versus paternal active X chromosome distribution using *knock-in* Mecp2-GFP reporter

112   mice[45-47] in which X-linked methyl-CpG-binding protein is tagged with GFP (Mecp2-GFP),

113   acting as a cellular reporter of the selection of the active X chromosome (Extended Data

114   Fig. 1-2).

115   We first compared the total number of brain cells with maternal X active in Mecp2-

116   GFP(m/+) mice that inherited the X-linked Mecp2-GFP allele maternally (n = 18) and the

117   total number of brain cells with paternal X active in Mecp2-GFP(p/+) mice that inherited

118   the Mecp2-GFP reporter allele paternally (n = 19). Surprisingly, this comparison revealed

119   significantly more GFP+ cells in the brains of the maternal Mecp2-GFP(m/+) mice,

120   demonstrating an average 58:42 bias towards higher paternal XCI and, consequently, an

121   average 58:42 ratio of cells with maternal Xm active to paternal Xp active in WT brain

122   (Fig. 1c, d; Supplementary Table 1). Notably, though, this average ~60:40 paternal XCI

123   bias comprised a considerable individual variability, including extreme examples of 84:16

124   Xm selection bias and 25:75 Xp selection bias (Fig. 1d). Therefore, stochastic variability

125   in XCI in early development, in addition to the systematic paternal bias, also plays an

126   important role in determining the overall Xm:Xp ratio in each brain (note that the Xm:Xp

127   ratios were calculated by normalizing the Mecp2-GFP(m/+) and Mecp2-GFP(p/+) cell

128   counts to the sum of Xm-active and Xp-active cell counts, which was equal to the 100%

129   control homozygous Mecp2-GFP(m/p) cell count; Fig. 1d; See Methods).

130   Next, we asked whether the paternal XCI bias seen at the whole-brain level exists

131 similarly across all brain areas or whether there may be regional differences in XCI patterns

132 in the brain. This analysis revealed that the average ~60:40 bias for maternal X selection is

133 seen across all major brain divisions, including the isocortex (58:42), cortical subplate

134 (58:42), olfactory areas (57:43), hippocampal formation (57:43), cerebral nuclei (57:43),

135 thalamus (58:42), hypothalamus (58:42), midbrain (60:40) and hindbrain (66:34) (Fig. 1e,

136 f; Supplementary Table 1, 2) as well as across all local subregions in these areas (Fig. 1g;

137 Supplementary Table 1, 2). These data thus argue against a previous model of cortical

138 versus subcortical differences in parent of origin XCI[48], suggesting instead that the

139 maternal X selection bias is seen not only in the cortex but also across the entire brain (note

140 that the anatomical segmentation of the imaged brains was done as previously described

141 by us using the 2011 ARA mouse brain atlas;[42,43,49] see Methods).

142   The detailed anatomical brain segmentation also allowed us to measure regional

143 XCI variability in each individual brain (Fig. 2; Supplementary Table 1), with the aim to

144 determine whether such variability is related to (or independent of) the overall whole-brain

145 Xm:Xp ratio, such as whether brains with highly skewed Xm:Xp ratios comprise different

146 (or the same) regional variability compared to brains with the overall Xm:Xp ratio close

147 equal. To investigate this question, we visualized regional variability in Xm and Xp

148 selection across all anatomical regions and for each brain in brain-wide 2D heatmaps (Fig.

149 2a) and collapsed box-and-whisker plots (Fig. 2b). This revealed a similar variability from

150 the mean for all imaged brains independent of their overall Xm:Xp ratio with the mean

151 coefficient of variations (CV) for both Mecp2-GFP(m/+) and Mecp2-GFP(p/+) groups

152 being ~20% compared to CV of ~10% in homozygous Mecp2-GFP(m/p) mice (Fig. 2c).

153 Taken together with the previous analyses, these data show that Xm versus Xp selection in

154 each brain can be described as a result of a modest overall bias favoring the selection of

155 the maternal X (and silencing of the paternal X) across all brain regions, combined with a

156 moderate ~20% local stochastic variability independent of the overall selection.

157

158

159 **Paternal XCI bias gates FXS disease penetrance**

160   Having quantified the XCI patterns in WT mice, we next asked whether the identified

161   biases may affect disease penetrance in a female heterozygous mouse model of the fragile

162   X syndrome (FXS), an X-linked disorder caused by the loss of expression of the Fragile

163   X mental retardation 1 (Fmr1) protein[18,50]. Based on the WT data, we envisioned the

164   following scenarios: First, the average ~60:40 bias favoring maternal X selection should

165   lead to more brain cells carrying the mutant allele inherited from the mother than from

166   the father, resulting in more pronounced phenotypes associated with the maternal

167   transmission. Second, stochastic variability in regional Xm:Xp selection may further

168   modify the phenotypic outcomes based on which brain areas comprise the least favorable

169   mutant-to-healthy X ratios. On the other hand, a positive selection for cells with the

170   healthy X chromosome may change the XCI distribution from what is seen in WT brain,

171   resulting in lesser than expected skewing and related phenotypes.

172   To test these scenarios, we crossed the Fmr1 knock-out (KO) mouse model of

173   FXS[51] with the Mecp2-GFP X reporter line, generating heterozygous Fmr1-KO/+ female

174   mice with the KO allele inherited either maternally in Fmr1-KO(m)/Mecp2-GFP(p) mice

175   or paternally in Fmr1-KO(p)/Mecp2-GFP(m) mice (Fig. 3a). We note that while this FXS

176   mouse model has been studied extensively as a complete knock-out in male hemizygous

177   Fmr-1 KO/Y mice, only three studies reported modest phenotypes (synaptic and social) in

178   female heterozygous Fmr1 KO/+ mice with the KO allele always transmitted maternally[52-

179   54]. Hence, our study is the first to directly compare the phenotypic effect of maternal versus

180   paternal Fmr1 KO allele transmission in heterozygous female mice, while also quantifying

181   the whole-brain distribution of the Fmr1-KO allele-expressing cells in each animal.

182   We first assayed the impact of the maternal versus paternal Fmr1-KO allele

183   transmission across three behavioral tests that were used previously to identify disease-

184   related phenotypes in FXS mice: the open field (OFT) test to assess sensorimotor functions

185   and anxiety-related behavior[55-61]; the T-maze spontaneous alternation test to assess working

186   memory[60,62,63]; and finally the 3-chamber test to assay sociability and social preference[61,64,65]

187   (Fig. 3b). Strikingly, these experiments revealed that while the Fmr1-KO(m)/Mecp2-

188   GFP(p) heterozygous female mice with maternal KO allele transmission showed deficits

189   in all three tests, whereas the paternal Fmr1-KO(p)/Mecp2-GFP(m) heterozygous mice

190   were not different from control Mecp2-GFP sibling mice in any measurement (Fig. 3c-g).

191   The behavioral deficits of the maternal Fmr1-KO(m)/Mecp2-GFP(p) mice included: 1)
192   reduced travel distance across the center arena in the OFT suggesting reduced exploratory
193   behavior due to sensorimotor deficits and/or increased anxiety (Fig. 3c), 2) reduced
194   frequency of spontaneous alterations in the T-maze suggesting impaired working memory
195   (Fig. 3d), and 3) a complete lack of social preference in the 3-chamber social interaction
196   test, reflected by no preference for time spent in the chamber with a stranger mouse
197   presented under a wire cup versus the control chamber comprising only an empty cup (Fig.
198   3e-g). Interestingly, the maternal Fmr1-KO(m)/Mecp2-GFP(p) mice were also hyperactive
199   in the 3-chamber apparatus, as reflected by an increased total distance traveled compared
200   to control Mecp2-GFP sibling mice, and this hyperactivity was restricted to the starting
201   middle chamber (Fig. 3f, g). This suggests a more complex social phenotype of a combined
202   hyperactivity and avoidance of both social and non-social stimuli in Fmr1-KO(m)/Mecp2-
203   GFP(p) mice.

204   Taken together, our behavioral results demonstrate that female mice with the Fmr1
205   KO allele transmitted maternally, but not paternally, display disease-related phenotypes.
206   This, in turn, suggests that the bias of higher maternal X selection (and higher paternal X
207   silencing) seen in WT mice persists in the heterozygous Fmr1-KO/+ mice and results in
208   more brain cells carrying the Fmr1 KO allele inherited maternally than paternally. To test
209   this prediction directly, we imaged the brains of all mice used in the above behavioral tests
210   by STPT as done for WT brains in Fig. 1 and determined the distribution of the WT Fmr1
211   allele-expressing cells marked by Mecp2-GFP expression from the same X chromosome.
212   These measurements revealed the following. First, the whole-brain Xm:Xp ratio in the
213   maternal Fmr1-KO(m)/Mecp2-GFP(p) mice was 54:46, representing an average 54% of
214   Fmr1-KO allele expressing brain cells compared to 46% Fmr1 WT allele expressing cells
215   (Fig. 3h, i; Supplementary Table 3, 4). Second, the regional Xm:Xp ratio differences were
216   more pronounced for cortical versus subcortical areas (Extended Data Fig. 3), suggesting
217   a modest compensation favoring the selection of the healthy paternal Xp chromosome
218   subcortically compared to WT brains. And third, the whole-brain Xm:Xp ratio in the
219   paternal Fmr1-KO(p)/Mecp2-GFP(m) mice was 41:59, reflecting an average 41% of Fmr1-
220   KO allele expressing brain cells compared to 59% Fmr1 WT allele expressing cells (Fig.
221   3h-i). These data thus demonstrate that an average ~55:45 mutant to healthy brain cell

222 density ratio is sufficient to cause behavioral phenotypes in the maternal Fmr1-

223 KO(m)/Mecp2-GFP(p) mice, while in contrast ~40:60 mutant to healthy brain cell density

224 ratio is below a threshold needed to produce phenotypic manifestations in the paternal

225 Fmr1-KO(p)/Mecp2-GFP(m) mice.

226

Local XCI variability contributes to phenotypic diversity

228 Brain-wide cellular distribution measurements of Fmr1 WT versus KO alleles allowed us

229 to further test whether regional stochastic XCI variability may further influence the

230 observed phenotypes in the affected maternal Fmr1-KO(m)/Mecp2-GFP(p) mice. For

231 example, it may be expected that mice with high Fmr1-KO allele cell density in brain areas

232 known to regulate social behavior will show more pronounced phenotypes in the 3-

233 chamber sociability test compared to those with a stochastically lower Fmr1 KO allele cell

234 density in the same brain areas. To test this hypothesis, we correlated the Fmr1 WT:KO

235 cell ratios across all brain regions to behavioral scores from all three behaviors for each

236 mouse tested. This correlation analysis identified two distinct sets of anatomical regions in

237 the maternal Fmr1-KO(m)/Mecp2-GFP(p) brains, in which the Fmr1 WT:KO cell ratios

238 were indeed correlated to behavioral performance in either the OFT or the 3-chamber test

239 (Fig. 4a; Extended Data Fig. 4).

240   The first set of brain regions comprised areas in which the Fmr1 WT:KO cell ratio

241 was positively correlated to OFT behavioral performance, specifically the distance traveled

242 in the center of the OFT arena. These regions included primarily sensory structures of the

243 thalamus, midbrain and hindbrain (Fig. 4a, d-f; Extended Data Fig 4a; Supplementary

244 Table 5), such as the sensory ventral posterolateral nucleus of the thalamus (VPL) (Fig 4b).

245 These data thus indicate that a higher density of cells expressing the Fmr1 WT allele across

246 the identified areas known to regulate sensorimotor functions, among others, translates to

247 increased exploration of the open field arena and hence a reduced OFT phenotype. The

248 second set of brain regions comprised areas in which the Fmr1 WT:KO cell ratio was

249 inversely correlated to the time spent in the center of the 3-chamber apparatus. These

250 regions, in contrast to the first set, contained primarily cortical, hippocampal and

251 hypothalamic brain areas (Fig. 4a, c, g-i; Extended Data Fig. 4a; Supplementary Table 5),

252 including the hypothalamic medial preoptic nucleus (MPN) that is well known for

8

253   regulating social behavior (Fig 4c; Extended Data Fig 4c). These data, in turn, indicate that

254   a higher density of cells expressing the Fmr1 KO allele across areas known to regulate

255   social behaviors, among others, translates to more time spent in the starting chamber of the

256   3-chamber apparatus and hence a more pronounced social deficit phenotype. The same

257   correlation analysis failed to identify a distinct set of brain regions with Fmr1 WT:KO

258   ratios related to behavioral performance in the T-maze test in which the Fmr1-

259   KO(m)/Mecp2-GFP(p) mice showed only a modest level of impairment (Fig. 3a;

260   Supplementary Table 5). In addition, whole-brain Fmr1 WT:KO ratios, in contrast to the

261   regional ratios described above, showed only a trend towards a positive correlation in the

262   OFT and negative correlation in the 3-chamber task (Extended Data Fig. 5). This suggests

263   that while the whole-brain WT:KO cell ratios set the overall risk for disease penetrance,

264   the regional Fmr1 WT:KO cell ratios determine the specific behavioral phenotypic

265   outcome in each animal. Finally, as expected, we also did not observe any significant

266   correlations for brain regions in the paternal Fmr1-KO(p)/Mecp2-GFP(m) mice which did

267   not show any behavioral phenotypes (Fig. 4a; Supplementary Table 5).

268

269   **Anatomical brain networks underlying distinct behavioral phenotypes**

270   The identification of the two sets of brain regions with Fmr1 KO allele density linked to

271   behavioral phenotypes suggests that these represent two distinct anatomically connected

272   brain networks regulating sensorimotor and anxiety-related versus social behaviors. To test

273   this hypothesis further, we next applied the recently established structural connectivity

274   matrix analysis derived from a whole-brain connectivity model of the mouse brain[66] (See

275   methods). This analysis indeed revealed much higher connection densities for brain regions

276   within each brain network than for matching randomly sampled brain structures: the OFT

277   network density (Fig. 5a-b) and 3-chamber network density (Fig. 5e-f) represented the 93rd

278   and 100th percentile of each sample network's distribution, respectively (Supplementary

279   Table 6; see Methods). This analysis thus supports the model where the brain areas with

280   Fmr1-KO cell density linked to different behavioral deficits represent two distinct

281   functional brain networks.

282   The identified correlations of local Fmr1-KO cell densities to behavioral

283   phenotypes also suggest that the distribution of the Fmr1-KO allele across the two brain

284   networks determines and can in fact predict the disease penetrance in each animal. To test

285   this hypothesis, we next calculated the Fmr1 WT:KO allele ratios selectively across the

286   two brain networks and regressed these values against the behavioral performance in the

287   OFT and 3-chamber test (Supplementary Table 7). As shown in Fig. 5, the Fmr1 WT:KO

288   allele ratios were indeed highly significant predictors of individual behavioral performance

289   in only maternal Fmr1-KO(m)/Mecp2-GFP(p) heterozygous mice in both the OFT (Fig.

290   5c) and 3-chamber (Fig. 5g) assays, and not for control or paternal Frm1-KO(p)/Mecp2-

291   GFP(m) mice (Extended Data Fig. 6. These data thus further support the model where the

292   cellular distribution of the Fmr1-KO allele across the two brain networks represent the

293   cellular and genetic substrate the respective OFT and 3-chamber test behavioral

294   phenotypes.

295   Finally, in the last set of analyses, we asked what is the local Fmr1 KO cell density

296   that can differentiate normal from disease-related behavior. Likelihood-ratio tests

297   performed on binary logistic regression models revealed that the Fmr1-KO allele

298   distributions across the brain networks indeed significantly predicts normal from disease-

299   related performance in both the OFT (Fig. 5d) and 3-chamber test (Fig. 5h). The equal-

300   odds ratio of normal versus disease-related behavioral outcome was calculated to be 55.20

301   ± 5.95% healthy cell density percent in the OFT brain network and 49.18 ± 5.19% healthy

302   cell density percent in the 3-chamber brain network. This phenotypic penetrance threshold

303   of ~50% regional Fmr1-KO cell density agrees with the lack of behavioral manifestations

304   when the Fmr1-KO allele is transmitted paternally in ~40% brain cells (Fig 3).

305

Discussion

307   We applied our automated whole-brain imaging platform[42] to comprehensively quantify

308   the respective distributions of active maternal and paternal X chromosomes across the

309   entire mouse brain at single cell resolution. This approach allowed us to discover subtle

310   yet both statistically and functionally significant patterns that were missed by previous

311   studies relying on semiquantitative observations typically from only a few selected brain

312   areas[48,67-69].

313   Clinical studies of the effects of XCI skewing on neurodevelopmental disorders

314   typically consider >80% (or even >90%) skewing in favor of the healthy X chromosome

315   as significant with respect to modifying X-linked phenotypes, with ratios below the 80%

316   threshold defined as balanced (i.e., non-skewed)[1-10]. Therefore, these studies suggest that

317   brain development can tolerate only 10 to 20% of brain cells carrying a deleterious

318   mutation and a higher percentage of affected brain cells should be expected to lead to

319   clinical manifestations. In contrast, our study revealed a lack of behavioral phenotypes in

320   paternal heterozygous Fmr1-KO(p)/+ mice carrying the Fmr1-KO allele in ~40% brain

321   cells, demonstrating an unexpectedly robust brain capacity to compensate for the presence

322   of a harmful mutation in nearly half of brain cells. Therefore, we propose that a threshold

323   of ~60% skewing in favor of the healthy X chromosome may be sufficient for modifying

324   neurodevelopmental phenotypic penetrance and should be considered clinically relevant.

325   This suggests that negative results from many clinical studies that considered >80% XCI

326   skewing as a threshold for interpretating clinical phenotypes may need to be reevaluated

327   with the lower threshold >60% as a skewed XCI definition[5,37-40,70-76].

328   In addition to challenging the dogma that only large degree of XCI skewing can

329   affect X-linked neurodevelopmental phenotypes, our results also show that stochastic XCI

330   variability, estimated from our measurements to be ~20% across all brain regions

331   independent of the overall brain XCI bias, can play an important role in determining the

332   specific phenotypic manifestations in each individual female. Our data revealed that in the

333   maternal heterozygous Fmr1-KO(m)/+ mice, the Fmr1-KO allele variations across two

334   distinct brain networks can predict the likelihood of disease-related phenotypes in two

335   behavioral tests – the open field and 3-chamber test measuring sensorimotor performance

336   and sociability, respectively – in each animal. Thus, while the overall ~60% brain cell

337   transmission of the maternal Fmr1-KO allele predisposes for disease related phenotypes,

338   the ~20% stochastic brain-wide variation on top of the overall pattern is likely to determine

339   the specific features of the phenotypic representation (Fig 6). This finding provides an

340   important etiological insight into the potential source of phenotypic variability in X-linked

341   neurodevelopmental syndromes disease in female patients.

342   The finding that the brain can tolerate the loss of as important a gene as Fmr1 in

343   nearly half brain cells may also be relevant for the interpretation of the significance of

344   somatic mutations in the brain, which occur during cell divisions after fertilization and lead

345   to a mosaic expression of a genetic lesion in a subset of brain cells and cell types depending

11

346 on the cell lineages affected[77-80]. While some genetic lesions can lead to

347 neurodevelopmental phenotypes even when expressed in a relatively local cell population

348 in the brain, such mutations linked to focal epilepsy or gross morphological development[81-

349 87], our data suggest that mutations related to more cognitive dysfunctions in

350 neurodevelopment, such as those linked to autism or intellectual disability, may require a

351 similarly high threshold of >50% brain cells (perhaps within a specific cell type lineage)

352 to be affected to lead to phenotypic manifestations.

353   Finally, our results also suggest a novel evolutionary role of the observed 60:40

354 XCI paternal bias. Maternally and paternally imprinted autosomal genes are expressed in

355 highly distinct regional patterns proposed to mediate competing interests of each parent in

356 terms of the evolutionary fitness of their genes, as proposed in the so-called kinship or

357 genetic conflict theory[88,89]. Our study revealed a systematic ~60:40 paternal bias in XCI

358 across all brain divisions and regions, suggesting that XCI is not part of such a maternal

359 versus paternal genetic competition. On the other hand, the paternal XCI bias may play a

360 different evolutionary role. It is well established that the mutation rate in the paternal

361 germline is significantly higher compared to that in the maternal germ cells, which should

362 result in a higher rate of X-linked mutations linked to neurodevelopmental deficits from

363 paternal transmission[11-16]. Our findings thus suggest that the selective bias to silence ~60%

364 of the paternal X chromosome and the surprising developmental capacity to tolerate the

365 mutant allele in nearly half brain cells may in fact represent a novel evolutionary

366 mechanism acting to counter the higher frequency of *de novo* mutations inherited from the

367 father compared to the mother in daughters.

368   In the current study we used the Fmr1-KO allele as an established mouse model of

369 X-linked genetic lesion, but we note that human FXS is caused by expansion (>200 repeats)

370 of the 5' UTR CGG sequence of an FMR1 premutation allele inherited exclusively

371 maternally[18,90-92]. Therefore, the observed ~60:40 paternal XCI bias is not directly pertinent

372 to FXS inheritance, but instead may be evolutionary important in protecting offspring from

373 a higher rate of paternally inherited *de novo* mutations in one of the more than 130 X genes

374 linked to non-syndromic intellectual disability and other neurodevelopmental phenotypes[17-

375 23].

696 **Fig. 1 | Whole-brain quantification of active maternal and paternal X chromosome**

697 **distribution. a**, Strategy for breeding maternal, paternal, and homozygous Mecp2-GFP

698   reporter mice. Left: heterozygous Mecp2-GFP(m/+) females with maternal Mecp2-GFP

699   allele are derived from breeding homozygous female Mecp2-GFP(m/p) and WT male

700   mice. Middle: heterozygous Mecp2-GFP(p/+) females with paternal Mecp2-GFP allele are

701   derived from breeding WT female and hemizygous Mecp2-GFP(m/Y) male mice. Right:

702   homozygous Mecp2-GFP(m/p) mice are derived from breeding Mecp2-GFP(m/p) female

703   and Mecp2-GFP(m/Y) male mice. **b**, Representative STPT images from brains with

704   maternal Xm-Mecp2-GFP (top), paternal Xp-Mecp2-GFP (middle) and homozygous Xm-

705   Mecp2-GFP/Xp-Mecp2-GFP (bottom) cells. **c**, Mecp2-GFP+ cell density in the three

706   genotypes represented as voxelized heat maps of a 16-color gradient scale from black (0

707   cells/voxel), yellow (150 cells/voxel) to white (300 cells/100 μm sphere voxel). **d**, Whole-

708   brain Mecp2-GFP+ cell counts (mean ± SD): Xm-GFP+ cells = $2.34 \times 10^7 \pm 4.96 \times 10^6$

709   (n=18); Xp-GFP+ cells = $1.69 \times 10^7 \pm 4.63 \times 10^6$ (n=19); and homozygous Xm-GFP+/Xp-

710   GFP+ cells = $3.92 \times 10^7 \pm 2.52 \times 10^6$ (n=6); p = 0.00023, Welch's t test. The sum of the

711   heterozygous Xm-GFP+ and Xp-GFP+ cell counts is shown as a black diamond. Solid

712   horizonal lines indicate 100% and 50% of homozygous Xm-GFP/Xp-GFP cell count.

713   Dashed gray lines indicate 75:25 and 25:75 Xm-active:Xp-active cell ratios based on the

714   homozygous Xm-GFP/Xp-GFP cell count. Dashed red and blue lines show the derived

715   mean 58:42 Xm-active:Xp-active and 42:58 Xp-active:Xm-active ratios. **e**, Xm-active

716   (red) and Xp-active (blue) cell densities (cells/mm³) demonstrate a comparable Xm

717   selection bias across all major ontological brain divisions (mean ± SD; Xm-active, Xp-

718   active): ISO (isocortex): 72118 ± 17083, 51810 ± 14188; OLF (olfactory areas): 82791 ±

719   16950, 62260 ± 17057; HPF (hippocampal formation): 65273 ± 21583, 53398 ± 13519;

720   CTXsp (cortical subplate): 63541 ± 14215, 46708 ± 12138; CNU (cerebral nuclei): 68663

721   ± 16025, 52269 ± 12254; TH (thalamus): 50224 ± 14088, 35745 ± 12424; HY

722   (hypothalamus): 70594 ± 14086, 51834 ± 13835; MB: 56670 ± 15046, 38513 ±1364; HB

723   (hindbrain): 30458 ± 13392, 15766 ± 7539; **p < 0.01, 2-way mixed effects ANOVA

724   with Holm-Sidak corrected post-hoc comparisons. **f**, Data from **e**, converted into cell

725   density ratios reveal ~60:40 Xm-active bias across all regions. Ratios for each ROI are

726   listed to the right and color-coded by Xm-active (red) and Xp-active (blue) samples. **g**, Xm

727   selection bias is seen across all brain regions. Left two columns: Heat map visualization of

728   normalized mean Xm-active and Xp-active ROI cell density on a color gradient of black

729   (50%) to green (100%). Right column: statistical significance across all ROIs (FDR-

730   corrected student's t tests), with each q value indicated by a color gradient from red (0.1)

731   to yellow (0.001).

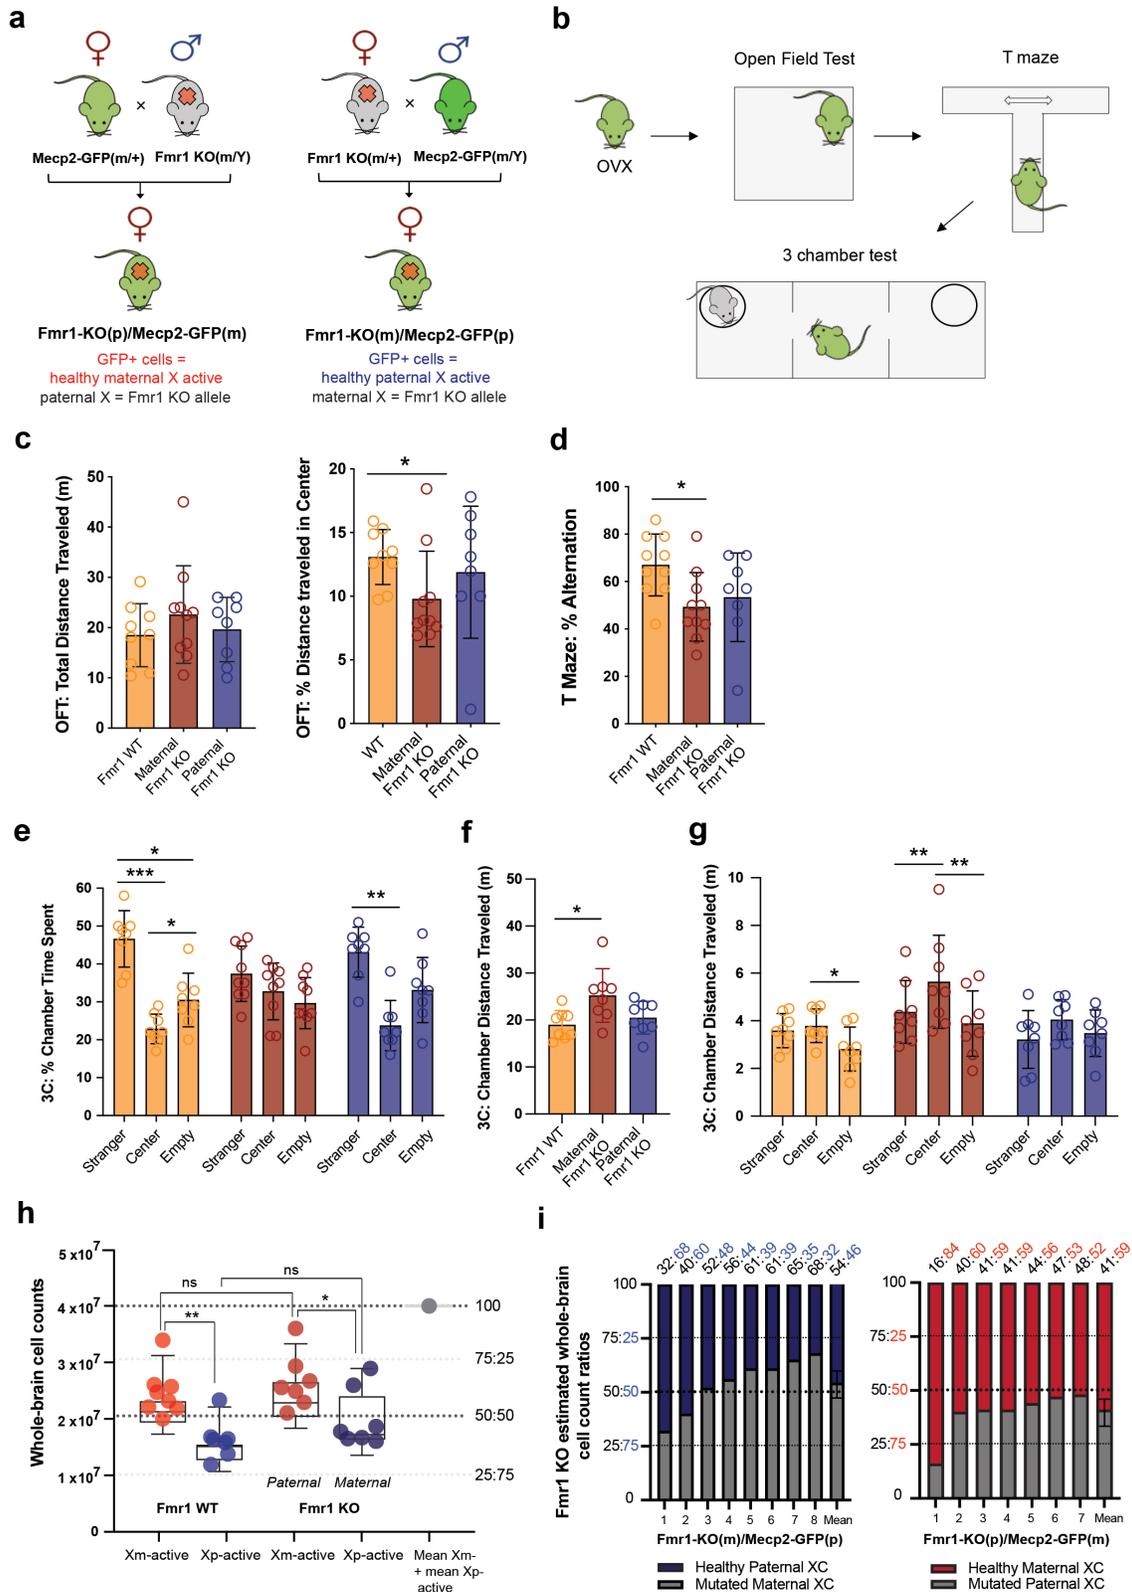

Fig. 3 | Maternal transmission of the Fmr1-KO allele at an average 46:54 Fmr1-WT:KO cell ratio is sufficient for phenotypic penetrance. a, The Fmr1 KO allele was

796   transmitted either maternally in Fmr1-KO(m)/Mecp2-GFP(p) mice (in figures for short

797   Fmr1-KO(m)/+; left) or paternally in Fmr1-KO(p)/Mecp2-GFP(m) mice (in figures Fmr1-

798   KO(p)/+; right) by breeding with Mecp2-GFP male or female mice, respectively. **b**,

799   Behavioral testing: ovariectomized (OVX) heterozygous maternal Fmr1-KO(m)/+,

800   paternal Fmr1-KO(p)/+ and WT littermate mice were sequentially tested in the open field

801   test (OFT), T maze, and 3-chamber social test (n=8 for each group). Data for each

802   individual test are derived from sequential data of the same animals. **c**, OFT results show

803   reduced exploration only in maternal Fmr1-KO(m/+) mice: Left: Total distance traveled

804   was not different among the three groups (mean ± SD; meters): WT: 19.2 ± 6.3; Fmr1-

805   KO(m/+): 23.2 ± 10.6; Fmr1-KO(+/p): 19.6 ± 6.3. Right: Percent distance traveled in

806   center arena was reduced in Fmr1-KO(m)/+ mice (mean ± SD): WT: 13 ± 2; KO(m/+): 9

807   ± 3; KO(+/p): 12 ± 5. ANOVA, K-W = 6.47; p = 0.039; Welch's ANOVA and Dunnet T3

808   post-hoc test: WT vs Fmr1-KO(m/+): p = 0.035. **d**, T maze results show reduced working

809   memory, seen in reduced percent spatial alterations, only in maternal Fmr1-KO(m/+) mice

810   (mean ± SD): WT: 69 ± 14; Fmr1-KO(m/+): 47 ± 15; Fmr1-KO(+/p): 53 ± 19. Welch's

811   ANOVA, Dunnet T3 post-hoc comparisons: WT vs Fmr1-KO(m/+): p = 0.023. **e**-**g**, 3-

812   chamber test identifies deficits only in maternal Fmr1-KO(m/+) mice. **e**, Fmr1-KO(m)/+

813   show a lack of sociability in the 3-chamber test. Time spent for the 3 genotypes in social

814   vs center vs empty chamber were (mean ± SD): WT = 47 ± 7 vs 23 ± 4 vs 31 ± 7; Fmr1-

815   KO(m/+) = 39 ± 6 vs 32 ± 8 vs 29 ± 7; Fmr1-KO(+/p) = 43 ± 7 vs 24 ± 7 vs 33 ± 9; 2-way

816   mixed effects ANOVA, Holm-Sidak post-hoc comparisons; *p<0.05; **p<0.01;

817   ***p<0.001. **f**, Fmr1-KO(m)/+ mice were hyperactive compared to WT mice as seen in

818   increased total distance traveled (mean ± SD): 24.25 ± 6.10, 18.96 ± 3.07 and 20.49 ± 3.48,

819   respectively. Welch's ANOVA and Dunnet T3 post-hoc comparisons, WT vs Fmr1-

820   KO(m/+): p = 0.037. **g**, The hyperactivity of the Fmr1-KO(m)/+ mice was restricted to the

821   starting central arena of the 3-chamber apparatus. Distance traveled for the 3 genotypes in

822   social vs center vs empty chamber were (mean ± SD): WT = vs 3.79 ± 0.71 vs 3.08 ± 1.17;

823   Fmr1-KO(m)/+ = 4.37 ± 1.32 vs 5.63 ± 1.96 vs 3.80 ± 1.36; Fmr1-KO(p)/+ = 3.22 ± 1.21

824   vs 4.05 ± 0.84 vs 3.71 ± 0.98; *p<.05; **p<.01, 2-way mixed effects ANOVA, Holm-Sidak

825   post-hoc comparisons. **h**, Quantification of whole-brain Xm vs Xp selection in WT mice

826   (left) and heterozygous Fmr1 KO mice (right) (mean ± SD): WT: Xm-active cells = 2.6 x

827    $10^7 \pm 4.7$ x 10^6 and Xp-active cells = 1.7 x $10^7 \pm 3.6$ x 10^6; maternal KO allele in Fmr1-

828   KO(m/+): healthy Xp-active cells in = 2.0 x $10^7 \pm 5.2$ and paternal KO allele in Fmr1-

829   KO(p/+): healthy Xm-active cells = 2.6 x $10^7 \pm 4.8$. *p<0.05, **p<0.01, ANOVA with

830   Holm-Sidak post-hoc comparisons. Estimated 75:25 and 25:75 whole-brain cell count

831   ratios are shown in dashed lines. **i**, Stacked bar graphs of each maternal Fmr1-KO(m/+)

832   (left) and paternal Fmr1-KO(+/p) (right) whole-brain X selection from (**h**): healthy Xp-

833   active cells in Fmr1-KO(m)/+ brains are highlighted in dark blue color (left) and healthy

834   Xm-active cells in Fmr1-KO(p/+) are highlighted in red color (right). Fmr1-KO:WT

835   cellular ratios of each sample is listed above.

836

837
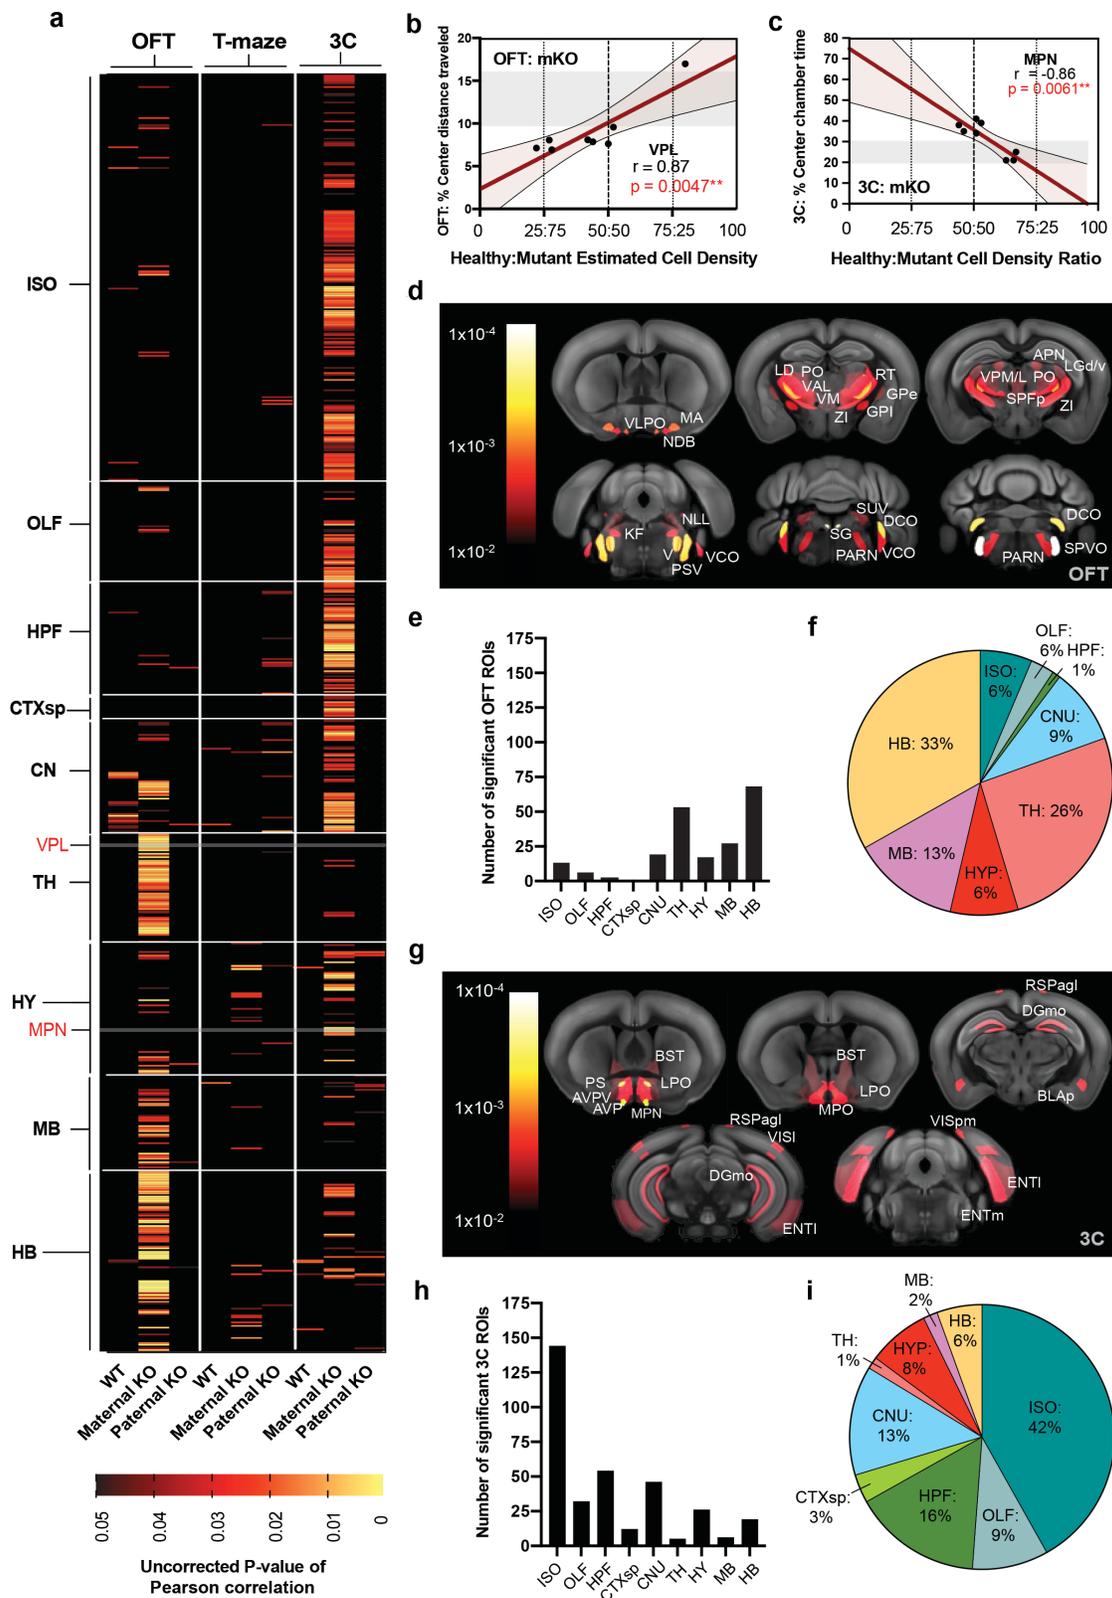

839 **Figure 4 | Identification of two sets of brain regions with local Fmr1-WT:KO cell**

840 **ratios linked to phenotypes in the OFT and 3-chamber test. a**, Identified brain regions

841 in Fmr1-KO(m)/Mecp2-GFP(p) ("Maternal KO") mice that correlate Fmr1 WT:KO allele

842 ratios to behavioral performance in the OFT and 3-chamber tests. Data are displayed as 2D

843 heat maps of statistically significant correlations across brain ROIs grouped by major

844 ontological structures. Uncorrected P values of Pearson correlations are represented on a

845 color gradient scale from 0.05 (black) to 0.005 (red) to 0.0005 (yellow). Results from Fmr1

846 WT ("WT"), maternal Fmr1-KO(m)/Mecp2-GFP(p) ("Maternal KO") and paternal Fmr1-

847 KO(p)/Mecp2-GFP(m) ("Paternal KO") mice are grouped by each behavioral test: left:

848 OFT, center: T maze, right: 3-chamber (3C). **b-c**, Representative scatterplot displays of

849 correlated ROI density from (**a**) shown for (**b**) VPL of thalamus in OFT and (**c**) MPN of

850 hypothalamus in 3 chamber tests. **d**, **g**, Selected ROIs from maternal Fmr1-KO(m)/Mecp2-

851 GFP(p)\ mice with significant correlation (cut-off at p=0.01) to performance in (**d**) OFT

852 and (**g**) 3 chamber tests are heat mapped and overlaid on a reference mouse brain template.

853 **e**, **h**, Number of significantly correlated ROIs from maternal Fmr1-KO(m)/Mecp2-GFP(p)

854 mice listed by major brain structure for (**e**) OFT and (**h**) 3 chamber tests. **f**, **i**, 100% pie

855 charts of significantly correlated ROIs from maternal Fmr1-KO(m)/Mecp2-GFP(p) mice

856 grouped by major brain structure and represented as a percent of total correlated ROIs for

857 (**f**) OFT and (**g**) 3-chamber test. ROI acronyms: VLPO – ventrolateral preoptic area; NDB

858 – nucleus of the diagonal band; MA – magnocellular nucleus; PO – posterior complex of

859 the thalamus; VPM/L – ventral posteromedial/lateral nucleus of the thalamus; PC –

860 paracentral nucleus; RT – reticular nucleus of the thalamus; ZI – zona incerta; GPi – globus

861 pallidus, internal; GPe – globus pallidus, external; SPFp – subparafacsicular nucleus,

862 parvicellular part; LGv – ventral part of the lateral geniculate nucleus; LGd – dorsal part

863 of the lateral geniculate nucleus; KF – Koelliker-Fuse subnucleus; V – motor nucleus of

864 the trigeminal; PSV – principal sensory nucleus of the trigeminal; VCO – ventral cochlear

865 nucleus; SG – supragenual nucleus; DCO – dorsal cochlear nucleus; VCO – ventral

866 cochlear nucleus; SPVO – spinal nucleus of the trigeminal, oral part, E, F) PS – parastrial

867 nucleus; BST – bed nuclei of the stria terminalis; AVP – anteroventral preoptic nucleus;

868 AVPV – anteroventral periventricular nucleus; MPO – medial preoptic nucleus; LPO –

869 lateral preoptic area; RSPAgl – retrosplenial cortex, agranular layer; DGmo – dentate

31

870   gyrus, molecular layer; BLAp – basolateral amygdala, posterior; VISpm – posteromedial

871   visual area; VISl lateral visual area; ENTl – entorhinal area, lateral; ENTm – entorhinal

872   area, medial.

949   **Methods**

950

951   **Animal breeding and husbandry.** Adult mice (8-10 weeks old) were used for whole-
952   brain imaging experiments. Animals were housed under a 12-hour light/dark cycle (0600
953   ON, 1800 OFF), had access to food and water ad libitum, and were housed with littermates.
954   All experimental procedures were performed in accordance with CSHL Animal Care and
955   Use Committee Guidelines. The Mecp2-GFP mouse line was obtained from the Jackson
956   laboratory (stock # 014610). Mecp2 is a gene located at chromosomal position X A7.3 and
957   is subject to XCI. Developed in the laboratory of Adrian Bird, this mouse line contains an
958   in-frame knock-in cassette at the 3' UTR of the Mecp2 locus [46,47,93,94]. Driven and regulated
959   by the endogenous Mecp2 promoter/enhancers, Mecp2-GFP expression leads to normal
960   Mecp2 levels and subcellular localization of Mecp2 protein that is fused at the C-terminus
961   with EGFP. Expression of the fusion allele does not alter neuronal physiology [94] and mice
962   are successfully bred to homozygosity without behavioral or reproductive complications
963   (data not shown). In addition, strong expression of Mecp2-GFP favors neurons of many
964   types [46] thereby circumventing biased effects of XCI determinations based on expression
965   profile. Mecp2-GFP(m/+) or Mecp2-GFP(p/+) mice were obtained in separate
966   heterozygotes by crossing homozygous females or hemizygous males with wild-type
967   C57Bl6/J (JAX stock # 000664) mice. A subset of these wild type reporter mice was
968   derived from Fmr1 KO or WT crosses that generated Mecp2-GFP(m/+)/Fmr1
969   KO(+/+) (n=7) and Mecp2-GFP(+/p)/Fmr1 KO(+/+) (n=8) mice that are congenic to the
970   C57Bl6/J crosses. Homozygous reporter mice were obtained by
971   crossing homozygous Mecp2-GFP(m/p) females with   hemizygous Mecp2-
972   GFP(m/Y) males. Fmr1 KO mice were obtained from the Jackson laboratory (#003025).
973   These mice were originally developed in the Oostra laboratory and contain a gene-
974   disrupting neomycin resistance cassette in exon 5 of the FMR1 locus [51]. Mecp2-
975   GFP(m/+)/Fmr1 KO(+/p) female mice were generated by breeding Mecp2-
976   GFP(m/p) females with hemizygous Fmr1 KO(m/Y) males. For imaging only, Mecp2-
977   GFP(m/+)/Fmr1 KO(+/+) female mice were generated by separately breeding
978   homozygous Mecp2-GFP(m/p) females   with   hemizygous Fmr1   KO(+/Y) males.
979   Conversely, Mecp2-GFP(+/p)/Fmr1 KO(m/+) or Mecp2-GFP(+/p)/Fmr1 KO(+/+) wild

36

980 type littermates were generated by breeding Fmr1 KO(m/+) females with

981 hemizygous Mecp2-GFP(m/Y) males. Using this genetic strategy, double heterozygous

982 mice used for behavior and imaging experiments contained the Mecp2-GFP and Fmr1 KO

983 alleles on opposing X chromosomes. All transgenic mice were maintained on a C57Bl6/J

984 background.

985

986 **Brain sample preparation.** Animals were euthanized via transcardial perfusion under

987 ketamine/dexmedetomidine anesthesia. Dissected brains were post-fixed overnight in 4%

988 paraformaldehyde at 4 C, incubated for 48 h in 0.1 M glycine/0.1 M PB for auto fluorescent

989 quenching, and then stored in 0.05 M PB at 4 C until confocal or serial two-photon

990 tomography imaging (STPT; see below). Prior to STPT imaging, brains were embedded

991 4% oxidized agarose in 0.05 M PB using custom molds and holders to maintain consistent

992 embedding position. Embedded brains were crosslinked in 0.2% sodium borohydrate

993 solution for 3h at room temperature or overnight at 4 C prior to STPT processing (below).

994

995 **Immunohistochemistry and confocal imaging.** Neuronal expression of the MeCP2-GFP

996 allele was studied though immunostaining and confocal imaging. 50 um vibratome-

997 processed, free-floating coronal sections of homozygous MeCP2-GFP mice brains (n=2)

998 were processed. Sections were washed 3 times in PBS followed by blocking for 1 h at room

999 temperature in PBS- T (PBS, 0.2% Triton-X 100) containing 5% donkey serum. Sections

1000 were then incubated overnight at 4 C in blocking solution containing rabbit anti-NeuN

1001 (Millipore, ABN78) primary antibody at 1:1000. After washing, NeuN-stained sections

1002 were incubated with anti-rabbit AlexaFluor-568-conjugated secondary antibody (Thermo-

1003 Scientific, A10042) diluted 1:500 for 1 h at room temperature. After washing excess

1004 secondary antibody, sections were mounted, DAPI- counterstained (Prolong Gold Antifade

1005 Mountant, Thermo Fisher), and coverslipped for imaging. Confocal images were acquired

1006 with a Zeiss LSM780 confocal microscope using a 561 laser and corresponding dichroic

1007 and filter sets. Single plane images were captured with a 40x oil immersion objective. Total

1008 colocalized populations for each marker of every FOV (212.55 um X x 212.55 um Y) were

1009 manually quantified using Fiji image processing package.

1010

1011   **Serial two-photon tomography whole-brain image acquisition**. The Tissuecyte1000

1012   instrument was used for all imaging experiments (TissueVision) [44]. This system combines

1013   a high-speed multi- photon microscope with a fully integrated vibratome for automated z-

1014   sectioning and image acquisition throughout the entire whole-mount sample. Embedded

1015   sample brains were imaged with a 20x objective at 50 µM below the sample surface. 270

1016   total serial sections were acquired at 50 um z-resolution (13.5 mm total z-length), with each

1017   section being comprised of a 12 (x-axis, 700 um) x 16 (y-axis, 700 um) field of view (FOV)

1018   mosaic. Images were acquired with laser scan settings of 1 um/pixel at an integration time

1019   of 1 us. A laser wavelength of 910 nm with ~322 mW power at the end of the objective

1020   was used for optimal excitation/emission of MeCP2-GFP fluorescence. Constant laser

1021   settings and PMT detector settings were used for all samples.

1022

1023   **Automated MeCP2-GFP+ cellular detection and counting.** Raw image tiles for each

1024   brain were illumination corrected, stitched in 2D with Matlab and aligned in 3D using Fiji

1025   software [44]. For reliable automated MeCP2-GFP detection from full brain datasets, we

1026   implemented convolutional networks (CNs) [95]. CN training for detection of MeCP2-GFP+

1027   cells in the STPT datasets was accomplished as in previous studies [43] with CN training

1028   performed on human marked-up ground truth data (biological expert identified MeCP2-

1029   GFP+ nuclei) of MeCP2-GFP brains. CN performance was determined based on F-score

1030   calculations (F-score = the harmonic mean of the precision and recall, where precision is

1031   the ratio of correctly predicted cells divided by all predicted cells and recall is ratio of

1032   correctly predicted cells divided by ground truth positive cells; ~1800 MeCP2-GFP+ cells

1033   were marked/expert/brain). Composite F-scores for MeCP2-GFP CN was obtained by

1034   determining F-scores in 8 FOVs (400 (X) um by 400 (Y) um) representing different cellular

1035   density and imaging content in 3 separate heterozygous MeCP2-GFP+ brains (24 FOVs

1036   total). Stable precision and recall was seen for all regions analyzed, delivering a composite

1037   F-score of 0.84 (Extended data Fig. 2). In the CN output images, signal smaller than 10

1038 μm^2 was removed as noise. In order to normalize the performance of CN for each brain,

1039   the brightness of MeCP2-GFP+ signal for each sample was normalized by the mean and

1040   standard deviation of tissue autofluorescence signal from a coronal section corresponding

1041   to bregma position of +0.20 mm. We did not analyze MeCP2-GFP+ cells in the cerebellum

1042   due to faulty brain-to-brain warping of this region (data not shown).

1043

1044   **3D brain registration and anatomical segmentation.** Registration of individual brains to

1045   a standardized reference space was computationally achieved as published previously [43].

1046   In short, affine transform was calculated using 4 resolution levels and B-spline with 3.

1047   Advanced Mattes mutual information [96] was the metric used to measure similarity between

1048   moving and fixed images. Image similarity function is estimated and minimized for a set

1049   of randomly chosen samples with each 23 images in a multi-resolution and iterative fashion

1050   [44]. Entire warping of whole-brain images is done using Elastix [97]. Anatomical segmentation

1051   of Allen Brain Atlas (ABA) labels onto sample brains was made possible also as previously

1052   published [43]. Version 2.2 ABA labels (836 total) were transformed onto individually

1053   registered samples. Quality control of ROI segmentation found and excluded 95 ROIs total

1054   from analysis due to erroneous counting most likely caused by small ROI size and/or

1055   warping location (Full ROI list found in Supplementary Table 1). In addition, cell counts

1056   from layer 6 a and b were combined into one layer, layer a.

1057

1058   **2D-3D cell count correction and density measurements.** Detected 2D cell count values

1059   obtained at 50 um Z resolution were transformed by a stereological 3D conversion factor

1060   obtained by the following way (Extended data Fig. 2). First, counting boxes of 200 um x

1061   200 um x 50 um (xyz) were acquired at 2.5 um Z resolution via optical imaging within 6

1062   brain regions comprising major anatomical divisions of a female heterozygous MeCP2-

1063   GFP mouse brain. 20 optical images were acquired at a depth range that spanned 50 um

1064   around the normal 50 um focal depth (i.e. 25-75 um below the tissue surface). Second,

1065   Mecp2-GFP CN was run on the middle optical section corresponding to the 50 um depth.

1066   Third, manual markup of Mecp2-GFP+ nuclei was performed in each counting box using

1067   the stereological counting rules of Williams and Rakic [98]. Lastly, a conversion factor for

1068   each region was calculated by dividing manual 3D counts by 2D CN count of the middle

1069   section. This factor was averaged over the 6 regions reaching a final conversion factor of

1070   2.6. (Extended data Fig. 2b). ROI cellular density was obtained by 1) transforming ABA

1071   labels onto individual brains, 2) converting ROI assigned pixel space to mm^3, 3) dividing

1072   2.5 um Z-corrected absolute cell counts by mm^3 values by to arrive at cells/mm3.

1073

1074   **Behavioral testing.** 6-8 month old ovariectomized female mice were behaviorally

1075   phenotyped in a sequential series of tests. All mice were ovariectomized at least 2 weeks

1076   prior to testing in order to remove estrous cycle influences from behavior. Each behavioral

1077   test was separated by 2-7 days to avoid acute post-testing and handling effects. Mecp2-

1078   GFP(+/p)/Fmr1 KO(+/+) mice served as behavioral controls for all behaviors studied. The

1079   following tests were sequentially performed on each mouse:

1080

1081   *Open field test (OFT)*. To measure activity and anxiety in an open field, unhabituated mice

1082   were placed in a 40 x 40 x 40 cm2 open plexiglass box containing a layer of fresh bedding.

1083   The open field arena was located in a non-sound-proof, enclosed environment under dim

1084   lighting. All mice were housed in the same facility room behavioral testing was performed.

1085   An overhead camera visually captured all tests and ANY-maze (Stoelting) automated

1086   behavior tracking software was used for real-time activity/location recording and analysis.

1087   A 20 x 20 cm center square designated within the tracking settings defined the center and

1088   perimeter boundaries of the arena. The software measured total and center distance

1089   traveled. For center-specific activity, center distance was normalized to total distance

1090   traveled and presented as percent total distance traveled. Adequate cleaning of the maze

1091   with bleach, water and drying was performed between each mouse. Fresh bedding was

1092   added to the arena for each subject.

1093

1094   *T-maze*. We studied mouse spatial memory by measuring spontaneous spatial alternations

1095   in the T-maze [99,100]. Spontaneous alternation is an innate exploratory behavior possessed by

1096   rodents which is hippocampus-dependent and serves as an index of spatial and working

1097   memory [99]. Our protocol was based off of the continuous version with minor modification

1098   [100]. The dimensions of the T-maze used was 35 cm stem length, 28 cm arm length, 10 cm

1099   arm height, and 5 cm lane width (Stoelting). For testing, the T-maze was located in a non-

1100   sound-proof, enclosed environment under dim lighting. All mice were housed in the same

1101   facility room behavioral testing was performed in. To begin the test, each mouse was

1102   carefully placed at the stem start position of the maze and was freely allowed to enter either
1103   arm. To prevent the mouse from entering the other arm after its initial choice, a metal block
1104   was placed at the entrance of the empty arm once the subject committed exploration to an
1105   arm. The subjects were allowed to freely explore the chosen arm and stem until it explored
1106   back to start of the stem. Once the beginning position was reached, the mouse was held in-
1107   between the start position and a metal block placed proximally to the start position for 5
1108   seconds. The metal block was then removed and the mouse was allowed again to enter an
1109   arm of its choice. Manual scoring of each arm choice and time to experimental completion
1110   was made after 14 trials. No more than 3 minutes/trial was allowed for each subject and
1111   encouragement was given to each subject at 3 minutes (in the form of hand movement
1112   behind the mouse) to return to start position. Mice that did not complete more than 9 trials
1113   were excluded from analysis. Adequate cleaning of the maze with bleach, water and drying
1114   was performed between each mouse. The number of trial-to-trial arm entry alternations
1115   (e.g. left-to-right or right-to-left) was calculated and expressed as a percent of total trials.

1116

1117   *3-chamber test*. Sociability was measured using the 3-chamber test based on the protocol
1118   developed in the Crawley laboratory[102]. The 3-chamber apparatus used consisted of a
1119   plexiglass box (60 x 40 x 22(h) cm) partitioned into 3 chambers (20 cm/each) (Stoelting).
1120   Doors (4 x 8 cm) connecting chambers allowed the mice to freely explore all areas of the
1121   box. The apparatus was located in a non-sound-proof, enclosed environment under dim
1122   lighting. All mice were housed in the same facility room that behavioral testing was
1123   performed in. An overhead camera visually captured all test sessions and ANY-maze
1124   (Stoelting) automated behavior tracking software was used for real-time activity/location
1125   recording and analysis. Chamber designations in tracking software were user-defined and
1126   used for chamber-specific activity measurements. Two metal-barred cylindrical cages (7
1127   cm (diameter) x 15 cm (height); 3 mm bar diameter and 7 mm spacing) were used for
1128   stranger mouse containment in one chamber and for an empty enclosure in the opposite-
1129   sided chamber. The cage bars are spaced such that close sniffing is the only interaction
1130   type possible. Ovariectomized adult female Fmr1 WT mice were used as stranger mice and
1131   were habituated to an enclosure cage for 10 minutes at least 1 day prior to any experiments.
1132   Each stranger mouse (n=8) was used 4 times only and were rotated every 4 experiments

41

1133   for use. Test mice were habituated to an empty 3 chamber apparatus for 10 minutes prior

1134   to actual experiments. For testing, mice were allowed to freely explore all chambers for 10

1135   minutes. For each experiment the enclosed stranger mouse was placed in the left chamber

1136   and the empty enclosure on the right. Chamber time spent and distance traveled was

1137   quantified for each chamber. Percent time spent or distance traveled was calculated as total

1138   value/individual chamber value.

1139

1140   **Quantification of structural connectivity within correlated brain networks of ROIs.**

1141   We determined if OFT and 3-chamber significantly correlated ROI groups (herein referred

1142   to as "networks") represented structural connectivity networks by comparing the median

1143   ROI network connection weight to a distribution of randomly sampled networks of the

1144   same size for both tasks. ROIs having significant correlation of $p<0.01$ were included in

1145   the analysis. We used the normalized connection density, a measure of connection strength

1146   normalized by both source and target region sizes, from the regional structural connectivity

1147   matrix [66]. We restricted the population of structures for each network to ROIs from which

1148   we could draw to an intermediate level of the ontology represented by 292 'summary

1149   structures' [101]. The intersection of these summary structures with the sets of ROIs for each

1150   task resulted in sets of 39 and 13 ROIs for the open field and 3-chamber tasks,

1151   respectively (**Table S6**). These ROIs included: OFT: ACVII, APN, DCO, GPe, GPi, IF,

1152   IGL, ISN, LAV, LGd, LGv, LT, MA, MG, NDB, NLL, NOT, PARN, PB, PO, POL, PSV,

1153   RT, SG, SGN, SPFp, SPVI, SPVO, SUT, SUV, V, VAL, VCO, VI, VLPO, VM, VPL,

1154   VPM, ZI; 3 chamber: ADP, AVP, AVPV, BST, ENTl, ENTm, LC, LPO, MPN, MPO, PS,

1155   VISl, VISpl. Additionally, since mesoscale connectivity is distance dependent [101] and the

1156   model in [66] is spatially dependent, we restricted the selection of random ROI networks to

1157   have similar inter-regional distance dependence as that of their respective cell density

1158   correlated ROI networks.

1159   The procedure for this selection is as follows:

1160   Given a set of N cell density correlated summary structure level ROIs:

1161   1) Randomly draw a set of N regions from the set of summary structures.

1162   2) Compute the pairwise inter-regional distances for the set of sampled regions.

42

1163   3) Compute the Kolmogorov-Smirnov statistic to measure the difference in distributions

1164   of distances for the sampled and cell-count correlated networks

1165   a) If the KS statistic shows a significant difference in distributions (having a p-value <

1166   0.01), reject the sample and return to (1).

1167   b) Else, return the sample.

1168   The above procedure is repeated 1000 times, after which the median normalized connection

1169   density of the experimental ROI networks is compared to the distribution of the sample

1170   medians. Since these connectivity measures are log-normally distributed [66,101] the t statistic

1171   is computed in log-transformed space to test the significance of the difference.

1172   Visualization of ROI-ROI connectivity for each behavioral network of ROIs was created

1173   with Cytoscape network visualization and analytic program (Version 3.7.1). Significantly

1174   correlated ROIs of the deepest ontological distance from root structures were chosen for

1175   visualization, except for the ROIs not annotated at the summary structure level and hence

1176   not   found   in   the   structural   connectivity   matrix.   Those   ROIs

1177   included: BSTmg, BSTpr, BSTif, BSTpr, PVHap, TTv3, isl, islm, MPNc, MPNl, PAA3,

1178   and COApl3. Log-transformed normalized connection densities were used for edge

1179   sizes and scaled for presentation. Edges with sizes < 0 were excluded from the

1180   visualization.

1181

1182   **Statistics.** Whole-brain absolute cell counts were compared amongst Xm-active and Xp-

1183   active reporter brains using a Welch's t test. A 2-way mixed effects ANOVA ([2] XC-

1184   active/KO or WT allele parent-of-origin x [9] major ROI) was used to compare XC-active

1185   (Fig. 1) or WT:KO allele (Fig. 2) parent-of-origin across cell densities from major ROIs.

1186   Holm-Sidak post-hoc tests were used to assess simple between-subjects effects. Brain-

1187   wide   screens   for   skewed   XCI   were   statistically   performed   using   Benjamini-

1188   Hochberg FDR-corrected student's t tests on XC-active cell density groups. Welch's

1189   ANOVAs with Dunnet's T3 post-hoc testing was used to compare group performances in

1190   the OFT, T maze, and 3 chamber total distance traveled. Chamber by group 3 chamber

1191   results were analyzed with 2-way mixed effects ANOVAs with Holm-Sidak post-hoc tests

1192   of between- and/or within-subjects simple effects. Whole-brain absolute healthy cell

1193   counts in Fmr1 WT and KO mice were analyzed via ANOVA with Holm-Sidak post-hoc

1194   comparisons. Whole-brain cell count data and behavioral scores were correlated with

1195   Pearson's correlation. Correlational screens were used to localize the physical source of

1196   behavioral penetrance using Pearson's correlation amongst cell density and behavioral

1197   score across 736 ROIs. In this analysis, we did not correct the p-values against Type I error

1198   risk in favor of revealing ROI networks or patterns that share behavioral dependencies.

1199   Additionally, noise correlations (Supplementary Table 5) in the control WT groups did not

1200   surpass 5% of ROIs in both OFT (20/736 ROIs = 2.7%) and 3 chamber (5/736 ROIs =

1201   0.6%) screens, further supporting the use of uncorrected p values in this dataset. ROI

1202   networks of behavioral penetrance were defined by $p<0.01$ bins of significance and each

1203   bin's distributed cell count, volume, and density across each OFT and 3 chamber networks

1204   were calculated (Supplementary Table 7) and used for linear and logistic regression

1205   modeling. Logistic regression was performed on ROI network healthy cell density percent

1206   as the continuous, independent variable and WT performance as the categorical, dependent

1207   variable. Mice (n=22) from all genotypes were categorized as WT or mutant performers

1208   for each test based on the performance range of Fmr1 WT mice. Fmr1 WT mice were coded

1209   as containing 100% healthy cell density. A likelihood ratio test was performed on each

1210   logistic model to determine statistical significance. All statistical testing was performed

1211   with Graphpad Prism software version 7.0 and R (R Core Team). Alpha level was set at

1212   0.05 in all analyses except where otherwise noted above.

Extended Data Fig. 3 | ROI-based healthy cell density analyses in Fmr1 WT and heterozygous KO mice. a-d, Healthy cell density (cells/mm³; mean ± SD) comparisons amongst (**a**) Xm-active and Xp-active Fmr1 WT, (**b**) Xm-active and Xp-active Fmr1 KO, (**c**) Xp-active Fmr1 WT and KO, and (**d**) Xm-active Fmr1 WT and KO mice across major ontological divisions of the brain. Fmr1 WT (Xm-active (n=8), Xp-active (n=7): ISO: 81354 ± 13598; 50458 ± 11153; OLF: 92208 ± 14279, 62357 ± 14412; HPF: 74715 ± 12112, 50902 ± 12888; CTXsp: 68989 ± 8458, 44848 ± 9479; CNU: 73486 ± 113216, 50317 ± 9551; TH: 54995 ± 16794, 33252 ± 11610; HY: 74840 ± 13100, 51308 ± 12890; MB: 61564 ± 16908, 36108 ±11524; HB: 35855 ± 15759 versus 12918 ± 4819) or

50

1321   heterozygous KO mice (Xm-active (n=7), Xp-active (n=8): ISO: 83006 ± 15294, 54469 ±

1322   13584; OLF: 92689 ± 13965, 67429 ± 13076; HPF: 71677 ± 14524, 52120 ± 10280;

1323   CTXsp: 67988 ± 13240, 48068 ± 10198; CNU: 74039 ± 15614, 55089 ± 10992; TH: 51358

1324   ± 12678, 39105 ± 11187; HY: 72572 ± 13680, 54570 ± 9459; MB: 60011 ± 14278, 43524

1325   ± 12182; HB: 25308 ± 10080, 17737 ± 7177) *p<0.05, **p<0.01, 2-way mixed effects

1326   ANOVA with Holm-Sidak multiple comparison correction. **e**) Brain-wide cell density

1327   comparisons in Fmr1 WT and heterozygous KO mice. Columns 1-4: Brain-wide heat map

1328   visualization of mean healthy Xm-active and Xp-active ROI cell densities (% of estimated

1329   total) on a color gradient of black (50%) to green (100%) amongst Fmr1 WT and KO mice.

1330   Columns 5-8: Brain-wide q values of ROI cell density statistical comparisons of active XC

1331   parent-of-origin amongst Fmr1 WT and Fmr1 KO mice (top), and cell density comparisons

1332   amongst mice with WT or KO Fmr1 alleles with matched active XC parent-of-origin

1333   (bottom). Legends indicating color scaling for mean cell density (left) and q values (right)

1334   are listed at the bottom.

1335
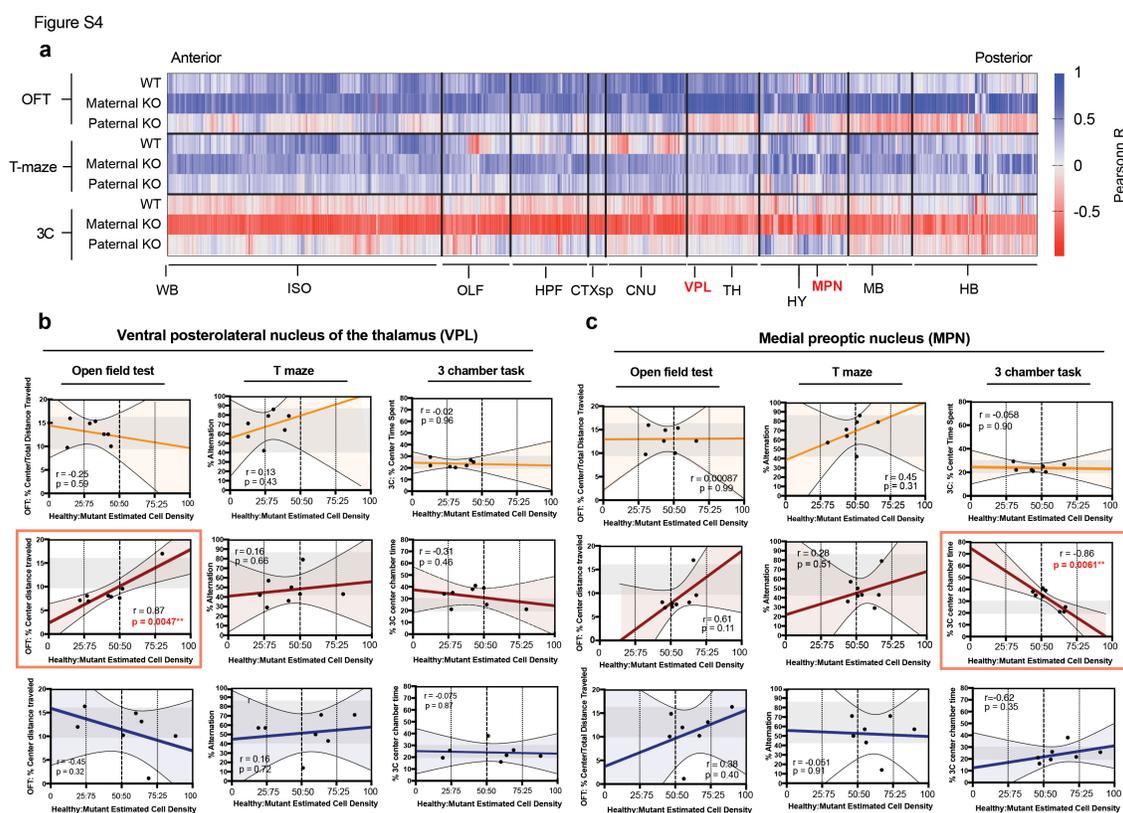

Figure S4

Extended Data Fig. 4 | Identification of two sets of brain regions with local Fmr1-WT:KO cell ratios linked to phenotypes in the OFT and 3-chamber test: Raw Pearson r values and scatterplot examples across genetic groups and behavioral tests. a, 2D heat maps of raw Pearson correlation r values corresponding to **Fig 4a** across brain ROIs grouped by major ontological structures from anterior (left) to posterior (right) positions of the whole-brain. Raw Pearson r values are represented on a color gradient scale from -1 (red) to 0 (white) to 1 (blue). Results from Fmr1 WT ("WT"), maternal Fmr1-KO(m)/Mecp2-GFP(p) ("Maternal KO") and paternal Fmr1-KO(p)/Mecp2-GFP(m) ("Paternal KO") mice are grouped by each behavioral test: top: OFT, middle: T maze, bottom: 3-chamber (3C). **b-c**, Individual scatterplot visualization of the data from (**a**) for each behavioral group and behavioral test for the (**b**) ventral posterolateral nucleus of the thalamus (VPL), and (**c**) medial preoptic nucleus (MPN). Raw r and p values of statistical tests are inlayed within each panel. Red boxes bound correlations that reached statistical significance.

52
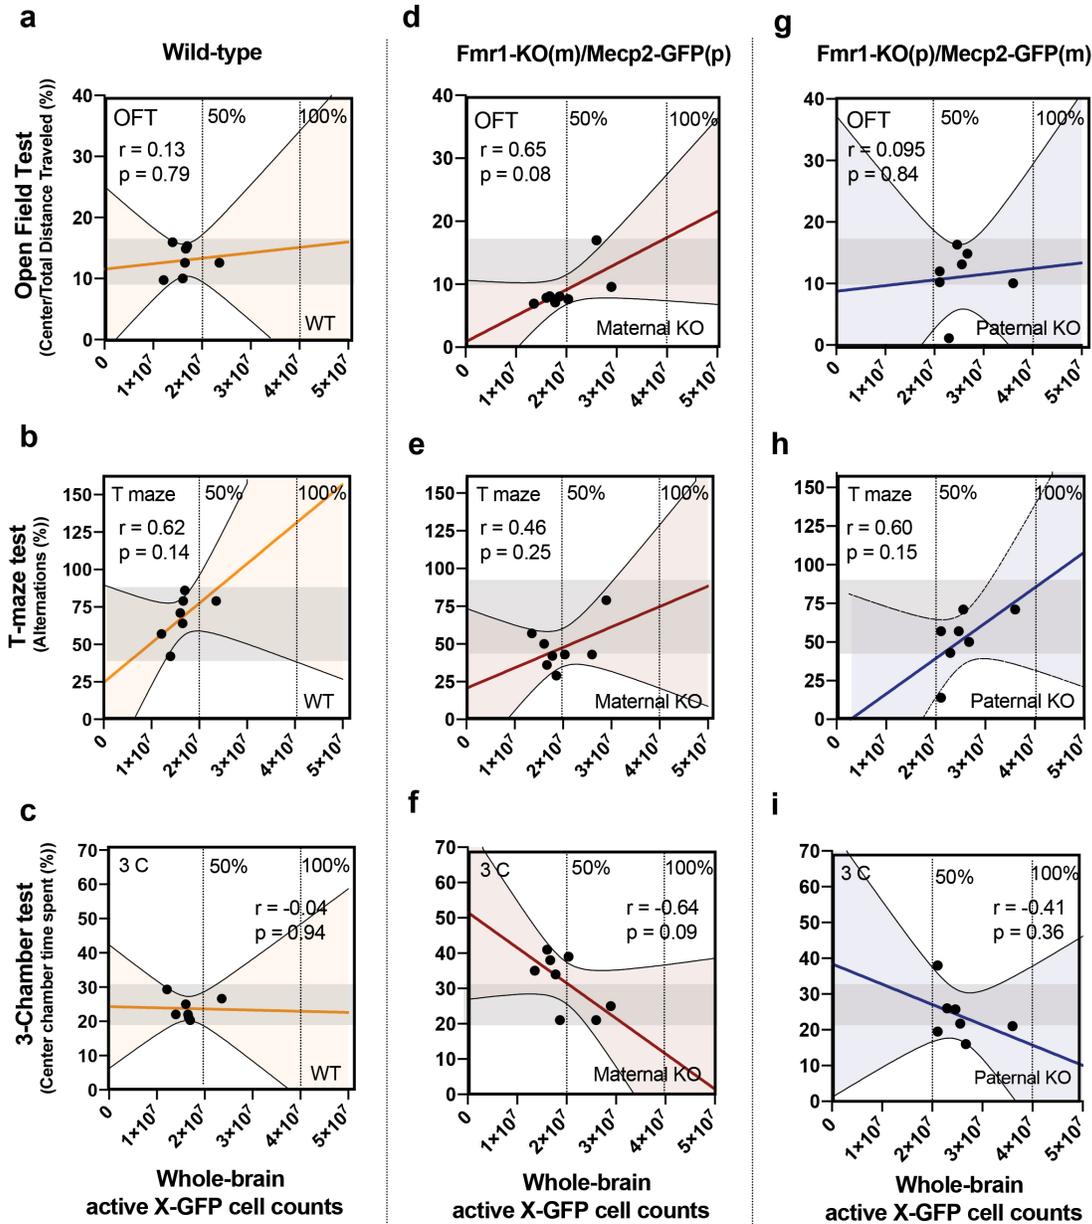

Extended Data Fig. 5 | Whole-brain cell count correlations with behavior. (**a**-**c**; left) Fmr1 WT, (**d**-**f**; center) maternal Fmr1 KO, and (**g**-**i**; right) paternal Fmr1 KO whole-brain cell counts correlated to (**a**, **d**, **g**; top) OFT, (**b**, **e**, **h**; middle) T maze, and (**c**, **f**, **i**; bottom) 3 chamber behavioral scores. Dashed lines indicate estimated 50 and 100% cell counts. Gray transparent boxes inside plots indicate Fmr1 WT range of behavioral scores for comparison across mutant groups. r and p value statistics are listed in each panel.

1361
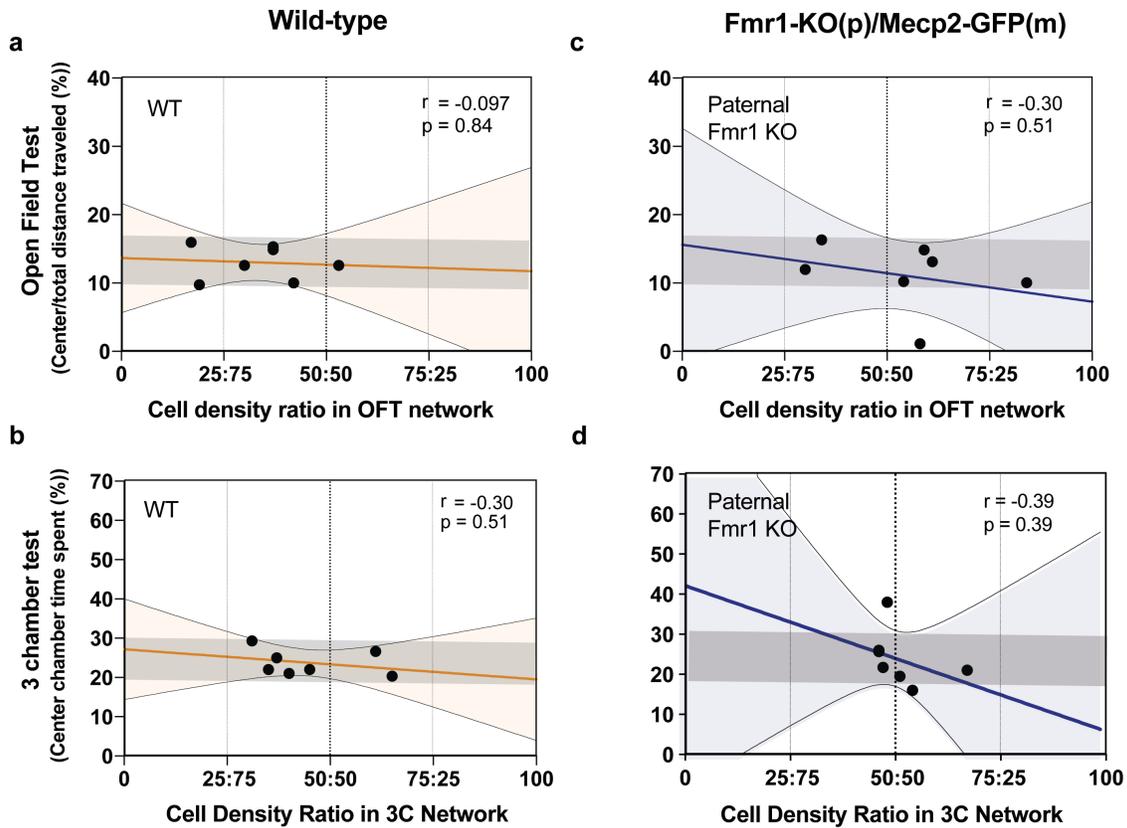

Extended Data Fig. 6 | Control group correlations of behavioral brain network cell density ratios with behavioral scores. Fmr1 WT (**a**, **b**; left) and paternal Fmr1 KO (**c**, **d**; right) linear regression models of ROI network cell density ratios and scores from (**a**, **c**; top) OFT and (**b**, **d**; bottom) 3C behavioral assays. Regression and statistical test values are listed for each panel.
