ABSTRACT

Recent searches for the hosts of $z \sim 4$ damped Ly α absorbers (DLAs) have detected bright galaxies at distances of tens of kpc from the DLA. Using the FIRE-2 cosmological zoom simulations, we argue that these relatively large distances are due to a predominantly cool and neutral inner circumgalactic medium (CGM) surrounding high-redshift galaxies. The inner CGM is cool because of the short cooling time of hot gas in $\lesssim 10^{12} M_{\odot}$ haloes, which implies that accretion and feedback energy are radiated quickly, while it is neutral due to high volume densities and column densities at high redshift that shield cool gas from photoionization. Our analysis predicts large DLA covering factors ($\gtrsim 50$ per cent) out to impact parameters $\sim 0.3[(1+z)/5]^{3/2} R_{\text{vir}}$ from the central galaxies at $z \gtrsim 1$, equivalent to a proper distance of $\sim 21 M_{12}^{1/3} ((1+z)/5)^{1/2}$ kpc (R_{vir} and M_{12} are the halo virial radius and mass in units of $10^{12} M_{\odot}$, respectively). This implies that DLA covering factors at $z \sim 4$ may be comparable to unity out to a distance ~ 10 times larger than stellar half-mass radii. A predominantly neutral inner CGM in the early universe suggests that its mass and metallicity can be directly constrained by absorption surveys, without resorting to the large ionization corrections as required for ionized CGM.

Key words: galaxies: evolution – galaxies: high-redshift – quasars: absorption lines.

1 INTRODUCTION

Observations of damped Ly α absorbers (DLAs) along lines of sight to background quasars (with HI columns $N_{\text{HI}} > 2 \times 10^{20} \text{ cm}^{-2}$) provide some of the most stringent observational constraints on galaxy formation physics in the early post-reionization universe. Statistical DLA samples are now available out to redshifts $z \sim 5$ (e.g. Prochaska & Wolfe 2009; Noterdaeme et al. 2012; Ho, Bird & Garnett 2020), revealing the distribution of HI-rich structures in and around galaxies far fainter than possible with emission surveys (Wolfe, Gawiser & Prochaska 2005). Metal-line absorption features from DLAs constrain their metallicity and kinematics, and thus the DLA enrichment histories and the potential wells in which DLAs reside (Prochaska & Wolfe 1997; Kulkarni & Fall 2002; Ledoux et al. 2006; Pontzen et al. 2008; Rafelski et al. 2012, 2014). However, the origin of high- z DLAs is still uncertain. The DLAs may originate in central HI discs (Prochaska & Wolfe 1997; Fynbo et al. 2008;

Berry et al. 2014), in ‘protogalactic clumps’ (Haehnelt, Steinmetz & Rauch 1998), in cosmic filaments (Faucher-Giguère & Kereš 2011; Fumagalli et al. 2011), in satellites and neutral outflows (Rhodin et al. 2019), or in quasi-spherical cosmological inflows (Theuns 2021).

A new window on high- z DLAs has recently been opened by the Atacama Large Millimeter/Submillimeter Array (ALMA), which can potentially detect [C II] 158 μm fine-structure emission from associated galaxies. Neeleman et al. (2017, 2019) detected [C II] at angular separations of 2–4 arcsec from five high-metallicity DLAs at $z \sim 4$, corresponding to proper distances of 20–40 kpc. While this is comparable to typical DLA–galaxy distances at $z \lesssim 1$ (Chen & Lanzetta 2003; Rahmani et al. 2016; Møller & Christensen 2020), at $z \sim 4$ this size scale is a substantial fraction of the halo virial radius ($R_{\text{vir}} \approx 60$ kpc for an $\sim 10^{12} M_{\odot}$ halo). This suggests that high- z DLAs originate either in the CGM or in as yet undetected satellite galaxies.

In this paper, we use the FIRE-2 (Feedback In Realistic Environments) cosmological zoom simulations (Hopkins et al. 2018) to examine the contribution of the volume-filling phase of the circumgalactic medium (CGM) to the DLA population, where by

* E-mail: sternjon@tauex.tau.ac.il

‘volume-filling phase’ we refer to gas that permeates the halo volume rather than gas associated with subhaloes or narrow filaments. We show that this phase is predominantly neutral with a large DLA covering factor at radii where two conditions are satisfied: (1) the cooling time of virial temperature gas $t_{\text{cool}}^{(s)}$ is shorter than the free-fall time t_{ff} , implying that heat from accretion and feedback is quickly radiated away, and (2) densities are sufficiently high that cool gas is shielded from ambient ionizing radiation. Our analysis builds on Stern et al. (2021, hereafter S21) where we studied condition (1) in the FIRE simulations. We found that in $\lesssim 10^{12} M_{\odot}$ haloes in FIRE the inner CGM volume has $t_{\text{cool}}^{(s)} < t_{\text{ff}}$ and a volume-weighted temperature well below virial. In this paper, we discuss the implications of this theoretical result for DLA observations. Our study also supplements previous FIRE results on CGM absorbers with lower HI columns (Faucher-Giguère et al. 2015, 2016; Hafen et al. 2017).

Our paper is organized as follows: In Section 2, we briefly summarize the relevant aspects of the FIRE simulations. In Section 3, we explore the two conditions for a neutral CGM in FIRE, and demonstrate in Section 4 that these conditions are associated with an order-unity DLA covering factor. Section 5 compares the predictions of the FIRE simulations with observations of high-redshift DLAs. We discuss our results in Section 6 and summarize in Section 7. We assume a flat Λ CDM cosmology with Hubble constant $H_0 = 67 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_{\text{m},0} = 0.32$, and baryon mass fraction $\Omega_{\text{m}}/\Omega_{\text{b}} = 0.158$ (Planck Collaboration VI 2018).

2 FIRE-2 ZOOM SIMULATIONS

The FIRE (Hopkins et al. 2014, 2018) project¹ was developed to explore the role of feedback in cosmological simulations of galaxy formation. We utilize the second version of these simulations, FIRE-2, which uses the multimethod gravity and hydrodynamics code GIZMO² (Hopkins 2015) in its meshless finite-mass mode. Gravity is solved using a modified version of the Tree-PM solver similar to GADGET-3 (Springel 2005). Heating and cooling processes include metal-line cooling, free-free emission, photoionization and recombination, Compton scattering with the cosmic microwave background, collisional and photoelectric heating by dust grains, and molecular and fine-structure cooling at low temperatures ($10\text{--}10^4$ K). Star formation occurs in self-gravitating, self-shielded molecular gas with $n_{\text{H}} > 1000 \text{ cm}^{-3}$, while the subgrid implementation of feedback processes from stars includes radiation pressure, heating by photoionization and photoelectric processes, and energy, momentum, mass, and metal deposition from supernovae and stellar winds. Active galactic nucleus (AGN) feedback is not included. A full description of the FIRE-2 simulations appears in Hopkins et al. (2018).

In the analysis, we project HI volume densities calculated in FIRE to predict observed HI columns along sightlines to background sources. The HI fraction of resolution element a is derived in FIRE by assuming equilibrium between recombination, collisional ionization, and photoionization. Photoionization is by a spatially uniform UV background (UVB) from Faucher-Giguère et al. (2009) and local hot stars. The contribution of a local stellar particle b to the ionizing flux at resolution element a is derived from the STARBURST99 stellar population models (Leitherer et al. 1999), after accounting for absorption by resolution elements neighbouring b (see appendix E in

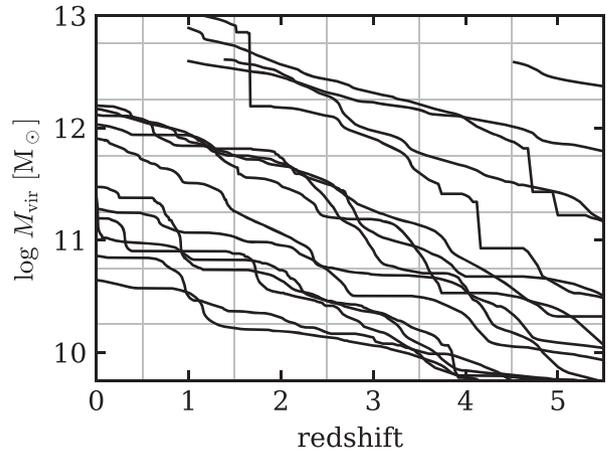

Figure 1. Tracks of central halo mass versus redshift in the 16 FIRE zoom simulations analysed in this work. Grid lines delineate bins in M_{vir} and z used below.

Hopkins et al. 2018) and an approximation for absorption near a as described next. The effect of other intervening absorbers between b and a on the stellar flux is neglected. At resolution element a , the incident UVB + stellar radiation is attenuated by a factor $e^{-n_{\text{H}}/n_{\text{H,shielded}}}$, where the shielding density $n_{\text{H,shielded}}$ is calculated from

$$n_{\text{H,shielded}} = 0.0123 \Gamma_{-12}^{2/3} T_4^{0.173} \text{ cm}^{-3}, \quad (1)$$

where $\Gamma \equiv 10^{-12} \Gamma_{-12} \text{ s}^{-1}$ is the photoionization rate and $T_4 \equiv T/10^4$ K. This density threshold for shielding is derived from the assumption that the size of the structure that includes resolution element a is equal to its Jeans length (Schaye 2001; see Appendix A). Using this approximation to attenuate the incident flux has been shown to reproduce the neutral columns derived from post-processing the simulations with full radiative transfer (see Faucher-Giguère et al. 2010, 2015; Rahmati et al. 2013, and further discussion in Section 6).

We analyse the 16 FIRE simulations discussed in S21, chosen so their central haloes span a diverse range in (M_{vir}, z) space, as shown in Fig. 1. These include five massive haloes from Anglés-Alcázar et al. (2017b) and Ma et al. (2018) for which M_{vir} exceeds $10^{12} M_{\odot}$ at $z > 2$, and eleven haloes with $M_{\text{vir}}(z=0)$ between $\sim 10^{10.5}$ and $\sim 10^{12} M_{\odot}$ (from Wetzel et al. 2016; Garrison-Kimmel et al. 2017, 2018; Chan et al. 2018; El-Badry et al. 2018; Hopkins et al. 2018). The mass of a baryonic resolution element is $m_b = 33\,000\text{--}57\,000 M_{\odot}$ in the five massive haloes and $m_b = 2100\text{--}7100 M_{\odot}$ in the lower mass galaxies. We refer the reader to table 1 in S21 and the original references for additional details on individual simulations. When binning is required below, we divide the simulation snapshots (separated by 25–30 Myr) into bins of $\Delta M_{\text{vir}} = 0.5$ dex and $\Delta z = 1$ as shown in Fig. 1.

Using the Amiga Halo Finder (Knollmann & Knebe 2009), we identify M_{vir} and R_{vir} of the main halo in each simulation snapshot based on the virial overdensity definition of Bryan & Norman (1998). The virial temperature T_{vir} is then calculated from

$$T_{\text{vir}} \equiv \frac{\mu m_p G M_{\text{vir}}}{2 k_B R_{\text{vir}}} \approx 2.6 \times 10^6 M_{12}^{2/3} \left(\frac{1+z}{5} \right)^{0.9} \text{ K}, \quad (2)$$

where $\mu \approx 0.62$ is the mean molecular weight, m_p is the proton mass, G is the gravitational constant, k_B is the Boltzmann constant, and $M_{12} \equiv M_{\text{vir}}/10^{12} M_{\odot}$. The numerical estimate of T_{vir} is based on the approximation of R_{vir} given by equation (B7) in the appendix.

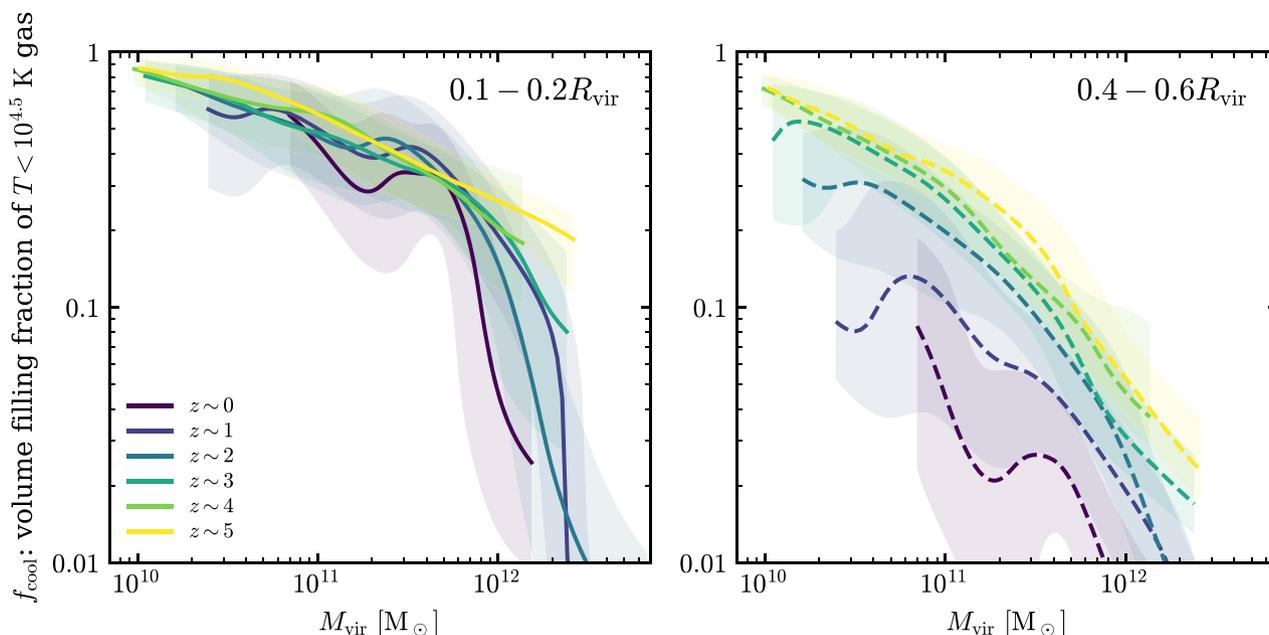

Figure 2. The volume filling fraction of cool gas versus halo mass in FIRE, at inner CGM radii ($0.1 < r/R_{\text{vir}} < 0.2$, left) and at outer CGM radii ($0.4 < r/R_{\text{vir}} < 0.6$, right). Coloured lines and bands denote the median relation and $\pm 1\sigma$ range for all snapshots within a redshift bin centred on the value noted in the legend. At all redshifts, the inner CGM typically has $f_{\text{cool}} \gtrsim 0.3$ in haloes with mass $< 5 \times 10^{11} M_{\odot}$, while f_{cool} tends to drop for haloes with mass above $10^{12} M_{\odot}$. In the outer CGM large cool gas filling fractions of $f_{\text{cool}} \gtrsim 0.3$ are apparent in $< 10^{11} M_{\odot}$ haloes at $z > 2$.

3 CONDITIONS FOR A NEUTRAL CGM

Two conditions must be met for the CGM to have a large neutral fraction and thus also a large DLA covering factor. First, gas shocked to a temperature $\sim T_{\text{vir}}$ must cool rapidly; otherwise, the volume-filling phase would be hot and collisionally ionized. Secondly, any cool CGM needs to be shielded from the UVB and local stars; otherwise, it would be photoionized. In this section, we explore both conditions and demonstrate how they occur in the FIRE simulations.

3.1 Cool gas filling fraction in the CGM

The first condition for a neutral CGM, that hot gas cools rapidly, is expected when the cooling time of the hot phase $t_{\text{cool}}^{(s)}$ is shorter than the free-fall time t_{ff} . This has been demonstrated in idealized hydrodynamic simulations, in which the CGM becomes predominantly cool and supported by turbulence/bulk motions when $t_{\text{cool}}^{(s)} \ll t_{\text{ff}}$ (McCourt et al. 2012; Fielding et al. 2017; Lochhaas et al. 2020; Stern et al. 2020), even when feedback heating is included. Similarly, in S21 we showed that at radii where $t_{\text{cool}}^{(s)} \lesssim t_{\text{ff}}$ in the FIRE cosmological simulations the volume-weighted CGM temperature is $\ll T_{\text{vir}}$. Here, we further explore this result by calculating the volume filling fraction of cool gas f_{cool} as a function of $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ and other halo parameters in FIRE. We define gas as ‘cool’ if its temperature is below $10^{4.5}$ K, and limit the analysis in this section to snapshots with $T_{\text{vir}} > 10^5$ K (i.e. $M_{\text{vir}} > 8 \times 10^9 M_{\odot}$ at $z = 4$), so the distinction between cool gas and virial temperature gas is well defined. The chosen threshold of $T < 10^{4.5}$ K includes gas that is heated by photoionization, and also allows for some further heating by compression. As we discuss below, such gas would be neutral if shielded from photoionizing radiation. We emphasize that f_{cool} is defined as a volume fraction rather than a mass fraction, in order to focus on the volume-filling CGM phase while

minimizing the effects of gas associated with narrow filaments and satellites.

We begin by exploring how f_{cool} depends on M_{vir} , z , and CGM radius r . To calculate $f_{\text{cool}}(r)$ in a simulation snapshot, we sum the volume of all resolution elements with $T < 10^{4.5}$ K that are within a given radial shell, and divide by the shell volume. Fig. 2 plots f_{cool} as a function of halo mass for shells that span $0.1 < r/R_{\text{vir}} < 0.2$ (left-hand panel) and $0.4 < r/R_{\text{vir}} < 0.6$ (right-hand panel). Coloured lines and bands plot the medians and dispersions ($\pm 1\sigma$) for all snapshots in a given redshift bin, where bins span $z_i - 0.5 < z < z_i + 0.5$ for z_i in $\{0, 1, 2, 3, 4, 5\}$ (see Fig. 1). Medians and dispersions are estimated by applying a Gaussian kernel density estimator (Scott 1992) on measurements of $[f_{\text{cool}}(r), M_{\text{vir}}]$ in all snapshots in the bin, using a kernel bandwidth of 0.3 dex. The dispersion thus includes both variability for a given halo and halo-to-halo variation, though note that the latter may be underestimated due to our relatively small halo sample size. The left-hand panel shows that in the inner CGM f_{cool} is a strong function of M_{vir} , decreasing from near-unity at $M_{\text{vir}} \sim 10^{10} M_{\odot}$ to near-zero at $M_{\text{vir}} \gtrsim 10^{12} M_{\odot}$, with no strong dependence on redshift. At larger CGM radii shown in the right-hand panel, f_{cool} depends both on halo mass and on redshift, with $f_{\text{cool}} > 30$ per cent apparent mainly in $\lesssim 10^{11} M_{\odot}$ haloes at $z \gtrsim 2$.

Next, to compare f_{cool} with $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ we estimate t_{ff} via (e.g. McCourt et al. 2012)

$$t_{\text{ff}} = \frac{\sqrt{2}r}{v_c}, \quad (3)$$

where $v_c = \sqrt{GM(< r)/r}$ is the circular velocity and $M(< r)$ is the total mass enclosed within radius r . The estimate of the cooling time of shocked gas $t_{\text{cool}}^{(s)}$ follows S21 (see equation 7 there)

$$t_{\text{cool}}^{(s)} \equiv t_{\text{cool}}(T^{(s)}, P_{\text{HSE}}, Z, z), \quad (4)$$

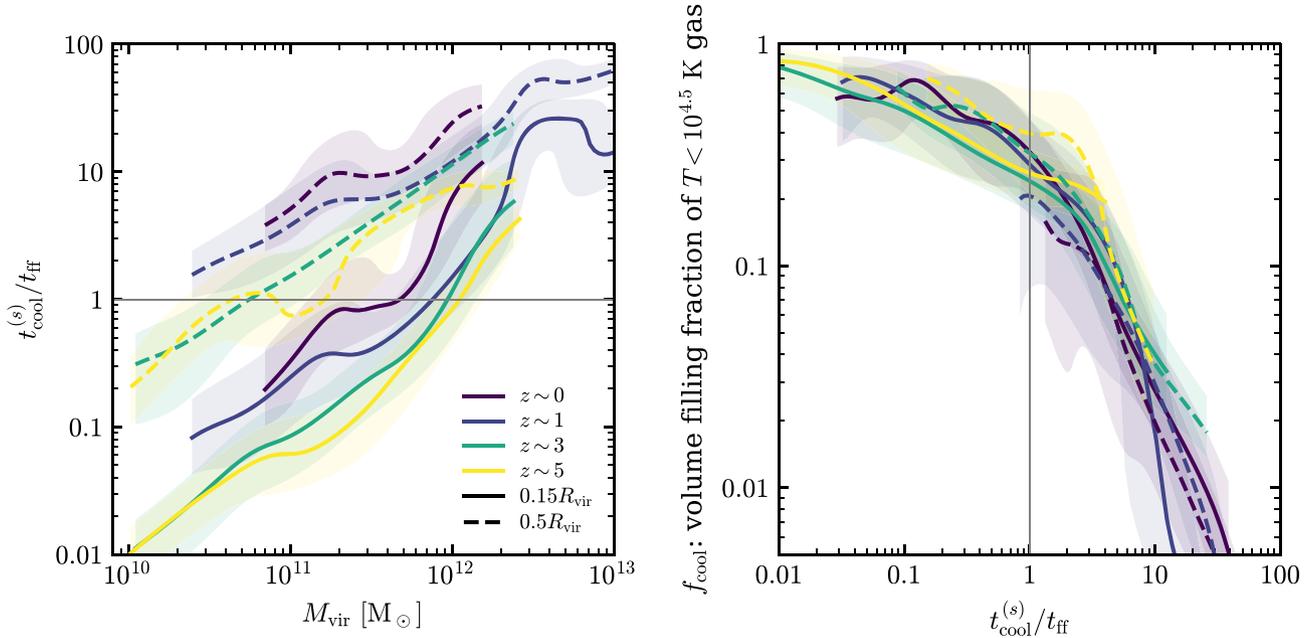

Figure 3. *Left:* The relation between halo mass and the ratio of the hot gas cooling time to free-fall time in FIRE. Solid and dashed lines correspond to measurements of $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ at inner and outer CGM radii, respectively. Coloured lines and bands plot the median and dispersion ($\pm 1\sigma$) for each redshift bin, as in Fig. 2. Note that $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ increases with halo mass and with halo radius, while it mildly decreases with increasing redshift. *Right:* Volume filling fraction of cool gas versus $t_{\text{cool}}^{(s)}/t_{\text{ff}}$. The ratio $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ is estimated at the same radii as in the left-hand panel, while f_{cool} is calculated within a shell spanning either $0.1 < r/R_{\text{vir}} < 0.2$ (solid) or $0.4 < r/R_{\text{vir}} < 0.6$ (dashed). The value of f_{cool} drops from ≈ 0.6 at $t_{\text{cool}}^{(s)} \approx 0.1 t_{\text{ff}}$ to $f_{\text{cool}} \approx 0.3$ at $t_{\text{cool}}^{(s)} \approx 10 t_{\text{ff}}$. This relation is rather independent of redshift and radius, suggesting that $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ is the dominant parameter determining f_{cool} .

where t_{cool} is the cooling time based on the Wiersma, Schaye & Smith (2009) tables, $T^{(s)} \equiv 0.6 \mu m_p v_c^2(r)/k_B$ is comparable to the virial temperature, P_{HSE} is the thermal pressure assuming hydrostatic equilibrium conditions, and Z is the shell-averaged metallicity in the snapshot. To estimate P_{HSE} , we assume that it equals the spherically averaged weight of overlying gas in the snapshot (equation 12 in S21). Equation (4) thus approximates the cooling time in a hot, thermal pressure-supported CGM, regardless of whether such a ‘virialized’ CGM actually exists in the snapshot.

We checked that estimating $t_{\text{cool}}^{(s)}$ based on the shell-averaged gas density rather than based on P_{HSE} yields similar results. This follows since when thermal pressure is absent, bulk motions and turbulence provide support against gravity (see below) and the resulting densities that go into the $t_{\text{cool}}^{(s)}$ calculation are comparable. We refer the reader to S21 for a discussion of $t_{\text{cool}}^{(s)}$ and its comparison to other estimates of the cooling time in the simulations.

The left-hand panel of Fig. 3 compares $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ with M_{vir} , using solid and dashed lines for the inner and outer CGM, respectively, and different colours for different redshifts as in Fig. 2. The ratio $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ increases strongly with M_{vir} and decreases relatively weakly with increasing redshift. The strong dependence on halo mass is mainly a result of the increase of T_{vir} with M_{vir} , while the lack of a strong dependence on redshift is due to the decrease in gas density with time roughly cancelling the effect of the decrease in T_{vir} at fixed M_{vir} . The left-hand panel of Fig. 3 also shows that $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ increases with radius. This increase with radius holds even if we calculate the cooling time using the actual volume-weighted temperature in the simulation rather than using $T^{(s)}$ (see equation 4). An increase in $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ with radius also occurs in cooling flow solutions for the CGM in which the entropy $S \equiv kT/n_{\text{H}}^{2/3}$ decreases inwards (Stern et al.

2019, 2020). In contrast, isentropic CGM solutions show an opposite trend where $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ decreases outwards (e.g. Faerman, Sternberg & McKee 2020).³

The right-hand panel of Fig. 3 compares f_{cool} with $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ in our simulations, which span a range of over 10^3 in $t_{\text{cool}}^{(s)}/t_{\text{ff}}$. The cool gas filling fraction shows a strong trend with $t_{\text{cool}}^{(s)}/t_{\text{ff}}$, decreasing from $f_{\text{cool}} \approx 0.6$ at $t_{\text{cool}}^{(s)}/t_{\text{ff}} \approx 0.1$ to $f_{\text{cool}} \lesssim 0.03$ at $t_{\text{cool}}^{(s)}/t_{\text{ff}} \approx 10$. We emphasize that this relation is non-trivial, since $t_{\text{cool}}^{(s)}$ is independent of the actual gas temperature in the simulation (equation 4). The panel shows that the median relations between f_{cool} and $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ are almost independent of redshift and radius, suggesting that the volume filling fraction of cool gas is determined mainly by $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ rather than by other system parameters.

In Fig. 4, we plot the radius where $t_{\text{cool}}^{(s)} = t_{\text{ff}}$ as a function of M_{vir} for different redshifts. In cooling flow solutions, this radius corresponds to the sonic point, since the Mach number of the flow roughly equals $(t_{\text{cool}}^{(s)}/t_{\text{ff}})^{-1}$ (Mathews & Bregman 1978; Stern et al. 2020). The figure shows that $R(t_{\text{cool}}^{(s)} = t_{\text{ff}})$ tends to be beyond $0.5 R_{\text{vir}}$ in haloes with mass $\lesssim 10^{11} M_{\odot}$, while it drops to disc scales ($\lesssim 0.1 R_{\text{vir}}$; see below) at $M_{\text{vir}} \gtrsim 10^{12} M_{\odot}$. At intermediate masses ($\sim 10^{11} - 10^{12} M_{\odot}$), we find $t_{\text{cool}}^{(s)} = t_{\text{ff}}$ between $0.1 R_{\text{vir}}$ and $0.5 R_{\text{vir}}$, and f_{cool} is large in the inner CGM while it is small in the outer CGM. Fig. 4 thus demonstrates the

³This difference can be understood by noting that at $10^5 \lesssim T \lesssim 10^7$ K where the cooling function scales as $\Lambda \propto T^{-0.5}$ one gets $t_{\text{cool}} \sim kT/n_{\text{H}} \Lambda \propto S^{1.5}$ (neglecting metallicity gradients). In cooling flows in an isothermal potential $S \propto r$ and $t_{\text{ff}} \propto r$, so $t_{\text{cool}} \propto r^{1.5}$ and hence $t_{\text{cool}}/t_{\text{ff}} \propto r^{0.5}$ increases outwards. In contrast, isentropic models give $t_{\text{cool}} \propto r^0$ and $t_{\text{cool}}/t_{\text{ff}} \propto r^{-1}$; i.e. this ratio decreases outwards.

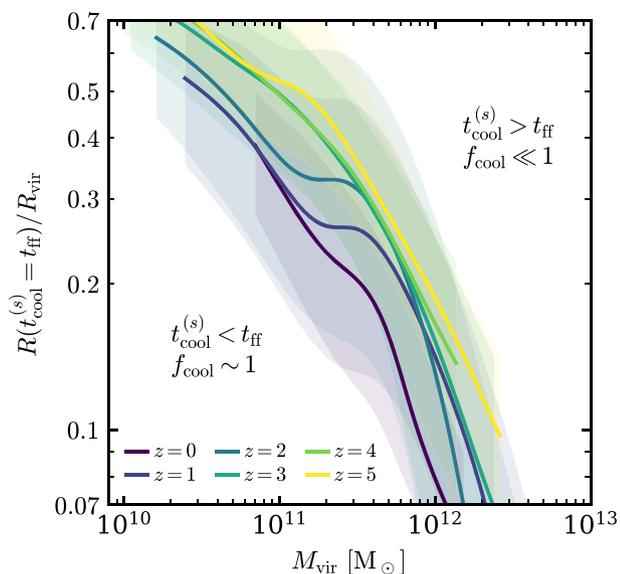

Figure 4. The radius where $t_{\text{cool}}^{(s)} = t_{\text{ff}}$ versus halo mass and redshift. Coloured lines and bands denote the median relation and $\pm 1\sigma$ range for each redshift bin, as in Fig. 2. The value of $R(t_{\text{cool}}^{(s)} = t_{\text{ff}})$ is beyond $0.5R_{\text{vir}}$ in haloes with mass $\lesssim 10^{11} M_{\odot}$ and drops to disc scales at $M_{\text{vir}} \gtrsim 10^{12} M_{\odot}$.

S21 result that as FIRE haloes grow in mass, f_{cool} drops and the hot phase becomes prevalent first in the outer CGM and only later in the inner CGM. This ‘outside-in’ formation of a stable hot CGM phase is opposite to the scenario suggested by Birnboim & Dekel (2003) based on idealized simulations, where an expanding accretion shock causes the hot phase to form from the inside out.

3.2 Self-shielding radius

In the previous section, we demonstrated that a large fraction of the inner CGM volume is cool in $\lesssim 10^{12} M_{\odot}$ FIRE haloes, where the cooling times of hot gas are short. Here, we explore under which conditions this volume-filling cool gas is also shielded from photoionization.

As mean CGM densities at a given r/R_{vir} are expected to scale with cosmic mass density and be roughly independent of halo mass (see equation B3 in the appendix), we expect the importance of shielding in a volume-filling cool phase to mainly depend on redshift. This is demonstrated in the top panel of Fig. 5, where we compare spherically averaged hydrogen density profiles $\bar{n}_{\text{H}}(r)$ in FIRE with the minimum density for shielding in FIRE $n_{\text{H,shielded}}$. The value of $n_{\text{H,shielded}}$ is estimated from equation (1) assuming $T \approx 10^4$ K and $\Gamma = 10^{-12} \text{ s}^{-1}$, as measured for the UVB at $z \sim 1-5$ (e.g. Faucher-Giguère 2020). To derive $\bar{n}_{\text{H}}(r)$, we divide each snapshot into radial shells of width 0.05 dex. We then sum the number of hydrogen particles in all resolution elements with centres within the shell and divide by the shell volume. Solid lines and coloured bands in Fig. 5 mark the median and $\pm 1\sigma$ range of these spherically averaged profiles, among all snapshots in the relevant (z, M_{vir}) bin. The median densities decrease with radius as $r^{-2.1} - r^{-2.3}$ and increase with redshift roughly as $\sim (1+z)^3$. The radius where \bar{n}_{H} exceeds $n_{\text{H,shielded}}$ increases from $\approx 0.05-0.1R_{\text{vir}}$ at $z \sim 1$ to $\approx 0.3R_{\text{vir}}$ at $z = 4$, and is roughly independent of halo mass.

The bottom panel of Fig. 5 plots the ratio of the spherically averaged density of $T < 10^{4.5}$ K gas, $\bar{n}_{\text{H, cool}}$, to the total gas density plotted in the top panel. The panel shows that $\bar{n}_{\text{H, cool}} \gtrsim 10\bar{n}_{\text{H}}$ in $10^{12.5} M_{\odot}$ haloes and $\bar{n}_{\text{H, cool}} \gtrsim 5\bar{n}_{\text{H}}$ beyond $0.5R_{\text{vir}}$ in $10^{11.5} M_{\odot}$

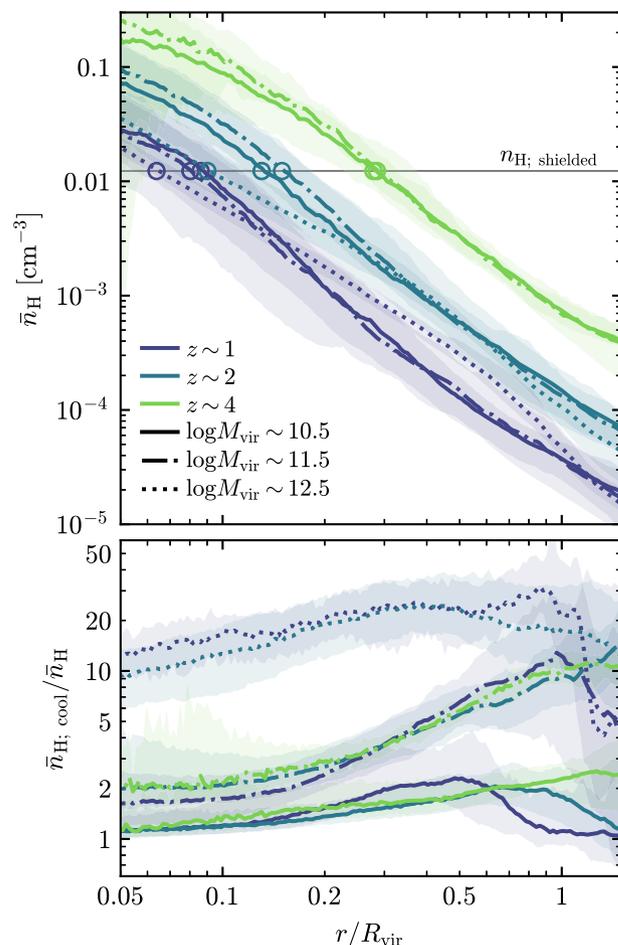

Figure 5. *Top:* Spherically averaged gas density profiles in FIRE, as a function of redshift and halo mass. For each bin in (z, M_{vir}) , a line and band denote the median and $\pm 1\sigma$ range of density profiles among all snapshots in the bin. Note that densities increase with redshift and are roughly independent of M_{vir} . Circles mark where the average densities exceed the shielding density, calculated using equation (1) with $\Gamma = 10^{-12} \text{ s}^{-1}$ and $T = 10^4$ K. *Bottom:* The ratio of the average cool ($T < 10^{4.5}$ K) gas density to the total density. The cool gas and total gas densities are comparable in $\sim 10^{10.5} M_{\odot}$ haloes and at small radii in $\sim 10^{11.5} M_{\odot}$ haloes, indicating no compression by an ambient hot phase.

haloes, consistent with the compression of cool gas by an ambient hot phase. In contrast, $\bar{n}_{\text{H, cool}} \sim \bar{n}_{\text{H}}$ in $10^{10.5} M_{\odot}$ haloes and at small radii in $10^{11.5} M_{\odot}$ haloes. These haloes and radii correspond to regions where $t_{\text{cool}}^{(s)} < t_{\text{ff}}$ and hence the hot phase is largely absent (Fig. 4), so \bar{n}_{H} roughly traces the density of the cool phase.

The radius where $\bar{n}_{\text{H}} = n_{\text{H,shielded}}$ can also be estimated analytically as a fraction of R_{vir} (Appendix B)

$$R(\bar{n}_{\text{H}} = n_{\text{H,shielded}}) = 0.33 f_{\text{gas}}^{1/2} \left(\frac{1+z}{5} \right)^{3/2} \Gamma_{-12}^{-1/3} T_4^{-0.09} R_{\text{vir}}, \quad (5)$$

and in physical units

$$R(\bar{n}_{\text{H}} = n_{\text{H,shielded}}) = 21 f_{\text{gas}}^{1/2} \left(\frac{1+z}{5} \right)^{1/2} \Gamma_{-12}^{-1/3} T_4^{-0.09} M_{12}^{1/3} \text{ kpc}, \quad (6)$$

where f_{gas} is the CGM mass in units of the halo baryon budget and $M_{12} \equiv M_{\text{vir}}/10^{12} M_{\odot}$. Taking Γ appropriate for the UVB in FIRE (i.e. neglecting ionization from local stars), and calculating f_{gas} based

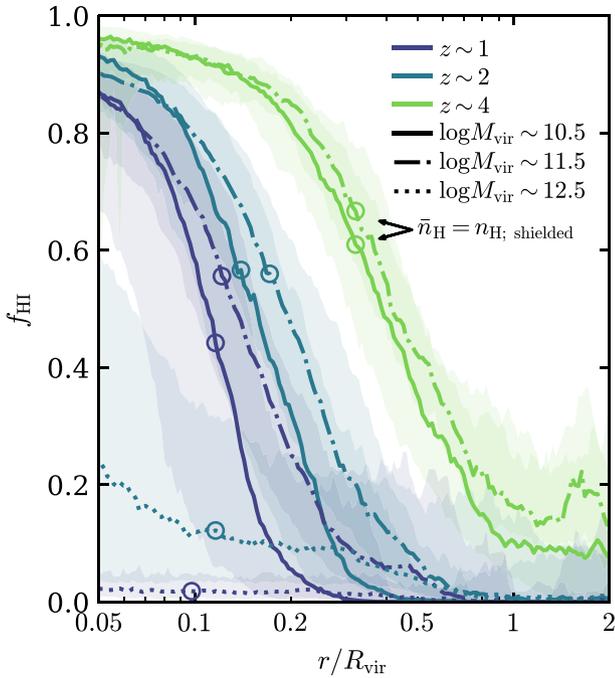

Figure 6. Neutral hydrogen fraction in the FIRE CGM, as a function of redshift and halo mass. For each (z, M_{vir}) bin, a line and band denote the median f_{HI} profile and $\pm 1\sigma$ range among all snapshots in the bin. The inner CGM is predominantly neutral in $\sim 10^{10.5} M_{\odot}$ and $\sim 10^{11.5} M_{\odot}$ haloes, and the extent of this neutral region increases with redshift. The radius where $f_{\text{HI}} \approx 0.5$ in $< 10^{12} M_{\odot}$ haloes roughly corresponds to where the mean density exceeds the shielding density (marked by circles; see Fig. 5). In $> 10^{12} M_{\odot}$ haloes, the CGM is predominantly ionized even at radii where $\bar{n}_{\text{H}} > n_{\text{H,shielded}}$, due to the dominance of the collisionally ionized hot phase.

on the total gas mass at $0.1 - 1R_{\text{vir}}$ in the snapshots, we find that the median value of the product $f_{\text{gas}}^{1/2} \Gamma_{-12}^{-1/3}$ somewhat decreases with redshift, from ≈ 1.5 at $z = 0$ to ≈ 0.9 at $z = 4$. Using these values in equation (5) demonstrates that it provides a good approximation for the radius at which $\bar{n}_{\text{H}} = n_{\text{H,shielded}}$, shown in Fig. 5.

The implications of rapid cooling and self-shielding for the hydrogen neutral fraction f_{HI} are shown in Fig. 6. To calculate f_{HI} as a function of r/R_{vir} in a given snapshot, we divide the gas into 0.05 dex-wide shells in radius, and divide the HI mass by the total hydrogen mass within each shell. For each bin of (z, M_{vir}) , we then calculate the median and $\pm 1\sigma$ range of the f_{HI} profiles among all snapshots in the bin. Fig. 6 shows that the inner CGM has a high neutral fraction in $< 10^{12} M_{\odot}$ haloes, while the extent of this neutral region increases with redshift. On average, we find $f_{\text{HI}} > 0.5$ out to $0.1 - 0.15R_{\text{vir}}$ at $z = 1$, out to $\approx 0.2R_{\text{vir}}$ at $z = 2$, and out to $\approx 0.4R_{\text{vir}}$ at $z = 4$. These radii are similar in the low mass ($10^{10.5} M_{\odot}$) and intermediate mass ($10^{11.5} M_{\odot}$) bins, and are comparable to the radii at which the mean gas density exceeds $n_{\text{H,shielded}}$ (marked by circles). In contrast, in the high mass bin ($10^{12.5} M_{\odot}$) the CGM is predominantly ionized at all radii, due to the collisionally ionized hot phase filling the halo when $t_{\text{cool}}^{(s)} > t_{\text{ff}}$.

3.3 Neutral CGM kinematics

Fig. 7 explores the kinematics of neutral inner CGM in FIRE. For each radial shell, we measure the distribution of radial velocities of resolution elements within the shell, combining shells with the same

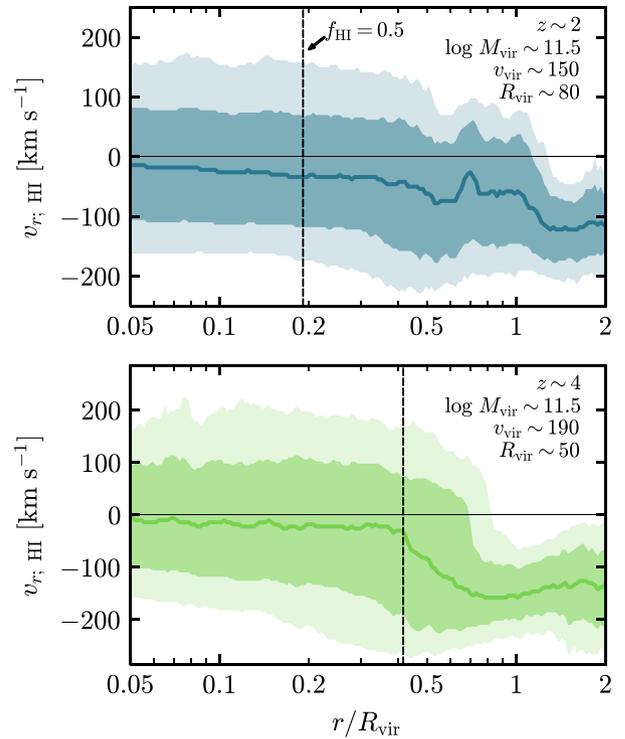

Figure 7. Radial velocity distribution of the neutral CGM in FIRE. Lines mark the median v_r (weighted by HI mass) at different radii, while coloured bands denote 16–84 and 5–95 percentiles. The combined distribution of all snapshots in the $(z \sim 2, M_{\text{vir}} \approx 10^{11.5} M_{\odot})$ bin is shown in the top panel, and similarly for the $(z \sim 4, M_{\text{vir}} \approx 10^{11.5} M_{\odot})$ bin in the bottom panel. Vertical lines mark the radius within which the CGM is predominantly neutral. Characteristic v_{vir} and R_{vir} are noted in the legend. The radial velocities in the neutral inner CGM span $\pm v_{\text{vir}}$, with a small net inflow.

r/R_{vir} from all snapshots in a given (M_{vir}, z) bin. To focus on the neutral CGM, we weigh each resolution element by its HI mass. The top panel shows the distributions in the $(z \sim 2, M_{\text{vir}} \approx 10^{11.5} M_{\odot})$ bin while the bottom panel shows the distributions in the $(z \sim 4, M_{\text{vir}} \approx 10^{11.5} M_{\odot})$ bin. Vertical lines mark the median radius at which $f_{\text{HI}} = 0.5$ (Fig. 6), which increases with redshift from $\approx 0.2R_{\text{vir}} \approx 16$ kpc at $z \sim 2$ to $\approx 0.4R_{\text{vir}} \approx 20$ kpc at $z \sim 4$. Lines mark the median of the distribution while coloured bands denote the 16–84 and 5–95 percentiles.

Fig. 7 demonstrates that at radii where the CGM is predominantly neutral (left of the dashed lines) the 5–95 percentile range of $v_{r,\text{HI}}$ spans ± 150 km s $^{-1}$ in the $z \sim 2$ panel and ± 200 km s $^{-1}$ in the $z \sim 4$ panel, roughly equal to the median virial velocity v_{vir} of snapshots in the bin (noted in the legends). The HI-weighted median velocity is negative (inflow), though with relatively small absolute values of 20–30 km s $^{-1}$. The mean of the distribution (not shown) is similar to the median. Other redshifts and masses in our sample exhibit a similar spread of $-v_{\text{vir}} \lesssim v_{r,\text{HI}} \lesssim v_{\text{vir}}$ and a small negative median $v_{r,\text{HI}}$.

While Fig. 7 demonstrates that the average inflow velocity in inner neutral CGM is small, we emphasize that the CGM is not thermal-pressure supported since there is no ambient hot phase with temperature $\sim T_{\text{vir}}$. Neutral CGM in FIRE more resembles ‘dynamically supported CGM’, where support against gravity is provided by bulk flows and turbulence arising from the interaction between cosmological inflows and outflowing galactic winds, as seen in idealized CGM simulations with $t_{\text{cool}}^{(s)} < t_{\text{ff}}$ (Fielding et al. 2017).

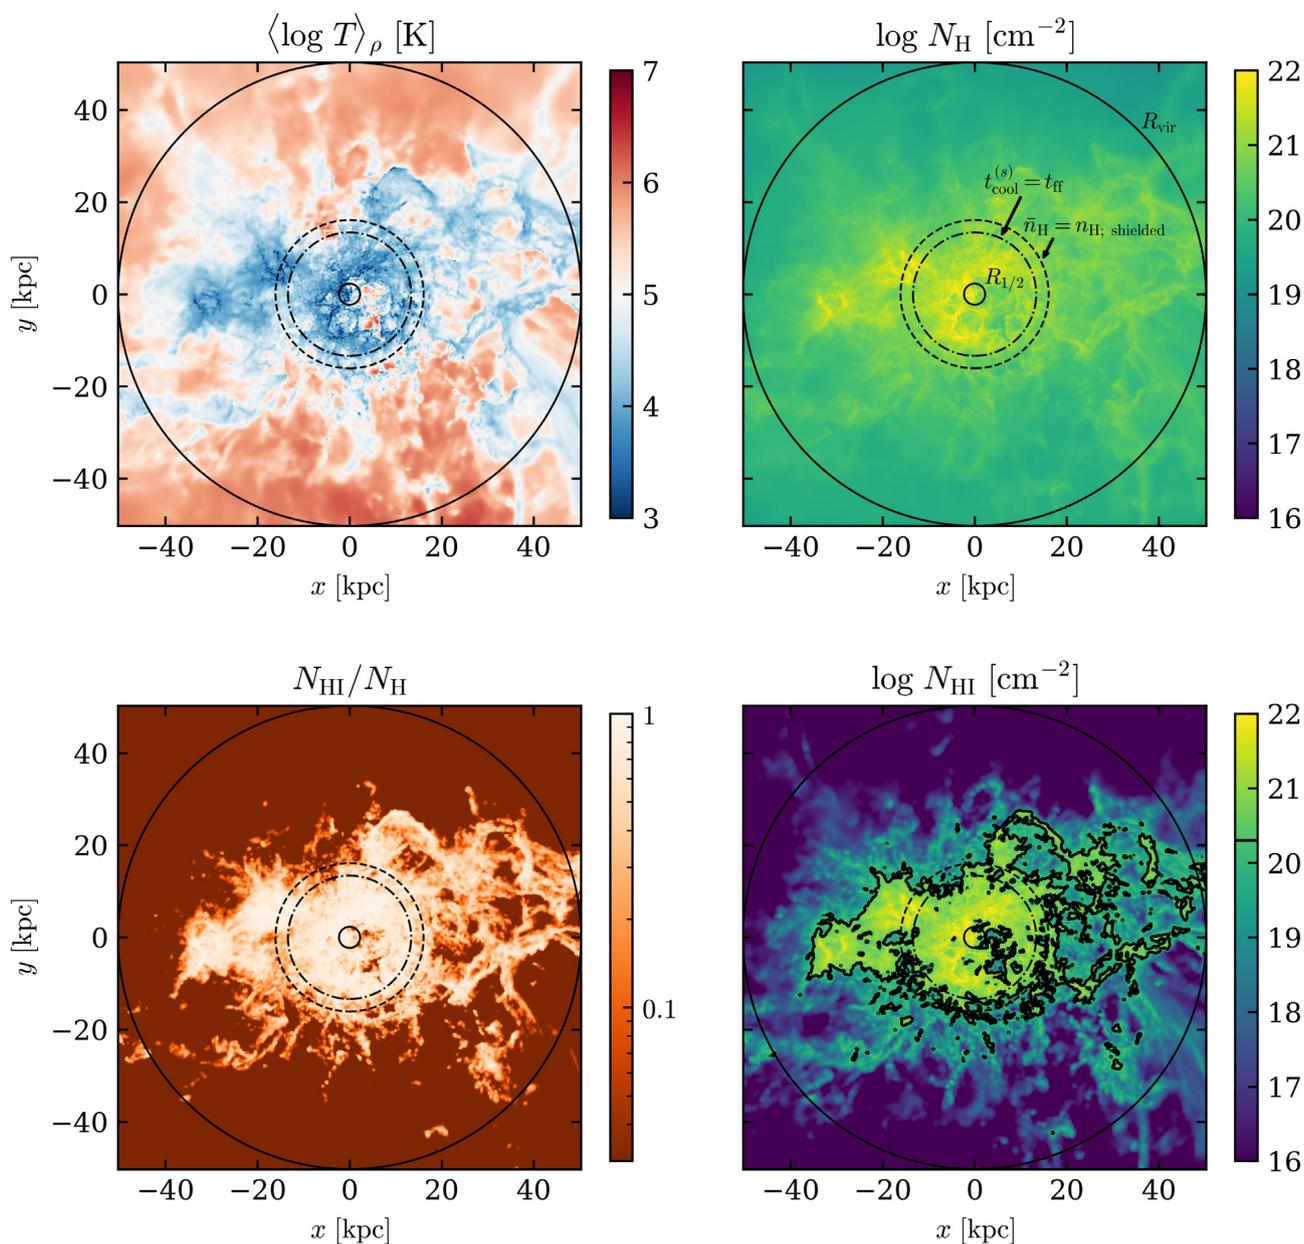

Figure 8. Projected properties of a $z = 4$ CGM in the m13A4 simulation. Halo and stellar masses are, respectively, 5×10^{11} and $0.8 \times 10^{10} M_{\odot}$. The panels show mass-weighted logarithmic temperature (*top-left*), hydrogen column (*top-right*), neutral hydrogen fraction (*bottom-left*), and neutral hydrogen column (*bottom-right*). Black circles mark the virial radius $R_{\text{vir}} = 50$ kpc, the shielding radius at which $\bar{n}_{\text{H}} = n_{\text{H,shielded}}$ (16 kpc, equation 1), the radius at which $t_{\text{cool}}^{(s)} = t_{\text{ff}}$ (13 kpc, equations 3–4), and the stellar half-mass radius $R_{1/2} = 2.3$ kpc. To minimize the cross-section of the central galaxy, the orientation of the images is *edge-on* with respect to the angular momentum of gas at the centre. DLA sightlines ($N_{\text{HI}} > 2 \times 10^{20} \text{ cm}^{-2}$) are delineated by black contours in the bottom-right panel. Note that at radii smaller than $R(t_{\text{cool}}^{(s)} = t_{\text{ff}})$ the CGM is predominantly cool and neutral, and has a DLA covering factor close to unity.

4 THE DLA COVERING FACTOR OF THE CGM IN FIRE

Above we demonstrated that FIRE haloes have a high neutral fraction at CGM radii where $t_{\text{cool}}^{(s)} < t_{\text{ff}}$ and $n_{\text{H}} > n_{\text{H,shielded}}$. We now discuss the implications for DLA covering factors.

Fig. 8 plots projected quantities in the $z = 4$ snapshot of the m13A4 simulation. The halo and stellar masses in this snapshot are $M_{\text{vir}} = 5 \times 10^{11} M_{\odot}$ and $M_{*} = 0.8 \times 10^{10} M_{\odot}$, and the galaxy star formation rate is $\text{SFR} = 16 M_{\odot} \text{ yr}^{-1}$. The top-left panel shows the mass-weighted logarithmic temperature $\langle \log T \rangle_\rho$, derived by depositing the temperature of particles on an evenly spaced grid according to their smoothing kernel, and then averaging over $\pm R_{\text{vir}}$

in the direction perpendicular to the image. The other panels show similar projection maps of N_{H} , $N_{\text{HI}}/N_{\text{H}}$, and N_{HI} . To focus on the CGM and minimize the effects of an extended gaseous disc, we choose an edge-on orientation, such that the total angular momentum vector of gas in the inner $0.05R_{\text{vir}}$ is directed upwards. We also mark in the panels the virial radius $R_{\text{vir}} = 50$ kpc, the stellar half-mass radius $R_{1/2} = 2.3$ kpc (measured using all stars within $0.15R_{\text{vir}}$), the radius where $\bar{n}_{\text{H}} = n_{\text{H,shielded}}$ (16 kpc), and the radius where $t_{\text{cool}}^{(s)} = t_{\text{ff}}$ (13 kpc).

The top-left panel of Fig. 8 shows that at radii smaller than $R(t_{\text{cool}}^{(s)} = t_{\text{ff}})$, the CGM is predominantly cool with temperatures of 10^3 – 10^4 K, orders of magnitude lower than the halo virial

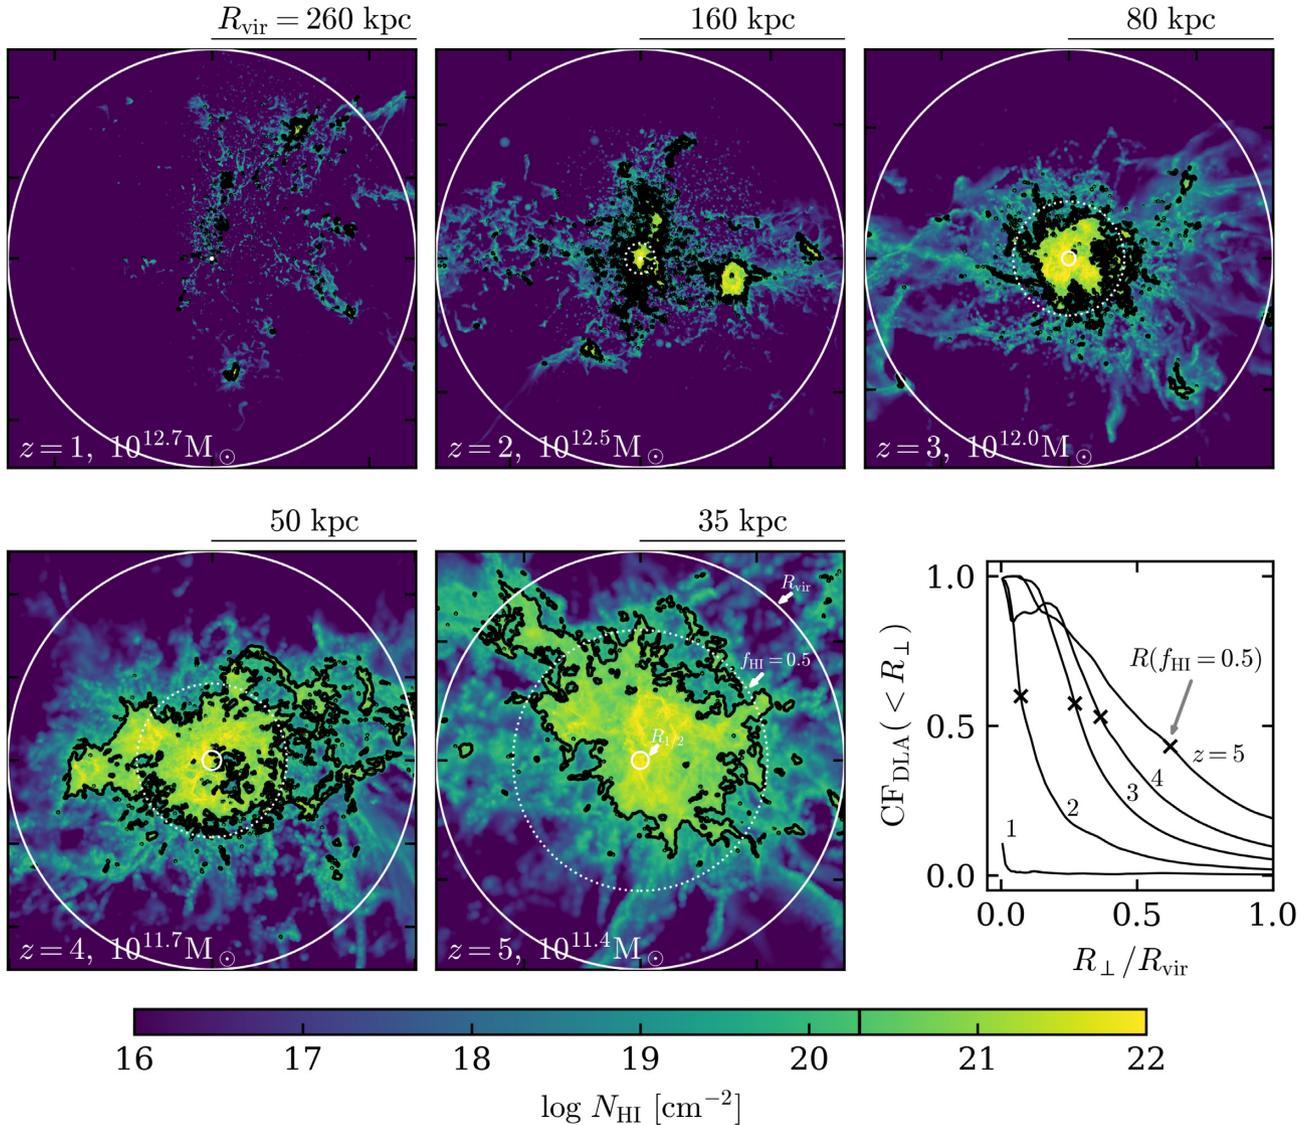

Figure 9. (Images) H I columns in the m13A4 simulation as a function of redshift. The redshift and halo mass are noted in the panels. Solid white circles mark R_{vir} and $R_{1/2}$, while dotted circles mark the radius where $f_{\text{HI}} = 0.5$. Black contours delineate DLA sightlines. As in Fig. 8, the projection axis is chosen so the angular momentum vector is pointed upwards. (Bottom right) The DLA covering fraction versus impact parameter for the five snapshots. Note how the region where CF_{DLA} approaches unity expands with increasing redshift, tracing the region where the CGM is predominantly neutral.

temperature of $T_{\text{vir}} = 1.5 \times 10^6$ K. The absence of a dominant hot phase is consistent with rapid cooling within this radius. The bottom-left panel shows that this inner region is also neutral along practically all sightlines, as expected since typical densities are above $n_{\text{H,shielded}}$. In contrast, at larger radii cool temperatures and high neutral fractions are seen only along specific angles.

The top-right panel in Fig. 8 shows that N_{H} exceeds 10^{20} cm^{-2} in the inner CGM of this halo, typically by a large factor of $\gtrsim 10$, as expected in haloes with a mass $M_{\text{vir}} \sim 10^9 M_{\odot}$ or larger (see Appendix B). A large neutral fraction in the inner CGM is hence a sufficient requirement for a large DLA covering factor in such haloes, as evident in the bottom-right panel. We find a DLA covering factor of $\text{CF}_{\text{DLA}} = 0.75$ at impact parameters $R_{\perp} < R(t_{\text{cool}}^{(s)} = t_{\text{ff}})$ in the edge-on projection shown in Fig. 8, and a similar $\text{CF}_{\text{DLA}} = 0.74$ at the same impact parameters in a face-on projection.

Fig. 9 plots N_{HI} maps (similar to the bottom-right panel of Fig. 8) for snapshots of the m13A4 simulation in the range of $1 \leq z \leq 5$. As in Fig. 8, the projection axis is chosen so the angular momentum vector of gas at the centre is pointed upwards in all images. A strong increase in the DLA covering fraction of the CGM with redshift is apparent, from a few small patches of DLA sightlines at $z = 1$ to a DLA covering fraction approaching unity out to $\sim 0.5R_{\text{vir}}$ at $z = 5$. This trend is quantified in the bottom-right panel, where we plot $\text{CF}_{\text{DLA}}(< R_{\perp})$ versus R_{\perp}/R_{vir} for each of the five snapshots. This panel also shows that the impact parameter where $\text{CF}_{\text{DLA}} = 0.5$ roughly corresponds to the 3D radius where $f_{\text{HI}} = 0.5$ (marked by crosses).

Fig. 10 plots the dependence of the DLA covering factor on halo mass and redshift in all 16 FIRE simulations. The left-hand panel plots $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)/R_{\text{vir}}$, where $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ is defined as

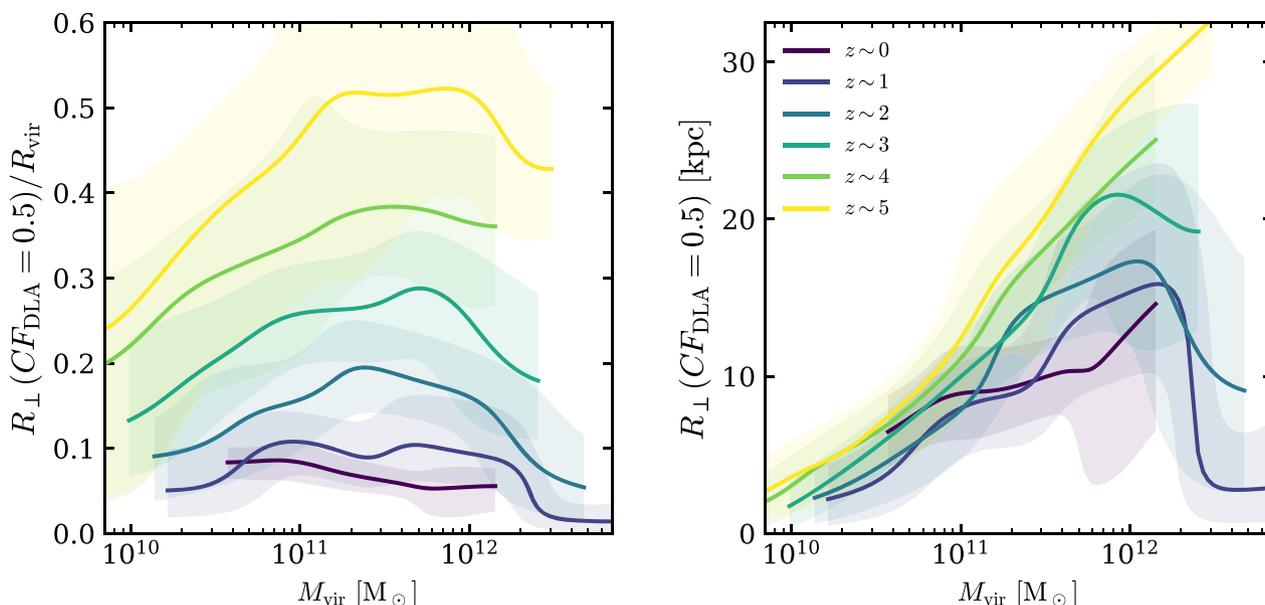

Figure 10. The extent of DLAs in FIRE versus halo mass and redshift, in units of R_{vir} (left) and in physical units (right). Coloured lines mark median relations for different redshift bins. The ratio $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)/R_{\text{vir}}$ shows a strong trend with redshift, due to mean densities exceeding $n_{\text{H,shielded}}$ at larger fractions of R_{vir} with increasing redshift (Fig. 5). At $M_{\text{vir}} \gtrsim 10^{12} M_{\odot}$, the value of $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ decreases relative to lower M_{vir} due to the decrease in the filling factor of cool gas (Fig. 2).

the impact parameter within which 50 per cent of sightlines have a DLA. We calculate $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ in a random edge-on projection of each simulation snapshot, and use coloured lines and bands to denote the median and dispersion of all snapshots in different redshift bins. The right-hand panel plots $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ in physical units.

The left-hand panel of Fig. 10 demonstrates that the DLA covering fraction of the CGM increases strongly with redshift. Specifically, in 10^{11} – $10^{12} M_{\odot}$ haloes the value of $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)/R_{\text{vir}}$ increases by an order of magnitude from ≈ 0.05 at $z = 0$ to ≈ 0.5 at $z = 5$. The ratio $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)/R_{\text{vir}}$ also exhibits a weak dependence on halo mass at $10^{10.5}$ – $10^{12} M_{\odot}$. Both these trends are expected from the relation between average CGM densities and $n_{\text{H,shielded}}$ shown in Fig. 5 and equation (5), which show that $R(\bar{n}_{\text{H}} = n_{\text{H,shielded}})/R_{\text{vir}}$ increases strongly with redshift and is roughly independent of halo mass. The right-hand panel shows that in physical units $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ depends only weakly on redshift, increasing by at most a factor of 2 from $z = 0$ to 5 for a given halo mass, and increases with halo mass up to $M_{\text{vir}} \approx 10^{12} M_{\odot}$, as expected from equation (6). At larger halo masses, $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ drops, as most evident in the $z \sim 1$ and 2 bins. This drop is due to the high $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ in the inner CGM of these haloes, which implies a small f_{cool} and hence a low neutral fraction (Fig. 6).

We note that the weak dependence of $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ on redshift in physical units (right-hand panel of Fig. 10) is a result of the relatively weak dependence of mean CGM densities on redshift at fixed physical radius and halo mass, so the physical radius where $\bar{n}_{\text{H}} = n_{\text{H,shielded}} \approx 0.01 \text{ cm}^{-3}$ weakly depends on redshift. This is in contrast with the strong evolution of $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ with redshift in units of R_{vir} (left-hand panel of Fig. 10). This behaviour is phenomenologically similar to the lack of evolution of the inner DM profile in physical units (e.g. Diemer, More & Kravtsov 2013; Wetzel & Nagai 2015), a similarity that warrants future investigation.

5 COMPARISON TO OBSERVATIONS

In this section, we compare neutral inner CGM in FIRE with observations of DLA–galaxy pairs at $z \sim 4$. To this end, we calculate the predictions of FIRE for the impact parameters, metallicities, velocity dispersions, and number densities of $z \sim 4$ DLAs.

5.1 DLA metallicities

In the top panel of Fig. 11, we plot DLA metallicity Z_{DLA} in FIRE as a function of impact parameter and halo mass. To derive $Z_{\text{DLA}}(M_{\text{vir}}, R_{\perp})$, we use all $3.5 < z < 4.5$ snapshots from the 16 FIRE simulations. We choose 50 randomly oriented mock sightlines with $N_{\text{HI}} > 2 \times 10^{20} \text{ cm}^{-2}$ through each snapshot, and calculate the average metallicity of each sightline, weighted by the HI mass of resolution elements along the sightline. As above, we include particles within $\pm R_{\text{vir}}$ from the mid-plane in the averaging. The sightlines are then binned by R_{\perp} and by M_{vir} of the snapshot, and in Fig. 11 we plot the median and 16–84 percentile range of each $(M_{\text{vir}}, R_{\perp})$ bin. The figure shows an increase of Z_{DLA} with halo mass, and a relatively flat metallicity profile out to $\approx 20 \text{ kpc} \approx 0.3$ – $0.5 R_{\text{vir}}$ in the two most massive bins. This suggests a relation between mass and metallicity in the inner CGM similar to that in the ISM.

We compare the predicted CGM metallicity profiles to the Neeleman et al. (2017, 2019) observations of DLA–galaxy pairs. The Neeleman et al. sample is based on a selection of six high-metallicity DLAs ($Z_{\text{DLA}} = 0.05$ – $0.2 Z_{\odot}$) from a larger sample of DLAs along random quasar sightlines (Rafelski et al. 2012), which were followed up with ALMA observations. [C II] 158 μm emission was detected around five of the six DLAs at impact parameters 20–40 kpc, potentially originating from the associated galaxy. Around one of the DLAs, two [C II] sources were detected, so the associated galaxy in this object is uncertain. Four of the six [C II] sources also have detected continuum infrared emission, while optical emission was

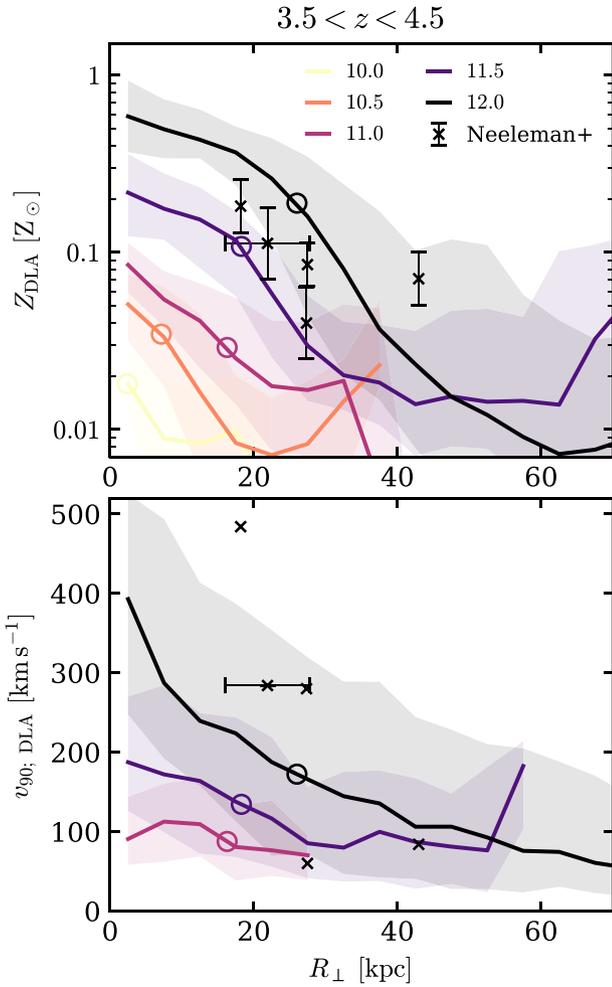

Figure 11. DLA metallicities (*top*) and velocity widths (*bottom*) in $z \sim 4$ FIRE haloes. Solid lines and coloured bands denote medians and 16–84 percentile ranges, as a function of impact parameter and halo mass (noted in the legend in $\log M_\odot$). Circles mark the radii within which the DLA covering factor is 50 per cent (typically $\approx 0.4R_{\text{vir}}$; see Fig. 10). Error bars mark impact parameters between high-metallicity DLAs and bright galaxies measured by Neeleman et al. (2017, 2019). The observed DLA impact parameters, metallicities, and velocities fall within the 16–84 percentile ranges of $10^{11.5}$ – $10^{12} M_\odot$ haloes in FIRE.

not detected in any object (potentially due to dust obscuration). The galaxy SFRs inferred by Neeleman et al. from the infrared luminosities are 7, 15, 24, and $110 M_\odot \text{ yr}^{-1}$. These SFRs are similar to those of luminous Lyman-break galaxies, and to the SFRs in the central galaxy of the four massive ($M_{\text{vir}} \sim 10^{11.5}$ – $10^{12} M_\odot$) haloes in our sample, which have 300 Myr-averaged SFRs of 2.5, 15, 75, and $78 M_\odot \text{ yr}^{-1}$ at $z = 4$ (see Fig. 15 in S21).

Error bars in the top panel of Fig. 11 plot metallicity and impact parameter measurements from the observed sample. In the object with two possible associated galaxies, we plot a horizontal error bar to denote the uncertainty in R_\perp . The figure shows that the metallicities and impact parameters in the Neeleman et al. sample fall within the $\pm 1\sigma$ range of $10^{11.5}$ – $10^{12} M_\odot$ haloes in FIRE, the same halo mass range suggested by the observed SFR.

Four of the five Neeleman et al. DLA–galaxy pairs have $R_\perp \lesssim 30$ kpc, while 1–2 objects have $R_\perp \lesssim 20$ kpc (depending on the actual R_\perp in the object with two possible hosts). These impact parameters

are comparable to $R_\perp(\text{CF}_{\text{DLA}} = 0.5)$ in the massive haloes, which equals 30 kpc in the $10^{12} M_\odot$ bin and 20 kpc in the $10^{11.5} M_\odot$ bin. Thus, a substantial fraction of the Neeleman et al. sample appears to originate in the region where the DLA covering factor is predicted to be close to unity, i.e. where the CGM is predominantly cool and neutral.

5.2 DLA kinematics

The bottom panel of Fig. 11 plots predicted DLA velocity widths, $v_{90,\text{DLA}}$. To estimate $v_{90,\text{DLA}}$ in the simulation, we create mock observations of Si II $\lambda 1808$ absorption spectra of sightlines through FIRE haloes, using the TRIDENT package (Hummels, Smith & Silvia 2017). We measure the velocity range that includes 90 per cent of the absorption flux in the mock spectra, excluding the outermost 5 per cent of the flux on both the red end and the blue end of the absorption spectrum. The range and dispersion in predicted $v_{90,\text{DLA}}$ are then calculated using the same binning in M_{vir} and R_\perp as in the top panel. The predicted $v_{90,\text{DLA}}$ in the $M_{\text{vir}} \sim 10^{11.5} M_\odot$ mass bin (blue) can be compared to the distribution of radial velocities ($v_{r,\text{HI}}$) shown in the bottom panel of Fig. 7. At $R_\perp = 20$ kpc ($\approx 0.4R_{\text{vir}}$), we find a 16–84 percentile range of $50 \lesssim v_{90,\text{DLA}} \lesssim 250 \text{ km s}^{-1}$, compared to $-150 \lesssim v_{r,\text{HI}} \lesssim 100 \text{ km s}^{-1}$, indicating that often both inflowing gas and outflowing gas contribute to the absorption along a single sightline.

Four of the five observed $v_{90,\text{DLA}}$ are within the 16–84 percentile range of $10^{11.5}$ – $10^{12} M_\odot$ haloes (the same halo mass range suggested by the DLA metallicities and galaxy SFRs). The largest observed $v_{90,\text{DLA}} = 500 \text{ km s}^{-1}$ is in the 5–95 percentile range of the $10^{12} M_\odot$ halo bin.

5.3 DLA number densities

The predicted number of DLAs along IGM sightlines is plotted in Fig. 12, separated into the contribution from different halo masses and different DLA metallicities. To estimate the expected number of DLAs, we use

$$\frac{d^3 N_{\text{DLA}}}{dX d \log M_{\text{vir}} d \log Z} = \frac{d^2 N_{\text{h}}}{dX d \log M_{\text{vir}}} \text{CF}_{\text{DLA}}(< R_{\text{vir}}, M_{\text{vir}}, Z), \quad (7)$$

where N_{DLA} is the number of DLAs along the line of sight, dX is the normalized path-length (e.g. Wolfe et al. 2005):

$$dX = (1+z)^3 \left| \frac{cdt}{dz} \right| \frac{H_0}{c} dz, \quad (8)$$

and $\text{CF}_{\text{DLA}}(< R_{\text{vir}}, M_{\text{vir}}, Z) d \log Z$ is the covering factor of DLAs with metallicity in the range of $(Z, Z + d \log Z)$ in FIRE haloes with mass in the range of $(M_{\text{vir}}, M_{\text{vir}} + d \log M_{\text{vir}})$. We calculate the number of haloes per normalized path-length and per decade in mass using

$$\frac{d^2 N_{\text{h}}}{dX d \log M_{\text{vir}}} = \frac{c}{H_0} \frac{dn_{\text{h}}}{d \log M_{\text{vir}}} \pi R_{\text{vir}}^2, \quad (9)$$

where $dn_{\text{h}}/d \log M_{\text{vir}}$ is the comoving halo number density taken from Behroozi et al. (2019), which is based on the Bolshoi–Planck dark matter simulation (Klypin et al. 2016). Fig. 12 demonstrates that 10^{10} – $10^{11} M_\odot$ haloes contribute a larger fraction of DLAs than more massive haloes, but high-metallicity DLAs with $Z > 0.1 Z_\odot$ are dominated by massive haloes with $M_{\text{vir}} > 10^{11.5} M_\odot$.

The Gaussian line in Fig. 12 marks the observed $d^2 N/dX d \log Z$ based on the analysis of Rafelski et al. (2012), which showed that observed metallicities of $z \approx 4$ DLAs follow a lognormal distribution with a mean of $10^{-1.54} Z_\odot$ and a width of 0.5 dex. We set the

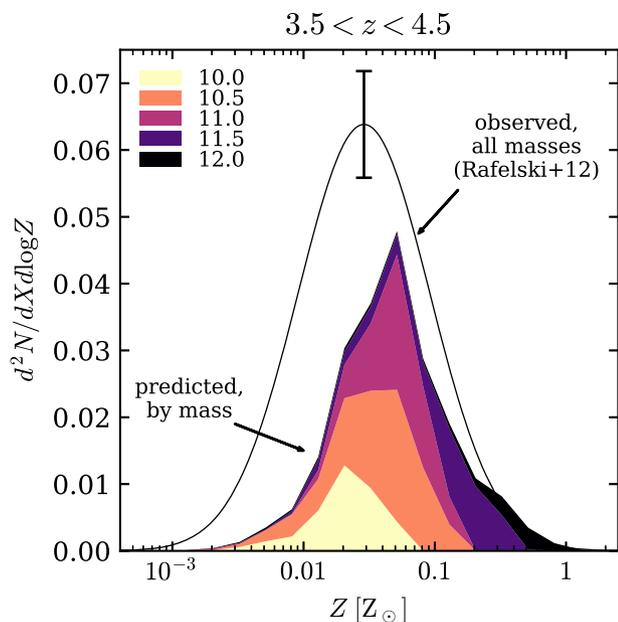

Figure 12. The contribution of haloes with different masses to the $z \sim 4$ DLA population, as a function of DLA metallicity. Colour bands plot predicted DLA number densities for different M_{vir} , derived from the covering area of DLAs in FIRE haloes convolved with the halo number densities from the Bolshoi–Planck dark matter simulation. Note that massive haloes ($\gtrsim 10^{11.5} M_{\odot}$) dominate the high-metallicity ($> 0.1 Z_{\odot}$) DLA population. The Gaussian line marks the Rafelski et al. (2012) fit to the observed DLA metallicity distribution, while the error bar denotes the uncertainty in the Gaussian normalization. The FIRE simulations of $> 10^{10} M_{\odot}$ haloes reproduce the observed number of DLAs with $Z > 0.05 Z_{\odot}$, while the number of lower metallicity DLAs is underpredicted.

normalization of the observed metallicity distribution to reproduce the integrated $dN/dX = 0.08 \pm 0.01$ measured by Prochaska & Wolfe (2009), while the error bar denotes the uncertainty in the dN/dX measurement. The predictions of the FIRE simulations are consistent with the observed number of DLAs with $Z > 0.05 Z_{\odot}$, while the number of lower Z DLAs is underpredicted, by a factor of ≈ 5 at $Z \lesssim 0.01 Z_{\odot}$. We discuss possible origins for this difference in Section 6.3 below.

6 DISCUSSION

In this paper, we showed that the inner CGM ($\lesssim 0.4R_{\text{vir}}$) of $z \sim 4$ haloes with mass $\lesssim 10^{12} M_{\odot}$ is predominantly neutral in FIRE, leading to large DLA covering factors. We further demonstrated that the inner CGM is also neutral in lower redshift haloes, though out to a smaller fraction of R_{vir} ($\lesssim 0.2R_{\text{vir}}$ at $z \sim 2$ and $\lesssim 0.1R_{\text{vir}}$ at $z \sim 1$; see Fig. 6). We showed that a high neutral fraction occurs in the CGM when two conditions are satisfied: cooling times are sufficiently short so that hot gas cools rapidly; and densities are sufficiently high so that cool gas is shielded from photoionization. Such a neutral CGM differs from the standard CGM picture based mainly on lower redshift observations and simulations, in which the CGM is a mixture of hot collisionally ionized gas and cool photoionized clumps or filaments (e.g. Tumlinson, Peebles & Werk 2017). In this section, we compare our results to previous studies, and discuss several uncertainties and implications.

6.1 Previous models of DLAs from the volume-filling phase of the CGM

Zheng & Miralda-Escudé (2002, hereafter ZME02) have also argued that high-redshift DLAs originate in a volume-filling neutral CGM. They assumed a spherical CGM in thermal and ionization equilibrium with the UVB, and calculated the optical depth along rays in different directions. They derived a radius R_{ZME02} within which gas is shielded from photoionization, which scaled to our assumed cosmology and UVB equals (see appendix B)

$$R_{\text{ZME02}} = 0.46 M_{12}^{1/9} \left(\frac{1+z}{5} \right)^{1.6} f_{\text{gas}}^{2/3} \Gamma_{-12}^{-1/3} R_{\text{vir}}. \quad (10)$$

The value of R_{ZME02} can be compared to the radius at which the average gas density equals $n_{\text{H,shielded}}$ (Fig. 5) and to the radius where the DLA covering factor is 50 per cent in FIRE (Fig. 10). These three estimates are comparable both in magnitude and in dependence on halo parameters. Our conclusion that inner CGM are neutral at high redshift is thus quantitatively similar to the conclusion of ZME02, despite the significant difference in calculation method.

More recently, Theuns (2021) showed that a model where the CGM is filled with cool cosmological accretion is consistent with the observed column-density distribution of DLAs, and with the independence of the DLA distribution function on redshift at $z \sim 2-5$. Their model is similar to our results based on FIRE in that the inner CGM is predominantly cool, though in FIRE the inner CGM is not pure inflow but rather a mixture of inflows and outflows (as indicated, e.g. by gas kinematics in Fig. 7 and by gas metallicity in Fig. 11). The CGM profile of $n_{\text{H}} \propto r^{-2.2}$ assumed by Theuns (2021) is also similar to the slopes of $r^{-2.3} - r^{-2.1}$ in FIRE, while their CGM density normalization is roughly a factor of 2 lower (compare their fig. 1 with Fig. 5 above).⁴ Thus, the DLA column density distributions predicted by Theuns (2021) for the inner CGM are expected to be similar to those in FIRE.

Our results extend the analytical studies of ZME02 and Theuns (2021) in two main ways. First, we demonstrate that their assumption of a cool and quasi-spherical CGM is valid in FIRE when $t_{\text{cool}}^{(s)} \lesssim t_{\text{ff}}$ (Fig. 3), and present simulation results where the range in halo mass, redshift, and radius in which this condition is satisfied. Specifically, we find that a large volume fraction of the inner CGM is cool at halo masses $\lesssim 5 \times 10^{11} M_{\odot}$ at all redshifts, while the outer CGM is cool at lower halo masses of $\lesssim 10^{11} M_{\odot}$ and mainly at $z > 2$ (Fig. 2). Secondly, we demonstrate that a neutral CGM occurs even when accounting for the complexities in the FIRE cosmological simulations neglected by these analytical studies, including deviations from spherical symmetry, heating by accretion and stellar feedback, and the contribution of winds from the central and satellite galaxies to the CGM (for an analysis of these processes in FIRE, see Muratov et al. 2015; Anglés-Alcázar et al. 2017a; Hafen et al. 2019, 2020).

6.2 The extent of neutral CGM versus disc sizes

HST observations of galaxy sizes at $z \sim 4$ find effective radii $r_e \approx 0.5-2$ kpc for stellar masses of $10^9-10^{11} M_{\odot}$, corresponding to $r_e \sim 0.01-0.035R_{\text{vir}}$ according to abundance matching estimates (Shibuya, Ouchi & Harikane 2015). These measurements are roughly

⁴The density profile assumed in Theuns (2021) is based on self-similar solutions for cool cosmological accretion (Bertschinger 1985). It is intriguing that this calculation roughly reproduces the profiles in FIRE despite the addition of outflows from the galaxy, which warrants further investigation.

consistent⁵ with the four simulated galaxies in our sample in this stellar mass range, which have stellar half-mass radii $R_{1/2} = 0.8\text{--}2.3$ kpc. Our result that neutral CGM and high DLA covering factors extend to $r \approx 20$ kpc $\approx 0.4R_{\text{vir}}$ at this redshift (Figs 6 and 10) thus implies that DLAs extend to radii more than an order of magnitude larger than r_e . This conclusion is consistent with previous studies that demonstrated that DLA number densities are higher than expected based on the cross-section of galactic discs (Berry et al. 2014; Di Gioia et al. 2020).

We find that the extent of the region where DLA covering factors are large decreases with cosmic time with respect to R_{vir} , due to lower gas densities and hence less shielding from photoionization. Since disc sizes are also expected to scale with R_{vir} (e.g. Mo, Mao & White 1998), this result suggests there is a critical redshift at which DLAs transition from originating in quasi-spherical neutral CGM to originating in central discs. In our sample of FIRE galaxies, angular momentum support becomes important at $\lesssim 0.1R_{\text{vir}}$ (see fig. 13 in S21), corresponding to the value of $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ at $z < 1$ (Fig. 10). Indeed, DLA covering factors at $z < 1$ differ between face-on and edge-on orientations, typically by ≈ 30 per cent, in contrast with at $z \gtrsim 1$ when there is no systematic difference between different orientations. Our results thus suggest that a transition occurs in the DLA population at $z \sim 1$, from being dominated by neutral CGM at higher redshifts to being dominated by central discs at lower redshifts.

6.3 CGM metallicities in FIRE versus observations

We find that the enrichment of the $z \sim 4$ CGM in FIRE is consistent with observations of high-metallicity DLAs at the same redshift. This is apparent in the impact parameters between DLAs and their associated galaxies (Fig. 11), and in the number densities of high-metallicity DLAs (Fig. 12). Our results, however, suggest a lack of low-metallicity DLAs (Fig. 12). Some of the missing low- Z DLAs could originate in $\sim 10^9 M_{\odot}$ haloes, which are not included in the predictions shown in Fig. 12. We can roughly estimate the total (metallicity-integrated) contribution of these haloes by extrapolating the $R_{\perp}(\text{CF}_{\text{DLA}} = 0.5)$ versus halo mass relation at $z = 4$ to $10^9 M_{\odot}$ (see Fig. 10), and multiplying by $d^2N_{\text{H}}/dX d\log M_{\text{vir}}$ calculated as in Section 5.3. This gives $d^2N/(dX d\log M_{\text{vir}}) \approx 0.02$, roughly half of the deficit in the FIRE prediction. Haloes with an even lower mass are unlikely to contribute significantly to the DLA population due to CGM depletion by UVB photoheating (Okamoto, Gao & Theuns 2008; Theuns 2021). Thus, the covering factors of DLAs in low-mass haloes and/or at large radii where metallicities are low may be underpredicted by FIRE. Larger samples of DLA–galaxy pairs that extend to lower masses will be able to test this possibility.

6.4 Ionizing radiation from local stars and AGN

Our result that the CGM can be largely neutral requires it to be shielded from local ionizing sources such as young stars and AGNs. This follows from the expected ionization rate of a young stellar population if absorption by the galaxy is neglected:

$$\Gamma_{\text{SF}} = \frac{Q_{\text{SF}}\sigma_{\text{HI}}}{4\pi r^2} \sim 1.7 \times 10^{-9} \frac{\text{SFR}}{10 M_{\odot} \text{ yr}^{-1}} \left(\frac{r}{10 \text{ kpc}} \right)^{-2} \text{ s}^{-1}, \quad (11)$$

⁵At lower redshifts $z \lesssim 2$, the four galaxies in our sample with $M_{\text{vir}} > 10^{12} M_{\odot}$ are more compact than in observations; see Wellons et al. (2020) and Parsotan et al. (2021).

where $\sigma_{\text{HI}} \approx 10^{-17.2} \text{ cm}^2$ is the HI opacity to ionizing radiation and $Q_{\text{SF}} \sim 3.3 \times 10^{53} (\text{SFR}/M_{\odot} \text{ yr}^{-1}) \text{ s}^{-1}$ is the emission rate of ionizing photons. The numerical value of Q_{SF} is evaluated based on Sternberg, Hoffmann & Pauldrach (2003) for an upper IMF mass cut-off of $120 M_{\odot}$, and is consistent with Q_{SF} in the stellar population model used in FIRE. Similarly, for an AGN

$$\Gamma_{\text{AGN}} = \frac{Q_{\text{AGN}}\sigma_{\text{HI}}}{4\pi r^2} \sim 1.9 \times 10^{-8} \frac{L_{\text{AGN}}}{10^{46} \text{ erg s}^{-1}} \left(\frac{r}{10 \text{ kpc}} \right)^{-2} \text{ s}^{-1}, \quad (12)$$

where we assumed an ionizing photon luminosity $Q_{\text{AGN}} = L_{\text{AGN}}/72 \text{ eV}$, where L_{AGN} is the bolometric luminosity (e.g. Telfer et al. 2002), and $\sigma_{\text{HI}} = 10^{-17.6} \text{ cm}^2$ for the hard AGN spectrum. At radii $r \approx 10$ kpc, the values of Γ_{SF} and Γ_{AGN} are factors of $\sim 10^3\text{--}10^4$ larger than $\Gamma_{\text{UVB}} \sim 10^{-12} \text{ s}^{-1}$ while the extent of shielded region extends as $\Gamma^{-1/3}$ (equation 5), so the CGM can be largely neutral only along directions in which local radiation is absorbed.

The FIRE simulations account for ionizing photons from young stars and for absorption of these photons by particles neighbouring the star particle (Section 2). In most cases where we find the inner CGM is neutral, the neighbouring particles entirely absorb the ionizing stellar radiation. This is evident from the extent of the neutral CGM being well approximated by $R(n_{\text{H}} = n_{\text{H,shielded}})$ (Fig. 6), where $n_{\text{H,shielded}}$ is calculated assuming that ionization by local stars is negligible.

A more accurate calculation of the escape fraction f_{esc} of ionizing photons from the galaxy was conducted by Ma et al. (2020), albeit in FIRE simulations with somewhat higher redshifts ($z \gtrsim 5$) than those analysed here. They post-processed the FIRE simulation snapshots with a Monte Carlo radiation transfer code, and found that the absorption of ionizing photons from young stars is bimodal, with f_{esc} approaching unity along low-column density paths from the most vigorously forming star-forming regions, while along other paths $f_{\text{esc}} \approx 0$ (see their fig. 8). It is thus conceivable that only a small fraction of the CGM is exposed to stellar ionizing radiation even if the average escape fraction is $\langle f_{\text{esc}} \rangle \sim 10$ per cent (e.g. Steidel et al. 2018). To test this possibility, we ran a preliminary Monte Carlo analysis on $z \sim 4$ snapshots with $M_{\text{vir}} \sim 10^{11.5} M_{\odot}$ in our sample, which have $t_{\text{cool}}^{(s)} < t_{\text{ff}}$ in their inner CGM (Fig. 3). We find that the average f_{HI} in the inner CGM are lower by $\lesssim 25$ per cent than those in the fiducial calculation, suggesting that our conclusions hold also when applying a more accurate radiation transfer calculation. A more thorough investigation is deferred to future work (Holguin et al., in preparation).

In active galaxies, the radiation from the central source is absorbed along ~ 50 per cent of sightlines, giving rise to the type 1 AGN/type 2 AGN dichotomy, with the covering factor of the absorbing gas potentially increasing to lower AGN luminosities (Maiolino et al. 2007; Stern & Laor 2012; Lusso et al. 2013). Thus, the CGM of active galaxies can be largely neutral only along type 2 directions. AGNs are, however, plausibly rare enough not to affect our conclusions regarding typical CGM. Even relatively weak AGNs with X-ray luminosities of $\approx 10^{42} \text{ erg s}^{-1}$ have an upper limit on their number density of $\sim 10^{-4} \text{ Mpc}^{-3}$ at $z \sim 4$ (Vito et al. 2016), compared to a number density of 10^{-3} Mpc^{-3} for $> 10^{12} M_{\odot}$ haloes and 0.03 Mpc^{-3} for $> 10^{11} M_{\odot}$ haloes (Rodríguez-Puebla et al. 2016).

7 SUMMARY

We use the FIRE-2 cosmological simulations to study when the CGM of galaxies is predominantly neutral and has a large DLA covering factor. We utilize a suite of zoom simulations that together span halo

masses of $10^{10} \lesssim M_{\text{vir}} \lesssim 10^{13} M_{\odot}$ at $0 < z < 5$. Our results can be summarized as follows:

(i) The volume filling fraction of cool $T < 10^{4.5}$ K gas is large ($f_{\text{cool}} \gtrsim 0.3$) at CGM radii where the cooling time of hot $T \sim T_{\text{vir}}$ gas is shorter than the free-fall time (Fig. 3). This condition is satisfied in FIRE in the inner regions of haloes with a mass of $\sim 10^{12} M_{\odot}$ or lower, and extends to the outer regions of haloes with a mass of $\sim 10^{11} M_{\odot}$ or lower (Fig. 4).

(ii) In $\lesssim 10^{12} M_{\odot}$ FIRE haloes where a large fraction of the inner CGM volume is occupied by cool gas, this gas is also neutral at radii where densities are large enough to shield it from photoionization. The maximum radius where the cool CGM is shielded increases relative to the halo size with redshift, roughly as $\sim 0.3[(1+z)/5]^{3/2} R_{\text{vir}}$ (Fig. 6).

(iii) Gas radial velocities in predominantly neutral inner CGM in FIRE typically span $\pm v_{\text{vir}}$, with a small mean inflow velocity ($< 0.2 v_{\text{vir}}$, Fig. 7), suggesting a mixture of inflowing and outflowing gas. The importance of galaxy outflows for the neutral inner CGM is also indicated by its high metallicity, which is within a factor of 2 of the ISM metallicity in the central galaxy (Fig. 11).

(iv) Predominantly neutral inner CGM have a DLA covering fraction approaching unity (Fig. 10). This implies that at $z \sim 4$ DLAs extend to radii that are an order of magnitude larger than the effective radius of the central galaxy. Our conclusions on the extent of DLAs in the CGM are quantitatively similar to those of Zheng & Miralda-Escudé (2002) and Theuns (2021), who assumed a spherical CGM in photoionization equilibrium with the UVB.

(v) The FIRE simulations predict that 10^{10} – $10^{11} M_{\odot}$ haloes contribute a larger fraction of DLAs than more massive haloes, but high-metallicity DLAs with $Z > 0.1 Z_{\odot}$ are dominated by massive haloes with $M_{\text{vir}} > 10^{11.5} M_{\odot}$ (Fig. 12). We also predict that the DLA covering fraction decreases at $M_{\text{vir}} \gg 10^{12} M_{\odot}$ since the inner CGM of massive haloes is filled with hot collisionally ionized gas (Fig. 10).

(vi) Comparison of FIRE predictions with the DLA–galaxy impact parameters recently observed by ALMA at $z \sim 4$ (Neeleman et al. 2017, 2019), together with the observed DLA metallicities, velocity widths, and galaxy SFRs, suggests that these DLAs originate in a predominantly neutral inner CGM of $10^{11.5}$ – $10^{12} M_{\odot}$ haloes (Fig. 11).

If the high-redshift inner CGM is largely neutral, as we find in the FIRE simulations, then its mass, metallicity, and dust-to-gas ratio can be directly constrained by DLA surveys without resorting to large ionization corrections ($\sim 10^3$ – 10^4) as required in the study of ionized low- z CGM (e.g. Werk et al. 2014). The high-redshift neutral CGM thus inherently avoids a major observational challenge of accounting for the hard-to-see ionized phase. As the CGM is the destination of galaxy-scale outflows, this possibility to accurately deduce its properties from high- z observations may allow to better constrain the physics of galaxy feedback in the early universe, a substantial uncertainty in current models of galaxy formation.

ACKNOWLEDGEMENTS

We thank the anonymous referee for insightful comments that substantially improved the paper. We thank F. Holguin and C. Hayward for conducting the radiation transfer analysis described in Section 6.4. JS is supported by the CIERA Postdoctoral Fellowship Program. This research was also supported by the German Science Foundation via DIP grant STE 1869/2-1 GE 625/17-1 at Tel Aviv University. CAFG was supported by NSF through grants AST-1715216 and CAREER award AST-1652522; by NASA through

grant 17-ATP17-0067; by STScI through grant HST-AR-16124.001-A; and by a Cottrell Scholar Award and a Scialog Award from the Research Corporation for Science Advancement. DAA acknowledges support by NSF grant AST-2009687 and by the Flatiron Institute, which is supported by the Simons Foundation. AW received support from NASA through ATP grants 80NSSC18K1097 and 80NSSC20K0513; *HST* grants GO-14734, AR-15057, AR-15809, and GO-15902 from STScI; a Scialog Award from the Heising-Simons Foundation; and a Hellman Fellowship.

APPENDIX A: JEANS SCALE APPROXIMATION

The Jeans scale approximation for $n_{\text{H,shielded}}$ (equation 1) is based on the assumption that absorbers are in hydrostatic equilibrium and have a gas fraction equal to the cosmic baryon fraction $f_g = \Omega_b/\Omega_m \approx 0.16$ (Schaye 2001). We repeat Schaye's derivation here for reference.

Writing hydrostatic equilibrium as an equality between the dynamical time and the sound-crossing time, we get

$$\sqrt{\frac{f_g}{G\rho}} = L\sqrt{\frac{\mu m_p}{\gamma k T}}, \quad (\text{A1})$$

where $L = N_{\text{H}}/n_{\text{H}}$ is the absorber size and $\gamma = 5/3$ is the adiabatic index. Using this relation and the hydrogen mass fraction $X \equiv n_{\text{H}}m_p/\rho$, we can derive the Jeans column density

$$\begin{aligned} N_{\text{H};J} &= \left(\frac{\gamma k X f_g}{\mu m_p^2 G}\right)^{1/2} n_{\text{H}}^{1/2} T^{1/2} \\ &\sim 1.5 \times 10^{20} T_4^{1/2} \left(\frac{n_{\text{H}}}{0.01 \text{ cm}^{-2}}\right)^{1/2} \left(\frac{f_g}{0.16}\right)^{1/2} \text{ cm}^{-2}. \end{aligned} \quad (\text{A2})$$

For highly ionized optically thin gas, we can approximate $f_{\text{HI}} = 0.46 T_4^{-0.76} \Gamma_{-12}^{-1} (n_{\text{H}}/\text{cm}^{-3})$, so from $N_{\text{H};J} = f_{\text{HI}} N_{\text{H};J}$ we get

$$N_{\text{H};J} \sim 6.9 \times 10^{17} T_4^{-0.26} \Gamma_{-12}^{-1} \left(\frac{n_{\text{H}}}{0.01 \text{ cm}^{-2}}\right)^{3/2} \left(\frac{f_g}{0.16}\right)^{1/2} \text{ cm}^{-2}. \quad (\text{A3})$$

The shielding density at which the cloud becomes optical thick can then be derived from requiring $\sigma_{\text{HI}} N_{\text{H};J} = 1$, where σ_{HI} is the opacity of H I to ionizing photons. This gives

$$\begin{aligned} n_{\text{H,shielded}} &\sim 0.01 \times T_4^{0.173} \Gamma_{-12}^{-2/3} \left(\frac{f_g}{0.16}\right)^{-1/3} \\ &\times \left(\frac{\sigma_{\text{HI}}}{10^{-17.6} \text{ cm}^2}\right)^{-2/3} \text{ cm}^{-3}. \end{aligned} \quad (\text{A4})$$

APPENDIX B: ANALYTICAL ESTIMATES OF CGM DENSITIES AND COLUMNS

Characteristic CGM columns and densities can be derived by assuming a spherically symmetric CGM with a power-law density profile $-a$:

$$\rho = \rho(R_{\text{vir}}) \left(\frac{r}{R_{\text{vir}}}\right)^{-a}. \quad (\text{B1})$$

The normalization of the density profile is chosen so that the total gas mass within R_{vir} equals $M_{\text{gas}} = f_{\text{gas}}(\Omega_b/\Omega_m)M_{\text{vir}}$, where f_{gas} is the CGM mass relative to the halo cosmic baryon budget. Typical f_{gas} in FIRE, estimated by summing the gas mass at $0.1 - 1R_{\text{vir}}$, are $\sim 0.15 - 0.35$ at $z \sim 0$ and $\approx 0.4 - 0.8$ at $2 < z < 5$ (see also Hafen et al. 2019). We thus get

$$\rho(R_{\text{vir}}) = \left(1 - \frac{a}{3}\right) \frac{\Omega_b}{\Omega_m} f_{\text{gas}} \Delta_c \rho_{\text{crit}}, \quad (\text{B2})$$

where $\rho_{\text{crit}} = 3H^2/8\pi G$ is the critical density (H is the Hubble parameter) and Δ_c is the mean halo mass overdensity with respect to ρ_{crit} (Bryan & Norman 1998). Assuming a hydrogen density $n_{\text{H}} = 0.7\rho/m_p$ and $a = -2$ similar to the slopes in FIRE (Fig. 5) we get for the inner CGM:

$$n_{\text{H}}(r) = 0.13 f_{\text{gas}} \left(\frac{1+z}{5}\right)^3 \left(\frac{r}{0.1R_{\text{vir}}}\right)^{-2} \text{ cm}^{-3}, \quad (\text{B3})$$

where we used an Einstein–deSitter approximation for $\sqrt{\Delta_c}H$, which is accurate to 10 per cent or less at $z > 1$ in our assumed cosmology:

$$\sqrt{\Delta_c}H \approx 5.8 \left(\frac{1+z}{5}\right)^{3/2} \text{ Gyr}^{-1}. \quad (\text{B4})$$

Using equation (B3) and the density threshold for shielding (equation 1), one can estimate the shielding radius R_{shielded} within which cool gas is shielded from ambient radiation. This gives

$$R(n_{\text{H}} = n_{\text{H,shielded}}) = 0.33 f_{\text{gas}}^{1/2} \left(\frac{1+z}{5}\right)^{3/2} \Gamma_{-12}^{-1/3} T_4^{-0.09} R_{\text{vir}}. \quad (\text{B5})$$

In units of R_{vir} , this radius has a strong dependence on redshift and no dependence on halo mass, similar to the comparison of mean densities with $n_{\text{H,shielded}}$ in FIRE (Fig. 5).

Equation (B3) can be used to estimate the hydrogen column at an impact parameter R_{\perp} :

$$\begin{aligned} N_{\text{H}}(R_{\perp}) &= \int n_{\text{H}} ds \\ &= 8.3 \times 10^{21} f_{\text{gas}} M_{12}^{1/3} \left(\frac{1+z}{5}\right)^2 \left(\frac{R_{\perp}}{0.1R_{\text{vir}}}\right)^{-1} \text{ cm}^{-2}, \end{aligned} \quad (\text{B6})$$

where $ds = dr/\sqrt{1 - (R_{\perp}/r)^2}$ and we calculated the integral using the equality $\int_1^{\infty} x^{-1}(x^2 - 1)^{-0.5} dx = \pi/2$. We also used the following approximation for the virial radius based on equation (B4):

$$R_{\text{vir}} = \left(\frac{2GM_{\text{vir}}}{\Delta_c H^2}\right)^{1/3} \approx 64 M_{12}^{1/3} \left(\frac{1+z}{5}\right)^{-1} \text{ kpc}. \quad (\text{B7})$$

Alternative density profiles with power-law slopes in the range of $-2.8 < a < -1.2$ yield columns that are within 50 per cent of the value in equation (B6). Equation (B6) demonstrates that for $f_{\text{gas}} \sim 0.5$ and halo masses above $\sim 10^9 M_{\odot}$, characteristic columns are substantially larger than the H I-column threshold for DLAs of $2 \times 10^{20} \text{ cm}^{-2}$. A large neutral fraction is hence a sufficient condition for a large DLA covering factor in these haloes. At halo masses

$< 10^9 M_{\odot}$ where $T_{\text{vir}} \lesssim 10^4 \text{ K}$ (see equation 2), haloes are expected to lose their gas due to photoheating by the UVB (Okamoto et al. 2008), and thus the volume-filling phase of their CGM is unlikely to significantly contribute to the DLA population.

We show also that our derivation of $R(n_{\text{H}} = n_{\text{H,shielded}})$ in FIRE is comparable to the idealized radiation transfer calculation of R_{shielded} by ZME02. Defining R_{ZME02} as the radius where the neutral hydrogen fraction in the ZME02 approaches unity (equal to $0.5r_{\text{ss}}$ in their notation; see their fig. 1), we get $R_{\text{ZME02}} = 14 \text{ kpc}$ for their fiducial parameters of $M_{\text{vir}} = 10^{12} M_{\odot}$, $M_{\text{gas}}(< R_{\text{vir}}) = 0.05M_{\text{vir}}$, $R_{\text{vir}} = 51.5 \text{ kpc}$, and $\Gamma_{-12} = 1.25$. Using their scaling of $R_{\text{ZME02}} \propto (f_{\text{gas}} M_{\text{vir}}/R_{\text{vir}})^{2/3} \Gamma_{-12}^{-1/3}$ and equation (B7), this yields

$$R_{\text{ZME02}} = 0.43 M_{12}^{1/9} \left(\frac{1+z}{5}\right)^{3/2} f_{\text{gas}}^{2/3} \Gamma_{-12}^{-1/3} R_{\text{vir}}, \quad (\text{B8})$$

which is comparable to equation (B5), and to the radius where $f_{\text{HI}} = 0.5$ in FIRE (Fig. 6). This similarity is despite that the calculation of $n_{\text{H,shielded}}$ is based on a Jeans-scale approximation for the size of the cool gas clouds, while the ZME02 calculation is based on radiation transfer in a spherically symmetric cool CGM.

APPENDIX C: DIFFERENT PHYSICAL IMPLEMENTATIONS AND RESOLUTION

In Fig. C1, we repeat the calculation of Fig. 3 for different implementations of the m12i simulation, which has $M_{\text{vir}}(z=0) \approx 10^{12} M_{\odot}$. Blue lines denote the fiducial calculation used in the main text, which includes a prescription for subgrid metal diffusion (Hopkins 2017; Escala et al. 2018) and a gas mass resolution of $7100 M_{\odot}$. Cyan lines denote a lower resolution calculation with a gas mass of $57000 M_{\odot}$, red lines denote an MHD calculation, and the yellow line denotes a calculation that does not include subgrid metal diffusion. The left-hand panel shows that the relation between $t_{\text{cool}}^{(s)}/t_{\text{ff}}$, halo mass, and radius is rather independent of physical implementation, except in the low-resolution simulation where $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ increases above unity at somewhat lower halo masses than in the other simulations (see also fig. 21 in S21). The right-hand panel shows that the shape of the relation between f_{cool} and $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ is similar across all calculations. The no metal-diffusion simulation is offset to a factor of 2–3 lower f_{cool} at a given $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ compared to the other calculations, potentially since without subgrid diffusion metals and cooling are concentrated in a small fraction of CGM resolution elements (Hafen et al. 2019).

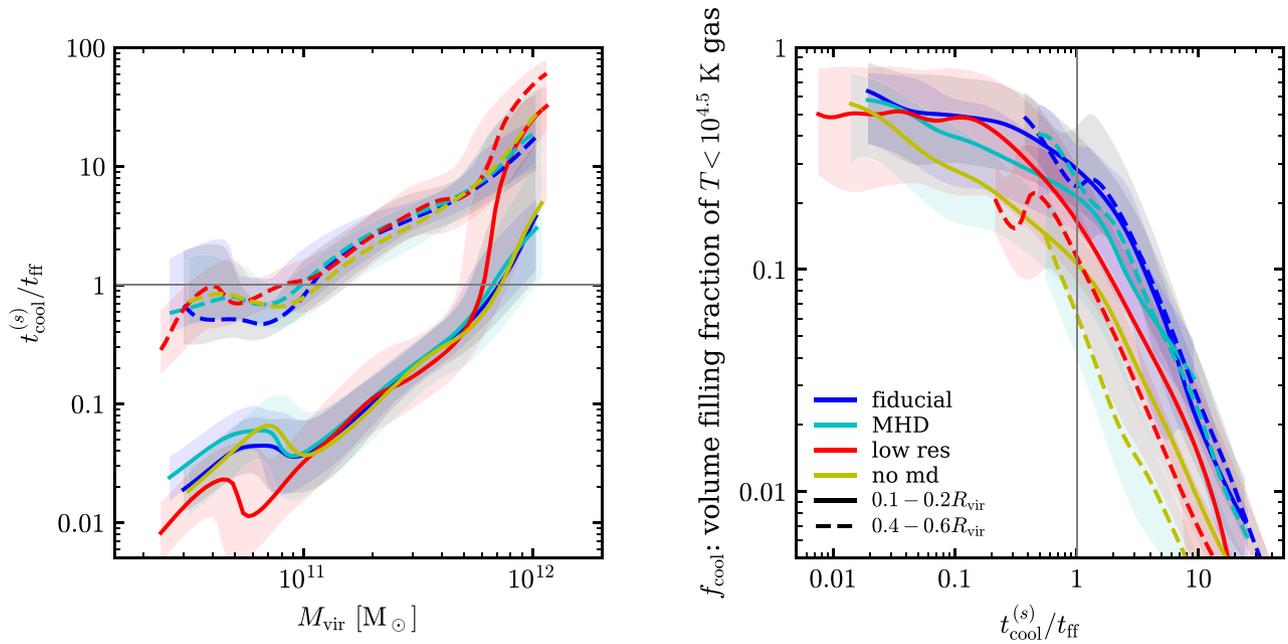

Figure C1. Similar to Fig. 3 for different implementations of the m12i simulation. Blue lines denote the fiducial calculation used in the main text, which includes a prescription for subgrid metal diffusion and a gas mass resolution of $7100 M_{\odot}$. Cyan lines denote a lower resolution calculation with a gas mass resolution of $57000 M_{\odot}$, red line denotes an MHD calculation, and the yellow line denotes a calculation that does not include subgrid metal diffusion. The left-hand panel shows that the relation between $t_{\text{cool}}^{(s)}/t_{\text{ff}}$, halo mass, and radius is rather independent of the inclusion of MHD, metal diffusion, or resolution at the tested range. The right-hand panel shows that the relation between f_{cool} and $t_{\text{cool}}^{(s)}/t_{\text{ff}}$ has a similar shape in all calculations, with the no metal-diffusion calculation offset to a factor of 2–3 lower f_{cool} at a given $t_{\text{cool}}^{(s)}/t_{\text{ff}}$.
