### ABSTRACT

We present a new multicomponent SED decomposition method and use it to analyze the UV to millimeter wavelength SEDs of a sample of dusty infrared-luminous galaxies. Each SED is decomposed into emission from populations of stars, an AGN accretion disk, PAHs, atomic and molecular lines, and distributions of graphite and silicate grains. Decompositions of the SEDs of template starburst galaxies and AGNs provide baseline properties to aid in quantifying the strength of star formation and accretion in the composite systems NGC 6240 and Mrk 1014. We find that obscured radiation from stars is capable of powering the total dust emission from NGC 6240. The presence of a small quantity of 1260 K dust in this source suggests a  $\sim 2\%$  AGN contribution, although we cannot rule out a larger contribution from a deeply embedded AGN visible only in X-rays. The decomposition of Mrk 1014 is consistent with  $\sim 65\%$  of its power emerging from an AGN and  $\sim 35\%$  from star formation. We suggest that many of the variations in our template starburst SEDs may be explained in terms of the different mean optical depths through the clouds of dust surrounding the young stars within each galaxy. Prompted by the divergent far-IR properties of our template AGNs, we suggest that variations in the relative orientation of their AGN accretion disks with respect to the disks of the galaxies hosting them may result in different amounts of AGN-heated cold dust emission emerging from their host galaxies. We estimate that 30%–50% of the far-IR and PAH emission from Mrk 1014 may originate from such AGN-heated material in its host galaxy disk.

### 1. INTRODUCTION

Optical and near-IR imaging has revealed that most luminous and ultraluminous infrared galaxies (LIRGs and ULIRGs; see Sanders & Mirabel 1996), as well as many lower luminosity dusty galaxies (e.g., starbursts and active galactic nuclei [AGNs]), are interacting systems that have recently merged or are in the process of merging (Armus et al. 1987; Sanders et al. 1988; Murphy et al. 1996). Large quantities of gas and dust driven into the nascent nuclei of these systems catalyze massive bursts of star formation and/or fuel accretion onto supermassive black holes (Mihos & Hernquist 1996; Struck 1999). Ultraviolet and optical emission from many of these dusty galaxies is significantly obscured by the same gas and dust providing their infrared power, a fact that greatly complicates the process of diagnosing the star formation and accretion contributions to their bolometric luminosities. LIRGs and ULIRGs are believed to be the largest contributors to the far-IR background and star formation energy density at  $z \approx 1-3$  (Blain et al. 2002; Elbaz & Cesarsky 2003), and local ULIRGs are frequently used as analogs for the luminous submillimeter galaxy population. The development of a proper understanding of the histories of star formation and galaxy evolution in the universe therefore requires the construction of robust and reliable methods for use in diagnosing the dominant luminosity source in obscured dusty galactic nuclei.

Great progress toward this goal was made using data from the *Infrared Space Observatory* (ISO). Diagnostic diagrams based on high-ionization mid-IR lines (e.g., [O IV] and [Ne v]), the slope of the mid-IR continuum, and the strengths of the 6.2 and 7.7  $\mu\text{m}$  polycyclic aromatic hydrocarbon (PAH) emission features were constructed to quantify the relative contributions from accretion and starburst activity in many sources (e.g., Genzel et al. 1998; Lutz et al. 1998; Laurent et al. 2000; Tran et al. 2001). These observations provided evidence that ULIRGs are powered primarily by star formation, with the fraction of AGN activity increasing with bolometric luminosity. However, due to the limited wavelength coverage and sensitivity of the ISO spectrometers, this analysis was limited to a relatively small number of bright nearby sources. These observational challenges have largely been abated with the improved wavelength baseline and sensitivity of the Infrared Spectrograph<sup>8</sup> (IRS; Houck et al. 2004) on the *Spitzer Space Telescope* (Werner et al. 2004). Large samples of starburst galaxies (Brandl et al. 2006), AGNs (Hao et al. 2005b; Weedman et al. 2005; Schweitzer et al. 2006), local ULIRGs (Armus et al. 2007), and their high-redshift counterparts (e.g., Houck et al. 2005; Yan et al. 2005; Lutz et al. 2005) have been observed with the IRS. As with the previous generation of studies with ISO, diagnostic diagrams have been constructed using the properties of high-ionization lines (with much improved sensitivity to place strict limits on [Ne v] emission), mid-IR spectral slopes (with a much broader mid-IR wavelength baseline), and PAH feature emission (now detected to  $z \gtrsim 2$ ).

In addition to these observational diagnostics, many tools have been developed to model the spectral energy distributions (SEDs) of emission from dusty galaxies. Models containing a variety of grain sizes and chemical compositions have been used to calculate

the spectrum of emission from astronomical dust embedded in single (e.g., Desert et al. 1990; Li & Draine 2001; Draine et al. 2007) and multiple (e.g., Dale et al. 2001; Li & Draine 2002) incident radiation fields. In addition, numerous radiative transfer models have been published, including several to calculate the emission from an AGN and its obscuring torus (e.g., Nenkova et al. 2002; Dullemond & van Bemmelen 2005). Finally, methods intended to decompose the SEDs of galaxies into a number of components have also been developed. For example, Klaas et al. (2001) present such a method and use it to decompose the far-IR SEDs of a sample of ULIRGs into contributions from several dust-modified blackbodies at different characteristic temperatures.

We present in this work a new method used to decompose the SEDs of galaxies into emission from populations of stars, an AGN accretion disk, PAH molecules, atomic and molecular lines, and distributions of thermally heated graphite and silicate grains at different fitted characteristic temperatures. Given the many observational and theoretical techniques to study dusty galactic nuclei described above, it is fair to question our decision to introduce yet another. We are motivated to do so for two principal reasons. First, while the radiative transfer methods incorporating realistic dust models described above provide the most physically complete method of calculating the SEDs of dusty galaxies, these methods are also the most dependent on the assumed geometry of the source. Unfortunately, detailed spatial information to constrain these assumptions is available for only a handful of nearby galaxies, so the parameter space in which to search for best-fitting models in agreement with observations is both sizable and degenerate. Second, the methods for calculating the emission from dusty galaxies described above are primarily intended to model starburst galaxies or AGNs. None of them, however, are particularly well suited to calculating the emission from sources containing a starburst and an AGN, each of which may be extinguished by different levels of obscuration (see § 5.4 for an expanded discussion).

Our goal for this paper is therefore to convince the reader that our decomposition method is well suited to analyzing the SEDs of composite sources and is motivated by the desire to address the following: (1) What energy source is primarily responsible for powering the emission from dusty galaxies? (2) How homogeneous are the SEDs of dusty galaxies that have similar AGN and starburst fractions? (3) What geometries can explain any inhomogeneities in the SEDs of similarly powered dusty galaxies? To meet this goal, we apply our decomposition method to a small sample of well-studied galaxies, including the relatively unextinguished starburst NGC 7714, the obscured starburst NGC 2623, the quasar PG 0804+761, and the Seyfert 2 Mrk 463. These fits provide templates by which to understand the properties of pure starburst galaxies and AGNs, the constituents of composite sources such as many ULIRGs. In addition, as examples of such composite sources, we present fits to the LIRG NGC 6240 (believed to be powered primarily by star formation) and the ULIRG Mrk 1014 (believed to be powered primarily by accretion).

We begin in § 2 with an overview of the spectral decomposition method. In § 3 we detail the method used to calculate the spectrum of emission from the various source components. In §§ 4 and 5 we describe the adopted dust model and the method used to calculate the thermal emission from dust. In §§ 6 and 7 we describe PAH feature and atomic and molecular line emission, respectively. In § 8 we describe the sample of galaxies analyzed in this work, in § 9 we present their decompositions, and in § 10 we present detailed analysis of the results. The breadth of our conclusions is clearly limited by the size of our sample. In a subsequent paper our method will be applied to a much larger sample of

starburst galaxies, AGNs, LIRGs, and ULIRGs obtained as part of the *Spitzer* GTO program.

## 2. SPECTRAL DECOMPOSITION METHOD

### 2.1. Decomposition Components

The principal assumption in our decomposition method<sup>9</sup> is that the ultraviolet to millimeter wavelength (10 Å–1000 μm) SED of a dusty galaxy may be completely described in terms of emission from evolved stars in the disk of the host galaxy (*ISRF*<sup>10</sup>), populations of young stars in starbursts (*SB*), an AGN accretion disk (*AGN*), PAH molecules (*PAHs*), atomic and molecular lines (*lines*), and several distributions of thermally heated graphite and silicate grains (*hot*, *warm*, *cool*, and *cold*). In this paper the *ISRF*, *SB*, and *AGN* components are collectively referred to as “source” emission components since they represent the primary illuminating sources heating dust within a galaxy. The *hot*, *warm*, *cool*, and *cold* components are collectively referred to as “dust” emission components. Assuming that these components form a complete basis describing the emission from dusty galaxies, the observed flux density may be expressed as<sup>11</sup>

$$f_{\nu}^{\text{total}} = \frac{L_{\text{source}}}{4\pi D_L^2} \sum_{\text{source}} \tilde{\alpha}_i \hat{f}_{\nu}^i + \frac{L_{\text{dust}}}{4\pi D_L^2} \sum_{\text{dust}} \tilde{\alpha}_j \hat{f}_{\nu}^j + f_{\nu}^{\text{PAHs}} + f_{\nu}^{\text{lines}}, \quad (1)$$

where  $L_{\text{source}}$  and  $L_{\text{dust}}$  are the total apparent luminosities of the source and dust components derived from the fit, respectively,  $D_L$  is the luminosity distance to the galaxy,  $\tilde{\alpha}_i \equiv L_i/L_{\text{source}}$  and  $\tilde{\alpha}_j \equiv L_j/L_{\text{dust}}$  are the fitted contributions to the total source and dust luminosities from each component, respectively, the  $\hat{f}_{\nu} \equiv f_{\nu}/\int f_{\nu} d\nu$  are the normalized flux densities of each source or dust component, and  $f_{\nu}^{\text{PAHs}}$  and  $f_{\nu}^{\text{lines}}$  are the fitted PAH and emission-line flux densities, respectively. We include a maximum of four dust components that are typically heated to characteristic temperatures of  $\bar{T}_{\text{hot}} \approx 1400$  K,  $\bar{T}_{\text{warm}} \approx 200$  K,  $\bar{T}_{\text{cool}} \approx 80$  K, and  $\bar{T}_{\text{cold}} \approx 35$  K. The actual temperature of each dust component is determined from the fitted magnitude of its illuminating radiation field energy density.

Figure 1 presents an illustration of one possible geometric structure of a dusty galaxy within which to interpret the roles played by each decomposition component in equation (1). Figure 1a depicts the optically thin (at mid-IR wavelengths) disk of the host galaxy from which evolved photospheric (*ISRF*) and *cold* dust emission emerges. Figure 1b shows an enlarged view of the central region of the galaxy consisting of an AGN and a starburst surrounded by screens of *cool* and *cold* dust. Figure 1c depicts the composite nucleus of the dusty galaxy, while the details of each nuclear component are shown in Figure 1d. The starburst is composed of *SB* emission from young stars, *warm* dust in the shells surrounding the young stars, and possibly *cool* and/or *cold* dust in spherical screens around each individual star-forming cloud. The AGN consists of emission from the AGN accretion disk, *hot* and *warm* dust on the illuminated and shaded sides of the dust clouds creating the obscuring torus (or dust in illuminated and shielded regions of a “classic” torus with a smooth dust distribution; see Fig. 6 below), and *warm* and *cool* dust in narrow-line region

<sup>9</sup> See <http://www.its.caltech.edu/~jam258/cafe.html> for more information about the method and the Continuum And Feature Extraction (CAFE) software.

<sup>10</sup> All names of decomposition components are printed in italic type throughout this work.

<sup>11</sup> Note that  $f_j$  units may be substituted for  $\hat{f}_j$  units throughout this work and that variables accented with tildes are free parameters in the fitting.

FIG. 1.— Example geometry of a dusty galaxy illustrating the potential roles played by each decomposition component. Panel (a) depicts the host galaxy disk containing *cold* dust and knots of *ISRF* emission from evolved stars. Panel (b) shows an enlarged view of the core of the galaxy containing a nuclear region embedded within obscuring screens of *cool* and *cold* dust. Panels (c) and (d) depict the composite nucleus. The starburst contains *SB* emission from young stars, *warm* dust in the surrounding shells, and possibly *cool* and/or *cold* dust in spherical screens around each individual star-forming cloud. The AGN contains an *AGN* accretion disk, *hot* and *warm* dust in the obscuring torus, and *warm* and *cool* dust in narrow-line region (NLR) clouds.

clouds (again from dust in illuminated and shaded regions). We emphasize that our method does not require the definition of *any* specific geometry (i.e., we derive the contributions from each emission component without the need to define its proximity to any other component), and the actual geometry of a dusty galaxy may look quite different from the one presented. The illustration in Figure 1 should therefore not be taken as a literal description of the geometry of a particular galaxy (since our method requires none), but instead it is intended to provide a structure within which to visualize the multiple roles potentially played by each decomposition component.

We note that star formation in the disk of the host galaxy and that in starburst regions are both explicitly accounted for via the *ISRF* and *SB* components. Furthermore, while Figure 1 depicts the specific case of a nuclear starburst, the actual location of the star formation (e.g., nuclear vs. off-center) has no effect on the decomposition (assuming that any off-center emission is contained within the spectroscopic slits and photometric apertures used to construct the SEDs). For example, in the decomposition of an off-center starburst, the *cool* and *cold* decomposition components (or portions thereof) could be interpreted as belonging to off-center obscuring clouds. Note, however, that if a galaxy contains both a highly enshrouded nuclear starburst and a less enshrouded off-center starburst, our decomposition method cannot explicitly

fit both components simultaneously. Instead, a mean optical depth somewhere between the optical depths of the two individual components is obtained. Thus, care must be taken when interpreting the optical depths inferred from a globally integrated SED (this admonishment is not unique to our analysis but is a general statement about the nature of spatially integrated data).

## 2.2. Decomposition Algorithm

Once assembled, the ultraviolet to millimeter wavelength SEDs of the galaxies in our sample are fitted to the model of the total flux density from equation (1). The best-fit parameters are determined using a Levenberg-Marquardt least-squares routine to minimize

$$\chi^2 = \sum_k w_k [f_{\nu}^{\text{data}}(\lambda_k) - f_{\nu}^{\text{total}}(\lambda_k)]^2, \quad (2)$$

where the  $w_k$  are the weights applied at each wavelength  $\lambda_k$  (see § 2.3),  $f_{\nu}^{\text{data}}$  is the observed flux density, and  $f_{\nu}^{\text{total}}$  is the modeled flux density from equation (1). For photometric data, we integrate the modeled flux density over the filter transmission curve (if available) to properly calculate the broadband flux density. This is important for photometric bands containing emission and absorption features (e.g., *L*-band photometry containing the 3.3  $\mu\text{m}$  PAH, 3.1  $\mu\text{m}$  water ice, and 3.4  $\mu\text{m}$  HAC features; see §§ 4.8 and 6), as well as those bands covering spectral regions that change rapidly with wavelength (e.g., *J*-band photometry sampling extinguished photospheric emission; see the near-IR fit to NGC 6240 in § 9.1).

Experience has taught us that the greater the number of free parameters in a fitting model, the less likely the resulting “best fit” will converge to the desired global minimum in the  $\chi^2$  function. Correspondingly, it becomes increasingly likely that the fit will converge to a local minimum, often with very unsatisfactory results. This is a practical matter and not a mathematical one since a fit with any number of parameters will reach the global minimum given sufficiently well chosen initial conditions. In practice, however, it is desirable to have a more robust fitting method such that any *reasonably* chosen initial conditions will converge to the global minimum. To meet this goal, we have developed an algorithm that separates the processes of fitting the continuum, defined as the sum of the source and dust components, and the individual PAH features and atomic and molecular emission lines. Such a division into two separate least-squares processes greatly reduces the total number of free parameters in each fit. Parameter errors are calculated after the first step of the fitting procedure and propagated through to the following fit (see § 2.3), so that the net accumulated uncertainty is reliably calculated.

After an SED has been fitted, we perform a series of tests to ensure that all components are well constrained (i.e., that the parameter errors are smaller than their values). First, if the *ISRF* luminosity is  $<1\%$  the sum of the luminosities of all source components, then the fit is repeated without the *ISRF* component. Similarly, if any of the observed dust component luminosities are  $<1\%$  the sum of the apparent luminosities of all dust components, the fit is repeated without those components. All three source components and the *hot* dust component emit strongly at ultraviolet to near-IR wavelengths. For some galaxies these overlapping emission components are degenerate and result in unconstrained parameters. Our second check is therefore to test if either the *SB* or *AGN* components are unconstrained (i.e., if their luminosity uncertainties exceed their luminosities). If the *SB* component is unconstrained, we fix the *SB*-to-*PAHs* luminosity ratio (i.e., the ratio of the unextinguished *SB* luminosity to the

*PAHs* luminosity; see § 9.2) to the value derived from fits to the template starbursts NGC 7714 and NGC 2623 and restart the fit. Similarly, if the *AGN* component is unconstrained, we fix the *AGN*–to–*hot* dust luminosity ratio (i.e., the ratio of the unextinguished *AGN* luminosity to the unextinguished *hot* dust luminosity; see § 9.2) to the value derived from fits to the template *AGNs* PG 0804+761 and Mrk 463 and restart the fit. As our final test, if any of the fitted optical depths are unconstrained, we fix the most unconstrained to zero and restart the fit. This sequence provides a well-defined method by which to sequentially impose constraints until a successful fit is obtained.

The steps in the fitting method are therefore as follows: (1) input the observed SED and the initial estimates of the *PAHs* and *lines* components (see §§ 6 and 7); (2) subtract the initial *PAHs* and *lines* components from the observed SED to create an observed continuum emission spectrum; (3) fit this spectrum to obtain the model continuum; (4) subtract the model continuum from the observed SED to create an observed *PAH* feature and line emission spectrum; (5) fit the individual features in this spectrum; (6) perform the sequence of tests to ensure that the fit is well constrained; and (7) if necessary, repeat the fitting process with the constrained components.

### 2.3. Data Weighting

The success or failure of a fitting algorithm and the reliability of the results are largely dependent on the chosen method of weighting the data in equation (2). We adopt the function

$$w_k = \frac{\hat{\Lambda}_k}{\sigma^2(\lambda_k)}, \quad (3)$$

where  $\sigma(\lambda_k)$  is the total  $1\sigma$  uncertainty in the flux density at wavelength  $\lambda_k$  and  $\hat{\Lambda}_k$  is a term that compensates for nonuniform wavelength sampling (i.e., ensuring that a region of the SED does not dominate the fit simply because it is sampled more finely; see Appendix A). The total uncertainty in any observed data is given by the quadratic sum of the statistical and calibration (i.e., systematic) uncertainties. For IRS spectroscopic data, we use the difference of two spectra obtained at different nod positions (as produced during a typical IRS observation) to calculate the statistical uncertainties (see Appendix B for details). Carefully extracted low-resolution IRS spectra may still exhibit some residual calibration uncertainties (e.g., fringes in the long-low modules), which we estimate to be  $\sim 2\%$  of the flux density at any given wavelength. For photometric data, the total uncertainty is taken to be equal to the quadratic sum of the uncertainties provided in the literature and an absolute calibration uncertainty (e.g., from scaling to the IRS apertures) taken to be 5%. The actual systematic uncertainties in the photometric data are difficult to estimate, although we note that the adopted uncertainties yield reasonable reduced  $\chi^2$  values and so are likely good estimates.

As described in § 2.2, each decomposition consists of two separate least-squares fits. In the first (step 3 above), the flux density to fit is obtained by subtracting the *PAHs* and *lines* components from the observed SED, i.e.,  $f_\nu = f_\nu^{\text{data}} - f_\nu^{\text{PAHs}} - f_\nu^{\text{lines}}$ . When a component is subtracted from observed data to create an SED to be fitted, the uncertainty of the subtracted component must be propagated through the analysis. Thus, the total uncertainty input into the least-squares routine for this first fit is  $\sigma^2 = \sigma_{\text{data}}^2 + \sigma_{\text{PAHs}}^2 + \sigma_{\text{lines}}^2$ . Here  $\sigma_{\text{data}}$  is the uncertainty in the observed flux density, while  $\sigma_{\text{PAHs}}$  and  $\sigma_{\text{lines}}$  are the uncertainties in the estimated *PAHs* and *lines* components, respectively. Since the estimated strengths of the *PAHs* and *lines* components are derived from the

FIG. 2.—Normalized 10 Å–1000 μm energy densities of the principal luminosity sources in dusty galaxies, including emission from starbursts 2, 10, and 100 Myr after an instantaneous burst (*SB*); evolved disk stars (*ISRF*); and an *AGN* accretion disk (*AGN*).

observed spectrum,  $\sigma_{\text{PAHs}}$  and  $\sigma_{\text{lines}}$  are dominated by the IRS uncertainties. We therefore adopt  $\sigma_{\text{PAHs}} = \sigma_{\text{lines}} = 0$ , since the uncertainties in the IRS data on which they depend are already included through  $\sigma_{\text{data}}$ . In the second fit (step 5 above), the flux density to fit is obtained by subtracting the fitted continuum from the observed SED, i.e.,  $f_\nu = f_\nu^{\text{data}} - f_\nu^{\text{cont}}$ , so that the total uncertainty input into the least-squares routine is  $\sigma^2 = \sigma_{\text{data}}^2 + \sigma_{\text{cont}}^2$ . Here  $\sigma_{\text{cont}}$  is the formal uncertainty in the continuum calculated using the full covariance matrix from the first fit.

## 3. SOURCE EMISSION

### 3.1. ISRF Component Emission

We adopt the model of the average interstellar radiation field presented in Mezger et al. (1982) and Li & Draine (2001) to represent the SED of emission from stars in the disk of a galaxy. In this model, the mean energy density in the solar neighborhood,  $cu_\nu^{\text{ISRF}} = f_\nu^{\text{ISRF},\odot} = 4\pi J_\nu^{\text{ISRF},\odot}$ , is given by

$$u_\nu^{\text{ISRF}} \propto \begin{cases} 0, & \lambda < 912 \text{ Å}, \\ \lambda^{5.4172}, & 912 \text{ Å} < \lambda < 1100 \text{ Å}, \\ \lambda^2, & 1100 \text{ Å} < \lambda < 1340 \text{ Å}, \\ \lambda^{0.3322}, & 1340 \text{ Å} < \lambda < 2460 \text{ Å}, \\ \sum_n W_n B_\nu(T_n), & \lambda > 2460 \text{ Å}, \end{cases} \quad (4)$$

where  $B_\nu$  is the Planck function per unit frequency and the  $W_n = (0.025, 0.25, 1)$  are weighting factors for each blackbody component of temperature  $T_n = (7500 \text{ K}, 4000 \text{ K}, 3000 \text{ K})$ . This model spectrum is shown in Figure 2, normalized to have unit integrated energy density. Emission from the *ISRF* decomposition component is assumed to emerge nearly unobscured from a galaxy disk, so that the line-of-sight extinction to the emitting stars is small in the infrared ( $\lambda > 1 \mu\text{m}$ ). The flux density per unit frequency interval of emission from the *ISRF* component for use in equation (1) is therefore

$$f_\nu^{\text{ISRF}} \propto u_\nu^{\text{ISRF}}. \quad (5)$$

An example *ISRF* component SED,  $f_\nu^{\text{ISRF}}$ , is shown in Figure 3. Displayed alongside the *ISRF* component is the emission from a 3500 K blackbody (characteristic of evolved stars) scaled to match at  $1.5 \mu\text{m}$ . The two curves are nearly identical at  $\lambda > 1 \mu\text{m}$ , so that

FIG. 3.—Example SEDs of emission from a starburst (SB) 10 and 100 Myr after an instantaneous burst, evolved disk stars (ISRF), and an AGN accretion disk (AGN). Also shown are the SEDs of the SB components extinguished by obscuring screens with the indicated optical depths, and the SEDs of the AGN component behind an  $\tau_V \approx 25$  screen for the indicated covering factors (dot-dashed lines). Note that emission from the 2 Myr starburst population declines steeply at  $\lambda > 3000 \text{ \AA}$  and that the ISRF component is very similar to a 3500 K blackbody for  $\lambda > 1 \text{ \mu m}$  (dotted lines; see text).

fitting near-IR data with the ISRF component is very similar to fitting with a 3500 K blackbody.

### 3.2. SB Component Emission

In contrast to the modest  $\sim 1 M_\odot \text{ yr}^{-1}$  star formation rate characteristic of emission from the ISRF component, the rates in starbursts are often much higher (e.g.,  $\gtrsim 10\text{--}100 M_\odot \text{ yr}^{-1}$ ), resulting in significantly different stellar populations. In order to properly characterize the spectral properties and bolometric luminosities of these populations, we use Starburst99 (Leitherer 1990) to generate SEDs of instantaneous bursts at different epochs. We assume a Kroupa initial mass function having an  $M^{1.3}$  power law in the  $0.1\text{--}0.5 M_\odot$  range and an  $M^{2.3}$  power law in the  $0.5\text{--}100 M_\odot$  range. We further assume Padova asymptotic giant branch tracks with solar metallicity. Populations of stars in starbursts evolve dramatically during the first 10 Myr after a burst. At 4 Myr the most massive stars still exist on the main sequence, but by 10 Myr all of the photoionizing stars have evolved into supergiants. As shown in Figure 2, the emission from a starburst 2 Myr after a burst emerges almost exclusively at ultraviolet wavelengths. Since we have very little data in this wavelength range for the sources in our sample, we are unable to explicitly constrain the presence or absence of such a population. In contrast to this, the 10 and 100 Myr populations emit a large fraction of their luminosity at optical and longer wavelengths, where our SEDs are better constrained. Therefore, in order to adequately sample the evolutionary stages in a starburst that we are sensitive to, and to smoothly transition into the evolved population modeled with the ISRF component, we create a composite starburst spectrum containing equal contributions from the 10 and 100 Myr populations, i.e.,  $u_\nu^{\text{SB}} = (u_\nu^{\text{SB}10} + u_\nu^{\text{SB}100})/2$ . We note, however, that the omission

of an ultraviolet-luminous young stellar population from  $u_\nu^{\text{SB}}$  may result in an underprediction of the total SB luminosity for some sources, perhaps by up to  $\sim \frac{1}{3}$  if the 2 Myr population contributes at the same level as each of the older populations.

Unlike emission from the ISRF component, we assume that SB component emission emerges from regions that may be obscured by screens of dust out to infrared wavelengths. If the obscuration to the SB component is dominated by dust in the cocoons of material surrounding each star-forming knot, and not by extinction between the various knots, then the majority of the obscuration occurs via a screened geometry. Levenson et al. (2007) use radiative transfer models to show that such a screened geometry is actually required to reproduce the deep  $9.7 \text{ \mu m}$  silicate features observed in many ULIRGs, suggesting that the assumption of a screened geometry is reasonable for highly obscured sources. At lower optical depths (i.e.,  $\tau < 1$ ), mixed and screened geometries both give rise to extinctions scaling approximately as  $f/f_0 \approx 1 - \tau$ , so that the choice between the form of extinction is less critical. We therefore model the flux density per unit frequency interval of emission from the SB component as

$$f_\nu^{\text{SB}} \propto u_\nu^{\text{SB}} e^{-\tau_{\text{SB}}}, \quad (6)$$

where the optical depth through the obscuring screen to the SB component is given by

$$\tau_{\text{SB}}(\lambda) = \tilde{\tau}_V^{\text{SB}} \frac{\Sigma_{\text{abs}}(\lambda)}{\Sigma_{\text{abs}}(5500 \text{ \AA})}. \quad (7)$$

Here  $\tilde{\tau}_V^{\text{SB}}$  is the screen optical depth to the SB component at  $5500 \text{ \AA}$  and  $\Sigma_{\text{abs}} = \Sigma_{\text{ext}} - \Sigma_{\text{scat}}$  is the total dust absorption opacity

obtained by subtracting the scattering opacity from the total extinction opacity (see § 4.7). We use the absorption and not the extinction opacity in equation (7) since scattering tends to cancel itself out in sufficiently spherical geometries, such as depicted in Figure 1 (i.e., light scattered out of the beam along the direct path to the observer is offset by light scattered into the beam along another path). Furthermore, the extinction and absorption opacities of dust in our model have similar slopes between 1000 Å and 3 μm, where the *SB* component emits strongly. Since the derived optical depth depends only on the opacity slope and not its absolute value, the omission of scattering has very little effect. We note, however, that this omission may introduce some small uncertainties at  $\lambda \lesssim 3 \mu\text{m}$ , where the scattering opacity is largest. Example 10 and 100 Myr SEDs,  $f_\nu^{\text{SB}10}$  and  $f_\nu^{\text{SB}100}$ , used to construct the composite *SB* model,  $f_\nu^{\text{SB}}$ , are shown in Figure 3. Also shown are example SEDs obscured by screens of dust with  $\tilde{\tau}_V^{\text{SB}} = 1, 2$ , and 4.

### 3.3. AGN Component Emission

The spectral properties of radiation emerging from an AGN accretion disk depend sensitively on the assumed geometry of the surrounding obscuring structure, i.e., the putative torus of AGN unification models (Antonucci 1993). Important geometrical factors include the height of the inner edge of the torus, its proximity to the nucleus, the clumpy versus smooth structure of the obscuring medium, and the orientation of the torus with respect to the observer. Radiative transfer calculations incorporating these geometric properties have been used to construct models of the emission from an AGN accretion disk and its obscuring torus (e.g., Pier & Krolik 1992; Laor & Draine 1993; Granato & Danese 1994; Nenkova et al. 2002; Dullemond & van Bemmelen 2005). Since our intent in this work is to characterize the general properties of the emergent SEDs of large samples of galaxies, and not to discern the detailed properties of the obscuring torus in individual sources, such modeling is unnecessary for our purposes.

Instead, we adopt an empirical model of the emission from an AGN accretion disk and assume that this SED may be extinguished by a foreground screen of dust. We use the accretion disk model from Schartmann et al. (2005), in which the emergent energy density, shown in Figure 2, is modeled by

$$u_\nu^{\text{AGN}} \propto \begin{cases} 0, & \lambda < 10 \text{ Å}, \\ \lambda^3, & 10 \text{ Å} < \lambda < 500 \text{ Å}, \\ \lambda^{1.8}, & 500 \text{ Å} < \lambda < 1216 \text{ Å}, \\ \lambda^{0.46}, & 1216 \text{ Å} < \lambda < 10 \mu\text{m}, \\ B_\nu(1000 \text{ K}), & \lambda > 10 \mu\text{m}. \end{cases} \quad (8)$$

The flux density per unit frequency interval of emission from the *AGN* component, including an obscuring screen with a nonuniform covering factor, is modeled as

$$f_\nu^{\text{AGN}} \propto u_\nu^{\text{AGN}} [(1 - \tilde{\epsilon}_{\text{AGN}}) + \tilde{\epsilon}_{\text{AGN}} e^{-\tau_{\text{AGN}}}], \quad (9)$$

where  $0 \leq \tilde{\epsilon}_{\text{AGN}} \leq 1$  is the fraction of the accretion disk obscured by a screen of optical depth  $\tau_{\text{AGN}}$ , with

$$\tau_{\text{AGN}}(\lambda) = \tilde{\tau}_V^{\text{AGN}} \frac{\Sigma_{\text{ext}}(\lambda)}{\Sigma_{\text{ext}}(5500 \text{ Å})}. \quad (10)$$

Here  $\tilde{\tau}_V^{\text{AGN}}$  is the screen optical depth to the *AGN* component at 5500 Å. An example unobscured *AGN* component SED,  $f_\nu^{\text{AGN}}$ , is shown in Figure 3. Also shown are the SEDs of *AGN* component emission obscured by a  $\tilde{\tau}_V^{\text{AGN}} = 25$  screen, for several values of

the screen covering factor  $\tilde{\epsilon}_{\text{AGN}}$ . Note that significant ultraviolet and optical emission may still emerge from a highly extinguished accretion disk if the covering factor is less than unity.

In the bottom panel of Figure 1, the *AGN* accretion disk is depicted as being surrounded by an obscuring structure composed of discrete clouds and/or a smooth dusty component. The covering factor,  $\tilde{\epsilon}_{\text{AGN}}$ , may therefore be interpreted as the fraction of the accretion disk covered by this obscuring material (from the point of view of the observer), which has an approximate visual band optical depth equal to  $\tilde{\tau}_V^{\text{AGN}}$ . Note that the same qualifications regarding the relative importance of scattering and the subsequent uncertainties in the emergent flux density for  $\lambda \lesssim 3 \mu\text{m}$  that were made for the *SB* component apply here as well. Since the clumpy torus is by definition not spherically symmetric, we use the full extinction opacity (including scattering) in equation (10). As described for the *SB* component, this choice has very little effect on the results since the extinction and absorption opacities have similar slopes from the ultraviolet to the near-IR, where the *AGN* component emits strongly.

## 4. ASTRONOMICAL DUST MODEL

### 4.1. Grain Properties

We adopt the grain size distribution function from Weingartner & Draine (2001, hereafter WD01) and the optical properties of graphitic carbon and smoothed astronomical silicate from Draine & Lee (1984) and Laor & Draine (1993) with modifications from WD01 and Li & Draine (2001). The WD01 distribution function has been modified to include a small grain size exponential cutoff to model the deficit of small grains resulting from sublimation in intense heating conditions (see § 4.2). The modified distribution function for graphite and silicate grains takes the form

$$\frac{1}{n_H} \frac{dn_i}{da} = \left( \frac{1}{n_H} \frac{dn_i}{da} \right)_{\text{WD01}} \left\{ 1 - \exp \left[ - \left( \frac{a}{a_-} \right)^{\beta_-} \right] \right\}, \quad (11)$$

where  $(n_H^{-1} dn_i/da)_{\text{WD01}}$  is the WD01 distribution function for grains with radii satisfying  $3.5 \text{ Å} \leq a \leq 1 \mu\text{m}$ ,  $a_- = a_-(\tilde{U})$  is the minimum surviving grain size in a distribution embedded in a radiation field with an energy density of magnitude  $\tilde{U}$  (see § 4.2 and eq. [12]), and  $\beta_-$  determines the exponential cutoff rate. In the limit of  $\beta_- \rightarrow \infty$ , the exponential provides a sharp cutoff at  $a = a_-$ . We choose  $\beta_- = 3$ , the same value adopted for the large grain size exponential cutoff in WD01. Absorption and extinction efficiencies,  $Q_{\text{abs}}^i$  and  $Q_{\text{ext}}^i$ , have been tabulated for graphite and silicate spheres as described in Laor & Draine (1993) for wavelengths  $10 \text{ Å} < \lambda < 1000 \mu\text{m}$ . Absorption cross sections are calculated using  $C_{\text{abs}}^{\text{gra}}(a, \lambda) = \pi a^2 Q_{\text{abs}}^{\text{gra}}(a, \lambda)$  and  $C_{\text{abs}}^{\text{sil}}(a, \lambda) = \pi a^2 Q_{\text{abs}}^{\text{sil}}(a, \lambda)$ , with similar expressions for the extinction cross sections  $C_{\text{ext}}^{\text{gra}}(a, \lambda)$  and  $C_{\text{ext}}^{\text{sil}}(a, \lambda)$ .

### 4.2. Grain Sublimation

Graphite and silicate grains sublimate when heated to temperatures above 1750 and 1400 K, respectively (Laor & Draine 1993). The minimum surviving grain size in a distribution,  $a_-$ , is determined by the size of the smallest grain that does not sublimate in the radiation field in which the distribution is embedded. As the magnitude of the radiation field energy density increases, the grain distribution becomes increasingly depleted of small grains. A stronger radiation field therefore changes the SED of emission from a distribution of grains both by increasing the temperature of the grains and by weighing the grain size distribution function

to larger grains. In addition, due to their lower sublimation temperatures, silicate grains become depleted before graphite grains. Sublimation is one of many physical processes that can set the minimum grain size within a distribution. Shock waves (Jones et al. 1994; Draine 1995), sputtering (Draine & Salpeter 1979), and grain-grain collisions (Tielens et al. 1994) can also influence the minimum grain size. However, these other effects are more difficult to model than sublimation, since they require a dynamic model of the region where the grains are located. We do not consider them further.

#### 4.3. Thermal Heating

The equilibrium temperature attained by a grain is a function of its composition, size, and the spectrum and strength of the radiation field in which it is embedded. Our adopted dust model contains grains spanning several orders of magnitude in size, so the temperatures of individual grains within a distribution embedded in a given radiation field vary greatly. For a graphite or silicate grain embedded in a radiation field with normalized energy density  $\hat{u}_\nu$  (see Fig. 2) that has a fitted magnitude  $\tilde{U}$ , energy conservation requires that

$$\int C_{\text{abs}}^i(a, \nu) \tilde{U} c \hat{u}_\nu d\nu = \int C_{\text{abs}}^i(a, \nu) 4\pi B_\nu [T_{\text{eq}}^i(a)] d\nu. \quad (12)$$

Here the left- and right-hand sides represent the rates at which energy is absorbed and emitted by a grain, respectively. Equation (12) is therefore an implicit equation for the equilibrium temperatures,  $T_{\text{eq}}^i(a)$ , of the graphite and silicate grains in a distribution. These temperatures are used in equation (15) to properly calculate the spectrum of emission from each decomposition component. We calculate the temperatures of grains in the *hot* dust component using the normalized AGN energy density,  $\hat{u}_\nu^{\text{AGN}}$ , and the temperatures of grains in the *warm*, *cool*, and *cold* dust components using the normalized ISRF energy density,  $\hat{u}_\nu^{\text{ISRF}}$  (see Fig. 2). Note that although the shape of the illuminating radiation field does affect the temperatures of grains (since grains absorb and emit more efficiently at certain wavelengths), similar grain temperatures may be obtained from two different radiation fields by suitably adjusting the magnitude of the energy density of each field. Thus, the specific choices about which illuminating radiation fields we use to calculate our dust equilibrium temperatures do not have a significant impact on our results. Note also that once the shape of the normalized energy density is chosen, the temperature of a grain in that field will scale with the fitted magnitude of the energy density,  $\tilde{U}$ .

#### 4.4. Stochastic Heating

The heat capacities of very small grains are sufficiently small that they undergo large temperature fluctuations on absorption of individual photons and reradiate most of the deposited energy on timescales much shorter than the typical time between photon strikes. To estimate the importance of this stochastic heating for our dust components, we calculate the threshold grain size below which grains fall out of thermal equilibrium. For graphite grains, Draine & Li (2001) calculate this to occur for

$$a_{\text{min}} \approx 100 \text{ \AA} \left( \frac{u}{u_{\text{MMP}}} \right)^{-0.2}, \quad (13)$$

where  $u \equiv \int u_\nu d\nu$  is the integrated spectral energy density of the illuminating radiation field and  $u_{\text{MMP}}$  is the integrated spectral energy density of the local interstellar radiation field from Mezger et al. (1982). For our *cold*, *cool*, *warm*, and *hot* dust components,

typical threshold grain sizes from equation (13) are  $a_{\text{min}} \approx 53$ , 14, 7.5, and 3 Å, respectively.

In the model of Li & Draine (2001) stochastically heated grains exhibit strong spectral feature emission (i.e., PAHs) but have very weak continua (due to the low continuum opacities of small grains). Most dusty galaxies contain a significant amount of thermally heated  $\bar{T} \gtrsim 100$  K dust that emits more continuum radiation than these stochastically heated grains (see also Laor & Draine 1993). Thus, the continuum radiation from stochastically heated grains in our *cold* component (i.e., grains with  $a < 53$  Å) is weak compared to the thermal emission from warmer dust. In addition, since the threshold grain size decreases as the magnitude of the illuminating radiation field energy density increases, stochastically heated continuum emission is even less important for grains in our *cool*, *warm*, and *hot* components. Since the stochastic continuum emission of all components is weak compared to the emission from thermally heated grains, and given that the stochastically heated feature emission attributed to PAHs is included in our model through the *PAHs* component, we do not incorporate a detailed model of stochastic heating.

#### 4.5. Dust Emissivity

The total emissivity per hydrogen nucleon of a distribution of grains (in units of  $\text{ergs s}^{-1} \text{ Hz}^{-1} \text{ sr}^{-1} \text{ H}^{-1}$ ) is obtained by summing over the emissivity of each grain species

$$E_\nu = E_\nu^{\text{gra}} + E_\nu^{\text{sil}}. \quad (14)$$

Here the emissivities of graphite and silicate grains are

$$E_\nu^i = \int_{50 \text{ \AA}}^\infty \frac{1}{n_{\text{H}}} \frac{dn_i}{da} C_{\text{abs}}^i(a, \lambda) B_\nu [T_{\text{eq}}^i(a, \tilde{U})] da, \quad (15)$$

which is an average over the individual emissivities of the grains in the distribution. Note that in contrast to models using a single effective grain size, the dust emissivity in our adopted model is *not* directly proportional to the dust opacity (see § 4.7), since the equilibrium grain temperatures in equation (15) depend on grain size and composition.

#### 4.6. Characteristic Distribution Temperature

As discussed in § 4.3, the many grains within a distribution are brought to different equilibrium temperatures through interactions with the radiation field in which they are embedded. In our decomposition method this distribution of equilibrium temperatures is determined from the fitted magnitude of the illuminating radiation field energy density,  $\tilde{U}$ . A given dust component therefore has many temperatures associated with it, none of which uniquely characterize the properties of the distribution. This is clearly not a desirable situation, as we would like to associate a single characteristic temperature with each value of  $\tilde{U}$ , preferably a temperature that communicates the position of the spectral peak of the resulting emission from the distribution. To meet this goal, we define the luminosity-weighted characteristic distribution temperature

$$\bar{T} \equiv \bar{T}(\tilde{U}) = \frac{\int_{50 \text{ \AA}}^\infty \sum_i f_L^i(a, \tilde{U}) T_{\text{eq}}^i(a, \tilde{U}) da}{\int_{50 \text{ \AA}}^\infty \sum_i f_L^i(a, \tilde{U}) da}, \quad (16)$$

where the sum is over the two grain compositions and

$$f_L^i(a, \tilde{U}) = \frac{1}{n_{\text{H}}} \frac{dn_i}{da} \int C_{\text{abs}}^i(a, \nu) B_\nu [T_{\text{eq}}^i(a, \tilde{U})] d\nu \quad (17)$$

FIG. 4.— Range of equilibrium temperatures,  $T_{\text{eq}}$ , of the grains within a distribution as a function of the characteristic distribution temperature  $\bar{T}$ . The dark shaded region shows the range of equilibrium temperatures within a given distribution (i.e., at a fixed value of  $\bar{T}$ ), while the solid line shows their luminosity-weighted characteristic temperature. Light shaded regions indicate typical characteristic temperature ranges for the decomposition components. The sublimation temperature of silicates is also labeled (dashed line).

is the grain-luminosity distribution function (which is essentially the spectrally integrated emissivity of an individual grain; see § 4.5). Note that the integration starts at  $a = 50 \text{ \AA}$ , since smaller grains are not in thermal equilibrium.

Using this weighting function,  $\bar{T}$  is properly interpreted as the composition-averaged temperature of the luminosity-dominating grain size. With this definition, the emission peak from a distribution of grains occurs near the wavelength expected from the dust-modified Wien's law

$$\lambda_{\text{peak}} \approx \left( \frac{300 \text{ K}}{\bar{T}} \right) 10 \text{ } \mu\text{m}, \quad (18)$$

where the peak is defined to occur at the wavelength coinciding with the maximum value of  $E_\nu = \Sigma_{\text{abs}} B_\nu(\bar{T})$  (i.e., the emissivity of a distribution in the limit in which the temperatures of its constituent grains are independent of their size and composition). Figure 4 shows the range of equilibrium temperatures,  $T_{\text{eq}}$ , of the grains within a distribution for a given value of the characteristic distribution temperature,  $\bar{T}$ . The dark shaded region spans the range of equilibrium temperatures in a distribution, while the solid line shows the luminosity-weighted average over that distribution. Note that this average temperature is weighted toward the warmer equilibrium temperatures since the grain size distribution function is weighted toward smaller (i.e., warmer) grains. The light shaded regions indicate the typical ranges of the characteristic distribution temperatures for the dust components in our decomposition (i.e., as determined by the fitted values of  $\tilde{U}$  for each component).

#### 4.7. Dust Opacity

The total absorption opacity per hydrogen nucleon of a distribution of grains (in units of  $\text{cm}^2 \text{ H}^{-1}$ ) is obtained by summing over the opacity of each grain species

$$\Sigma_{\text{abs}}(\lambda) = \Sigma_{\text{abs}}^{\text{gra}}(\lambda) + \Sigma_{\text{abs}}^{\text{sil}}(\lambda). \quad (19)$$

Here the opacities of graphite and silicate grains are

$$\Sigma_{\text{abs}}^i(\lambda) = \int_{50 \text{ \AA}}^{\infty} \frac{1}{n_{\text{H}}} \frac{dn_i}{da} C_{\text{abs}}^i(a, \lambda) da, \quad (20)$$

which is an average over the individual opacities of the grains in the distribution. The total extinction opacity per hydrogen nucleon,  $\Sigma_{\text{ext}}$ , is calculated in an analogous way with  $C_{\text{abs}} \rightarrow C_{\text{ext}}$ . According to Li & Draine (2001, Table 6),  $\Sigma_{\text{abs}} \propto \lambda^{-2}$  over the range  $20 \text{ } \mu\text{m} < \lambda < 700 \text{ } \mu\text{m}$  and  $\Sigma_{\text{abs}} \propto \lambda^{-1.68}$  over the range  $700 \text{ } \mu\text{m} < \lambda < 10^4 \text{ } \mu\text{m}$  to within  $\pm 10\%$ .

#### 4.8. Water Ice and HAC Opacity

Mid-IR spectra often exhibit 5.6–7.8  $\mu\text{m}$  opacity produced from a combination of water ice absorption near 6.1  $\mu\text{m}$  (see, e.g., Chiar et al. 2000; Gibb et al. 2000) and absorption from hydrogenated amorphous carbon (HAC) near 6.85 and 7.25  $\mu\text{m}$  (Furton et al. 1999). Such water ice and HAC absorption is particularly prominent in ULIRG spectra (e.g., Spoon et al. 2002). We derive 5.6–7.8  $\mu\text{m}$  water ice and HAC opacity templates from the IRS spectrum of the heavily obscured ULIRG IRAS F00183–7111 (Spoon et al. 2004). This high signal-to-noise ratio spectrum exhibits strong water ice and HAC absorption with very little PAH emission, thereby providing a clean spectrum from which to extract profiles of the various opacity sources. We fit a smooth spline to the observed spectrum between continuum points on either side of the water ice and HAC features and use the ratio of the observed spectrum to the estimated continuum to obtain the opacity templates displayed in the right panel of Figure 5.

Additional opacity from 3.1  $\mu\text{m}$  water ice and 3.4  $\mu\text{m}$  HAC features may significantly affect the broadband photometry of some sources (see Fig. 5). We therefore use the  $L$ -band spectra of ULIRGs presented in Imanishi et al. (2006) to derive opacity templates for these features to use in our decompositions. The opacities of the 3.1  $\mu\text{m}$  water ice and 3.4  $\mu\text{m}$  HAC features are derived from spectra of the deeply obscured ULIRGs IRAS 00188–0856 and IRAS 08572+3915, respectively. Note that we do not derive the 6.1  $\mu\text{m}$  water ice template from the IRS spectrum of IRAS 00188–0856 since it is contaminated by 6.2  $\mu\text{m}$  PAH emission. As measured from their  $L$ -band and IRS spectra, the water ice features of IRAS 00188–0856 have apparent  $\tau_{3.1}^{\text{ice}}/\tau_{6.1}^{\text{ice}} \approx 3.9$ , while the HAC features of IRAS 08572+3915 have apparent  $\tau_{3.4}^{\text{HAC}}/\tau_{6.85}^{\text{HAC}} \approx 3.3$ . Our full opacity templates, shown in Figure 5, are constructed using these optical depth ratios to set the scalings between the 3.1–3.4  $\mu\text{m}$  and 5.6–7.8  $\mu\text{m}$  features.

#### 4.9. Total Optical Depth

The total optical depth along a line of sight is the sum of the optical depths from each opacity source. Thus, in our case

$$\tau(\lambda) = \tau_{\text{dust}}(\lambda) + \tau_{\text{ice}}(\lambda) + \tau_{\text{HAC}}(\lambda). \quad (21)$$

The optical depth through a column of dust having total absorption or extinction (depending on the situation) opacity  $\Sigma(\lambda)$  is given by

$$\tau_{\text{dust}}(\lambda) = N_{\text{H}} \Sigma(\lambda) = \tilde{\tau}_{9.7}^{\text{dust}} \frac{\Sigma(\lambda)}{\Sigma(9.7 \text{ } \mu\text{m})}, \quad (22)$$

where  $N_{\text{H}}$  and  $\tilde{\tau}_{9.7}^{\text{dust}}$  are the hydrogen nucleon column density and 9.7  $\mu\text{m}$  optical depth through the dust, respectively. The optical depth due to ice absorption is given by

$$\tau_{\text{ice}}(\lambda) = \tilde{\eta}_{\text{ice}} \tilde{\tau}_{9.7}^{\text{dust}} \frac{\Sigma_{\text{ice}}(\lambda)}{\Sigma_{\text{ice}}(6.1 \text{ } \mu\text{m})}, \quad (23)$$

where  $\Sigma_{\text{ice}}$  is the ice opacity template from Figure 5 and  $\tilde{\eta}_{\text{ice}} \equiv \tau_{6.1}^{\text{ice}}/\tau_{9.7}^{\text{dust}}$  determines the amount of ice opacity for a given dust

FIG. 5.— Water ice and HAC opacity templates derived from *L*-band (Imanishi et al. 2006) and IRS (Spoon et al. 2004) spectra of ULIRGs (see text). Also shown in the left panel is the arbitrarily scaled IRAC 3.6  $\mu\text{m}$  transmission curve for sources at  $z = 0, 0.1$ , and  $0.2$  (right to left).

opacity. Similarly, the optical depth due to HAC absorption is given by

$$\tau_{\text{HAC}}(\lambda) = \tilde{\eta}_{\text{HAC}} \tilde{\tau}_{9.7}^{\text{dust}} \frac{\Sigma_{\text{HAC}}(\lambda)}{\Sigma_{\text{HAC}}(6.85 \mu\text{m})}, \quad (24)$$

where  $\Sigma_{\text{HAC}}$  is the HAC opacity template from Figure 5 and  $\tilde{\eta}_{\text{HAC}} \equiv \tau_{6.85}^{\text{HAC}}/\tau_{9.7}^{\text{dust}}$  determines the amount of HAC opacity for a given dust opacity. The ratios of the apparent 6.1  $\mu\text{m}$  water ice and 6.85  $\mu\text{m}$  HAC optical depths to the apparent 9.7  $\mu\text{m}$  silicate optical depth are both  $\sim 0.1$  for the various ULIRGs used to derive the opacity templates. We therefore restrict the fitted values of

these ratios to satisfy  $0 \leq \tilde{\eta}_{\text{ice}} \leq 0.1$  and  $0 \leq \tilde{\eta}_{\text{HAC}} \leq 0.1$  in our decomposition method.

## 5. DUST EMISSION

### 5.1. Optically Thin Dust Emission

Figure 6 presents an illustration of the optically thin dust shell approximation used to calculate the SEDs of emission from the dust components in our decomposition that are heated directly by ultraviolet and optical photons from the *SB* and *AGN* source components (see also Fig. 1). The left panel depicts a starburst containing an *SB* source component surrounded by a shell of dust. The

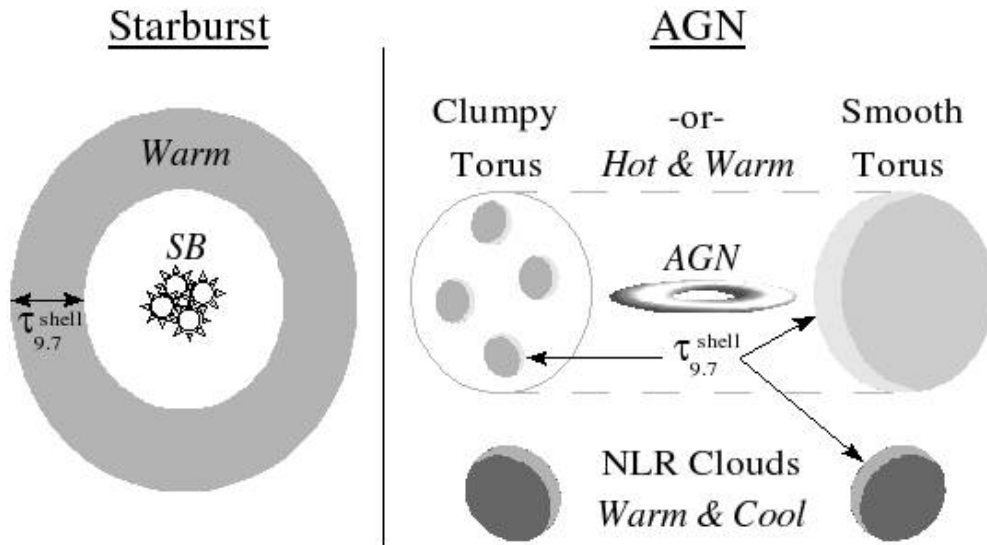

FIG. 6.— Cross-sectional views illustrating the optically thin dust shell approximation used to calculate the SEDs of dust components that are directly heated by ultraviolet and optical radiation from the *SB* and *AGN* source components (see text). The left panel depicts an *SB* source component surrounded by a shell of dust. The right panel shows an *AGN* accretion disk and torus (made of either discrete clouds as on the left or a smooth dust distribution as on the right) and more distant narrow-line region clouds.

right panel shows an AGN comprised of an *AGN* accretion disk, a dusty torus (either smooth or made of discrete clouds), and more distant narrow-line region clouds. In this geometry, ultraviolet and optical photons emitted by the source components either escape freely or are absorbed within shells of dust on the illuminated sides of clouds. By definition, these shells have an optical depth of order unity at the wavelength of peak energy absorption

$$\lambda_{\text{peak}} = \frac{\int \Sigma_{\text{abs}}(\lambda) u_{\lambda} \lambda d\lambda}{\int \Sigma_{\text{abs}}(\lambda) u_{\lambda} d\lambda}. \quad (25)$$

Here the absorption-weighted distribution function is obtained by integrating the energy absorbed by a single grain (i.e., the left-hand side of eq. [12]) over the distribution. As described in § 4.3, we assume that grains in the *hot* component are heated by the *AGN* radiation field (Fig. 2), while grains in the other dust components are heated by the *ISRF* field. The peak absorption wavelengths from equation (25) for these fields are 1470 and 4550 Å, respectively. At these wavelengths, the dust absorption opacity is approximately 20 and 5 times greater than its value at 9.7 μm, so that the 9.7 μm optical depths of the thin dust shells illuminated by the *AGN* and *ISRF* radiation fields are  $\tau_{9.7}^{\text{shell}} \approx 0.05$  and 0.2, respectively.

All emission from these shells therefore emerges from regions that are optically thin at all infrared wavelengths (i.e.,  $\lambda \gtrsim 1$  μm). The emerging intensity from these shells, calculated from the radiative transfer equation, is therefore

$$I_{\nu} = \int_0^{\tau_{\text{shell}}} S_{\nu}(\tau') e^{-(\tau_{\text{shell}} - \tau')} d\tau' = (1 - e^{-\tau_{\text{shell}}}) S_{\nu}. \quad (26)$$

Here the source function  $S_{\nu} \equiv E_{\nu}/\Sigma_{\text{abs}}$  is assumed to be constant (i.e., the magnitude of the radiation field energy density, and thus the dust temperature distribution, is assumed to be uniform). As shown above,  $\tau_{\text{shell}} < 1$  for all infrared wavelengths, so that equation (26) simplifies to

$$I_{\nu} \approx N_{\text{H}}^{\text{shell}} E_{\nu}, \quad (27)$$

where  $N_{\text{H}}^{\text{shell}}$  is the hydrogen nucleon column density through the dust shell (i.e.,  $\tau_{\text{shell}} = N_{\text{H}}^{\text{shell}} \Sigma_{\text{abs}}$ ).

### 5.2. Hot and Warm Component Emission

Using equation (27), the flux densities per unit frequency interval of emission from the *hot* and *warm* components are

$$f_{\nu}^{\text{hot}} \propto E_{\nu}(\tilde{U}_{\text{hot}}) e^{-\tau_{\text{hot}}}, \quad f_{\nu}^{\text{warm}} \propto E_{\nu}(\tilde{U}_{\text{warm}}) e^{-\tau_{\text{warm}}}, \quad (28)$$

where  $\tilde{T}_{\text{hot}} = \tilde{T}(\tilde{U}_{\text{hot}})$  and  $\tilde{T}_{\text{warm}} = \tilde{T}(\tilde{U}_{\text{warm}})$  are the characteristic component temperatures determined from the fitted values of  $\tilde{U}_{\text{hot}}$  and  $\tilde{U}_{\text{warm}}$  (see § 4.6) and

$$\tau_{\text{hot}} = \tilde{\tau}_{9.7}^{\text{hot}} \frac{\Sigma_{\text{abs}}(\lambda)}{\Sigma_{\text{abs}}(9.7 \mu\text{m})}, \quad \tau_{\text{warm}} = \tilde{\tau}_{9.7}^{\text{warm}} \frac{\Sigma_{\text{abs}}(\lambda)}{\Sigma_{\text{abs}}(9.7 \mu\text{m})} \quad (29)$$

are the optical depths through the screens of dust obscuring the *hot* and *warm* components (e.g., provided by the *cool* and *cold* components in the geometry of Fig. 1). Here  $\tilde{\tau}_{9.7}^{\text{hot}}$  and  $\tilde{\tau}_{9.7}^{\text{warm}}$  are the screen optical depths to the *hot* and *warm* components at 9.7 μm. Note that we use the absorption and not the extinction opacity since scattering is negligible for  $\lambda \gtrsim 3$  μm, where essentially all dust emission is radiated. Example *hot* and *warm* component SEDs,

FIG. 7.— Example SEDs of emission from the *hot*, *warm*, *cool*, and *cold* dust components for typical characteristic temperatures of  $\tilde{T} = 1400, 200, 80$ , and  $35$  K (black lines). Also shown are the SEDs obscured by screens (gray lines) having  $\tau_{9.7} = 1, 2$ , and  $3$  (top to bottom).

$f_{\nu}^{\text{hot}}$  and  $f_{\nu}^{\text{warm}}$ , are shown in Figure 7 for the characteristic temperatures  $\tilde{T}_{\text{hot}} = 1400$  K and  $\tilde{T}_{\text{warm}} = 200$  K. The fitted *hot* component characteristic temperature is constrained to satisfy  $500 \text{ K} < \tilde{T}_{\text{hot}} < 1500 \text{ K}$ , and the fitted *warm* component characteristic temperature typically satisfies  $150 \text{ K} < \tilde{T}_{\text{warm}} < 500 \text{ K}$ . Also shown in Figure 7 are example *hot* and *warm* component SEDs obscured by screens having  $\tau_{9.7} = 1, 2$ , and  $3$ . Note that departures from a smooth continuum near 9.7 and 18 μm are caused by emission and absorption from silicates.

### 5.3. Cool and Cold Component Emission

In the geometry of Figure 1, dust in the *cool* and *cold* components may serve as sources of opacity to obscure the emission from other components. Given this geometry and the observation that the mid-IR obscuration in dusty galaxies is often quite high (e.g.,  $\tau_{9.7} \approx 3-5$  for many of the local ULIRGs in Armus et al. 2006), the optically thin approximation used to obtain equation (27) is not necessarily valid for the *cool* and *cold* components. However, as a result of their relatively cool characteristic temperatures and 40–100 μm SED peaks, the optical depth through these components at the wavelengths over which they emit strongly is  $\sim 10-30$  times smaller than at 9.7 μm. Therefore, despite potentially large 9.7 μm optical depths, both components are actually optically thin at the wavelengths over which the majority of their emission is radiated. Thus, the conditions required for the validity of equation (27) are in fact still satisfied so that the flux densities per unit frequency interval of emission from the *cool* and *cold* dust components are

$$f_{\nu}^{\text{cool}} \propto E_{\nu}(\tilde{U}_{\text{cool}}), \quad f_{\nu}^{\text{cold}} \propto E_{\nu}(\tilde{U}_{\text{cold}}), \quad (30)$$

where  $\tilde{T}_{\text{cool}} = \tilde{T}(\tilde{U}_{\text{cool}})$  and  $\tilde{T}_{\text{cold}} = \tilde{T}(\tilde{U}_{\text{cold}})$  are the characteristic component temperatures determined from the fitted values of  $\tilde{U}_{\text{cool}}$  and  $\tilde{U}_{\text{cold}}$ . We assume that emission from both the *cool* and *cold* components emerges unextinguished since the optical depths required to achieve significant extinctions at  $\lambda \gtrsim 50$  μm where they emit strongly would imply implausibly high optical depths at shorter wavelengths. Example *cool* and *cold* component SEDs,  $f_{\nu}^{\text{cool}}$  and  $f_{\nu}^{\text{cold}}$ , are shown in Figure 7 for the characteristic temperatures  $\tilde{T}_{\text{cool}} = 80$  K and  $\tilde{T}_{\text{cold}} = 35$  K. The fitted *cool* and *cold* component characteristic temperatures typically satisfy  $50 \text{ K} < \tilde{T}_{\text{cool}} < 100 \text{ K}$  and  $25 \text{ K} < \tilde{T}_{\text{cold}} < 40 \text{ K}$ , respectively. Also shown

in Figure 7 are the *cool* and *cold* SEDs obscured by screens having  $\tau_{9.7} = 1, 2$ , and 3, demonstrating that the obscured *cool* and *cold* component SEDs are changed very little.

#### 5.4. Comparison with Other Methods

The emergent flux density from dust embedded in a distribution of radiation fields with energy densities  $U$  is

$$f_\nu^{\text{dust}} \propto \int \frac{dM_{\text{dust}}}{dU} E_\nu[\bar{T}(U)] dU. \quad (31)$$

Here  $M_{\text{dust}}(U)$  is the mass of dust heated to the characteristic temperature  $\bar{T}(U)$  by the field with strength  $U$ . Our four-component dust model characterizing the emission from a galaxy is derived from equation (31) by taking

$$\frac{dM_{\text{dust}}}{dU} = \sum_{i=1}^4 M_{\text{dust}}^i \delta(U - U_i), \quad (32)$$

where the sum is over four discrete values of  $U_i$  illuminating a mass  $M_{\text{dust}}^i$  of dust each. Clearly, equation (32) is an oversimplification of the true distribution of mass in a galaxy. Dale et al. (2001) and Li & Draine (2002) both calculate the integrated emission from dust in galaxies by assuming a power-law distribution of dust mass over heating intensity

$$\frac{dM_{\text{dust}}}{dU} \propto U^{-\alpha}, \quad (33)$$

where  $\alpha$  determines the relative contributions from each value of the radiation field energy density. Given a sufficient number of discrete temperature components, the model in equation (32) can be used to approximate the emission from the power-law model to arbitrary precision (with the appropriate weighting of each component through the  $M_{\text{dust}}^i$ ). The fact that both our multicomponent model and these power-law models produce excellent fits to the integrated spectra of galaxies implies that the required “sufficient number” of discrete components postulated above must be approximately four.

The real power of our multicomponent approach stems from the fact that it is capable of approximating not only the emission from the mass distribution of star-forming galaxies in equation (33) but also the emission from mass distributions that are *not* characterized by a power law (since we do not make the geometrical assumptions concerning the distribution of dust within a galaxy implied by eq. [33]). For example, the composite emission from a galaxy containing both a starburst and an AGN may have a total mass distribution function dominated by a star formation-driven power law at low energy densities superposed with an AGN-driven power law (having a different exponent) at high energy densities. Since the sum of two power laws with different exponents is not necessarily itself a power law, a model such as equation (33) cannot properly model this scenario. This, coupled with the fact that our method allows us to fit for different levels of obscuration toward each component (as expected for physically distinct AGN and starburst regions), drives our decision to utilize the multicomponent discrete temperature approach to describe the composite SEDs of dusty galaxies.

#### 5.5. Dust Emission in Previous Publications

The decompositions of IRAS 10214+4724 in Teplitz et al. (2006), NGC 6240 in Armus et al. (2006), and the BGS sample of ULIRGs in Armus et al. (2007) were performed using an earlier

version of the method described in this work, which utilized a different model to calculate the emission from each dust component. In these previous publications, dust emission is calculated from an optically thin shell of constant density material surrounding the illuminating source. As in equation (33), the dust in this shell is exposed to different radiation fields (depending on its distance from the central source) and is therefore brought to different equilibrium temperatures. In these previous works, we assume that the dust shells had a thickness  $r_{\text{out}}/r_{\text{in}} = 10$ , which fixes the range of radiation fields and therefore dust temperatures, once the temperature at the minimum radius is defined (taken to be the sublimation temperature). Since each of these dust components contains a range of temperatures (from dust at different radii), only three components were needed to fit the sources instead of the four used in the current work. We choose to adopt the four-component method for this work since it improves the fits at long wavelengths and simplifies the interpretation.

### 6. PAH EMISSION

Observations with *ISO* and *Spitzer* have shown that the presence of PAHs (Leger & Puget 1984; Allamandola et al. 1985) can be used as an indicator of star formation (e.g., Förster Schreiber et al. 2004; Peeters et al. 2004). We note, however, that Calzetti et al. (2005) find that PAH emission does not correlate well with other star formation tracers in M51. In addition, Engelbracht et al. (2005) and Wu et al. (2006) find that PAH emission varies with metallicity and so may therefore not be a useful tracer of star formation in low-metallicity systems. With these cautionary notes in mind, the presence or absence of PAH emission nevertheless provides an important clue to help distinguish between star formation and accretion-dominated ULIRGs (e.g., Genzel et al. 1998), thereby necessitating the development of a method to carefully decompose the contributions from PAHs to the total emission from dusty galaxies.

This process is complicated by the fact that it is difficult to establish the level of the continuum beneath the PAH features, especially in the presence of 9.7  $\mu\text{m}$  silicate absorption. The method presented here provides a systematic means of estimating this continuum, and therefore the strength of the PAH features, without the need for the observer to define the continuum level by hand. We model the flux density per unit frequency interval of the *PAHs* component as

$$f_\nu^{\text{PAHs}} = f_0^{\text{PAHs}} \frac{\hat{f}_\nu^{\text{PAHs}}}{\hat{f}_\nu^{\text{PAHs}}(6.2 \mu\text{m})}, \quad (34)$$

where  $f_0^{\text{PAHs}} \equiv f_\nu^{\text{data}}(6.2 \mu\text{m}) - f_\nu^{\text{cont}}(6.2 \mu\text{m})$  is the estimated peak flux density of the 6.2  $\mu\text{m}$  PAH feature obtained from the local continuum-subtracted observed spectrum and

$$\hat{f}_\nu^{\text{PAHs}} = \sum_i \frac{\gamma_i^2 f_{\nu,0}^i}{(\lambda/\lambda_0^i - \lambda_0^i/\lambda)^2 + \gamma_i^2} \quad (35)$$

is the PAH emission template shown in Figure 8 constructed by summing over a series of Drude profiles with the parameters presented in Table 1. As suggested by the definition of  $f_0^{\text{PAHs}}$ , the overall strength of the PAH template is held fixed during the continuum fit, but the strengths of the individual features are allowed to vary in the subsequent PAH fit (see § 2.2 and the following paragraph).

The central wavelengths and widths of our  $\lambda_0 > 3.3 \mu\text{m}$  features are adapted from those used in the analysis of Smith et al.

Fig. 8.— PAH emission template (black line) derived from the spectrum of the mean starburst galaxy from Brandl et al. (2006). The individual complexes (gray lines) are modeled with Drude profiles (see Smith et al. 2007). Note the significant “continuum” emission created by the addition of flux in the wings of the broad features. Also shown for reference are the four arbitrarily scaled IRAC transmission curves.

(2007), and their relative strengths are derived using PAHFIT<sup>12</sup> to fit the low-obscuration ( $\tau_{9.7} \approx 0.24$ ) mean starburst galaxy spectrum created from 13 IRS spectra in Brandl et al. (2006). The 3.3  $\mu\text{m}$  PAH feature central wavelength and width are obtained from Li & Draine (2001), and the peak flux density of this feature is derived from the ratio of the strengths of the PAH features at 3.3 and 6.2  $\mu\text{m}$  in the *L*-band and IRS spectra of the star-forming ULIRG IRAS 12112+0305 presented in Imanishi et al. (2006) and Armus et al. (2006). We include this 3.3  $\mu\text{m}$  PAH feature so that its contribution to the integrated *L*-band (or IRAC 3.6  $\mu\text{m}$  channel; see Fig. 8) flux density is explicitly included in the fitting method. As described in § 2.2, after fitting the continuum, we fit the continuum-subtracted observed spectrum to refine our *PAHs* component (the properties of which are held fixed during the continuum fit). In this fit, the central wavelengths and FWHM of the PAH features are fixed to the values in Table 1, and the peaks are allowed to vary freely. This fit provides accurate luminosities for all PAH complexes, as well as error estimates derived from the full covariance matrix.

## 7. ATOMIC AND MOLECULAR LINE EMISSION

In order to accurately fit the continuum and PAH features in an IRS spectrum, the contributions from atomic and molecular lines must be properly fitted as well. Of course, the strength of these lines is scientifically interesting, but we caution against using our decomposition method to measure them since the fitted continuum around each line is not necessarily as accurate as one estimated by hand (a statement that cannot be made concerning the underlying continuum beneath PAH features). Therefore, although we obtain integrated flux values for the lines we fit, we do not recommend using these measurements for scientific purposes (at least not without carefully checking the validity of the fitted local continuum around each line). The one caveat to this recommendation where we do suggest using the fitted integrated line flux is for the [Ne II] 12.81  $\mu\text{m}$  line, which our decomposition method is capable of deblending from the 12.7  $\mu\text{m}$  PAH complex in low-resolution IRS spectra.

<sup>a</sup> Fraction of total PAH luminosity emerging from each complex *j*.

<sup>b</sup>  $L_j = \sum_{i \in j} L_i$  is the total luminosity of a complex of Drude profiles, where  $L_i = 4\pi D_L^2 (\pi/2) \lambda_0^i \gamma_i f_{\nu,0}^i$  is the apparent total luminosity of a single profile, with  $D_L$  the luminosity distance to the source.

<sup>c</sup> As defined in Smith et al. (2007), the 7.7, 11.3, 12.7, and 17  $\mu\text{m}$  complexes are each composed of multiple Drude profiles.

We create our atomic and molecular emission line spectrum by estimating the peak flux density of each line in Table 2 from the local continuum-subtracted IRS spectrum. The flux density per unit frequency interval of the *lines* component is modeled as a sum over unresolved Gaussian profiles having central wavelengths  $\lambda_0$ , widths  $\gamma_i$ , and peak flux densities  $f_{\nu,0}$ :

$$f_{\nu}^{\text{lines}} = \sum_i f_{\nu,0}^i \exp \left\{ -\frac{1}{2} \left[ \frac{\lambda - \lambda_0^i}{\lambda_0^i \gamma_i / (2\sqrt{2} \ln 2)} \right]^2 \right\}. \quad (36)$$

Since the Gaussian profiles are unresolved, the width of each line is a function of the IRS module in which it is detected (see Table 2 for values of  $\gamma$  as a function of source redshift). As described in § 6 for the *PAHs* component, after fitting the continuum we perform a fit to the continuum-subtracted observed spectrum in order to refine the *lines* component (the parameters for which are held fixed in the continuum fit). In this fit, the central wavelengths and FWHM of the atomic and molecular emission lines are fixed to the values in Table 2, and their peak flux densities are allowed to range freely. From this fit, we obtain line luminosities and their uncertainties, although, as noted above, we recommend measuring all unblended line fluxes by hand.

## 8. CONSTRUCTING DUSTY GALAXY SEDs

### 8.1. Sample Selection

Table 3 presents a summary of the galaxies in our sample. They have been selected with the goal of demonstrating the capabilities of our decomposition method on a variety of dusty galaxy SEDs, representative of the diverse properties of the group. We include examples of unextinguished and obscured starbursts, a quasar, a

NOTES.—The FWHM =  $\lambda_0^i \gamma_i$  of a particular atomic or molecular line is a function of the IRS module in which it is detected and therefore depends on the redshift of the source. We give example values of  $\gamma_i$  for all lines at  $z = 0, 0.1, 0.25$ , and  $0.5$ . Values of  $\gamma_i$  are not given for lines that fall out of the IRS wavelength range at a given redshift.

Seyfert 2 galaxy, and two composite systems powered by both AGN and starburst activity (see § 10.1 for details about each source). The first four galaxies in this sample serve as templates to aid in understanding the properties of the components from which composite systems are built. Our sample includes star-forming galaxies covering a range of infrared luminosities: from a minimum  $L_{\text{IR}} \approx 5 \times 10^{10} L_{\odot}$  for NGC 7714 to more than a factor of  $\sim 10$  higher for NGC 6240. While it is true that this sample does not include examples of “normal” star-forming galaxies, our decomposition method is nonetheless valid for these sources as well. In fact, our method is applicable to *all* galaxies, including

AGNs, starbursts, normal, dwarfs, and ellipticals, so long as their SEDs are composed of emission from stars, dust, PAHs, atomic and molecular lines, and possibly an AGN accretion disk (i.e., our decomposition components).

### 8.2. IRS Spectroscopy

The IRS spectra of the sources in our sample were first presented in the papers referred to in Table 3. All spectra in this paper have been extracted using the method described in Armus et al. (2006). In brief, the IRS pipeline at the *Spitzer* Science Center was used to reduce the data, and one-dimensional spectra were extracted using the SMART package (Higdon et al. 2004). After scaling and stitching the individual orders together, each spectrum was scaled to match the MIPS 24  $\mu\text{m}$  flux density if available (see § 8.4), or the *IRAS* 25  $\mu\text{m}$  flux density otherwise.

### 8.3. Supplementary Photometry

The spectral coverage of the IRS low-resolution modules ends at an observed-frame wavelength of  $\sim 38 \mu\text{m}$ . Emission from typical *cool* component dust ( $\bar{T} \sim 80 \text{ K}$ ) therefore only contributes to the last few microns, while emission from typical *cold* component dust ( $\bar{T} \sim 35 \text{ K}$ ) contributes negligibly at IRS wavelengths. To better constrain these cooler components that dominate the dust mass and frequently provide  $\sim 50\%$  of the total dust luminosity, we supplement our IRS spectra with far-IR to millimeter wavelength photometry from the literature. Furthermore, the spectral coverage of the IRS modules begins at an observed-frame wavelength of  $\sim 5.2 \mu\text{m}$ . As seen in Figure 2, our source components all radiate significantly at shorter wavelengths. Thus, to better constrain these components, we supplement our SEDs with ultraviolet to near-IR photometry from the literature. Table 4 provides references to the literature for all photometry used in our decompositions.

In each wavelength range, we construct our SEDs using data that most closely sample the spatial region contained within the IRS slits. We treat photometric points that sample larger spatial regions (i.e., for wavelength ranges where no data at a similar spatial resolution are available in the literature) as upper limits to the flux density of the area covered by the IRS spectrum. To include such a limit as input to the  $\chi^2$  fitting routine (which requires both the flux density of each data point and its associated error), we assign the data to have an upper limit flux density  $f_{\nu}^{\text{ul}} = 0$  and an uncertainty  $\sigma_{\text{ul}} = f_{\nu}^{\text{data}}/3$ . If, in addition to an upper limit to the flux density contained in the IRS slit, we also have an estimate of the lower limit (e.g., as estimated using a very small aperture

TABLE 5  
IRAC AND MIPS NUCLEAR PHOTOMETRY

Mrk 1014.....	32	19.2	23.2	...	...	...

NOTES.—IRAC flux density errors are estimated to be 5% for Mrk 1014 and Mrk 463 and 10% for the other three sources. MIPS flux density errors are driven by the post-BCD calibration uncertainties and are  $\sim 10\%$  for the 24  $\mu\text{m}$  band and  $\sim 20\%$  for the 70 and 160  $\mu\text{m}$  bands. No color corrections are applied since they are much smaller than the uncertainties. The PIDs are the *Spitzer* program numbers for the IRAC and MIPS observations.

measurement), we assign the data point to have a flux density of  $f_{\nu}^{\dagger} = (f_{\nu}^{\downarrow} + f_{\nu}^{\uparrow})/2$  with an associated uncertainty of  $\sigma_{\dagger} = (f_{\nu}^{\uparrow} - f_{\nu}^{\downarrow})/3$ , so that the fit is constrained to fall between these two limiting values.

#### 8.4. IRAC and MIPS Photometry

All of the source components and the *hot* dust component radiate significantly from 3 to 5  $\mu\text{m}$ , i.e., between the *JHK* bands and the onset of the IRS spectral range (see Figs. 3 and 7). To better constrain the fits in this critical region, we derive observed-frame 3.6 and 4.5  $\mu\text{m}$  nuclear flux densities of the central point source for five of six galaxies in our sample using archival IRAC images. This photometry is presented in Table 5 and is derived using the post-BCD products provided by the *Spitzer* Science Center. Flux densities for NGC 7714, NGC 2623, and NGC 6240 are calculated using a  $5''$  radius circular aperture to match both the near-IR literature photometry and the IRS slit width. We do not apply any aperture corrections for these sources since they are all extended at these wavelengths. Mrk 1014 and Mrk 463 are both pointlike at these wavelengths, so we calculate their flux densities using a  $12.2''$  radius aperture, which requires no aperture correction to recover the full point-source value. Uncertainties are estimated to be 5% for Mrk 1014 and Mrk 463 and 10% for the other three sources.

The *IRAS* and *ISO* beam sizes are both much larger than the  $5''$ – $11''$  IRS slit widths, so that far-IR photometry of nearby extended sources contains emission from regions outside the slits. We therefore derive mid-IR and far-IR nuclear flux densities of the central point sources for five of six galaxies in our sample using archival MIPS images. This photometry is presented in Table 5 and is derived using the post-BCD products provided by the *Spitzer* Science Center. We use Mrk 463 to derive aperture corrections since it is well detected in all three bands and appears very pointlike. To calculate the nuclear flux densities, we measure the emission from each source within small apertures ( $3''$ ,  $8''$ , and  $20''$  radii at 24, 70, and 160  $\mu\text{m}$ , respectively) and scale these values by the appropriate aperture correction (3.37, 4.09, and 2.95 for 24, 70, and 160  $\mu\text{m}$ , respectively). The *Spitzer* beam sizes at 24, 70, and 160  $\mu\text{m}$  are  $\sim 6''$ ,  $17''$ , and  $39''$ , respectively. The 24  $\mu\text{m}$  beam is therefore very similar to the  $5''$ – $11''$  IRS slits, justifying our choice to scale the IRS spectrum to this MIPS point. The beams at 70 and 160  $\mu\text{m}$  are significantly smaller than the  $>100''$  *IRAS* and *ISO* beams, so that the MIPS data provide a much better estimate of the nuclear flux density. Flux density errors are dominated by the post-BCD calibration uncertainties

and are estimated to be 10% at 24  $\mu\text{m}$  and 20% at 70 and 160  $\mu\text{m}$ . No color corrections are applied to the IRAC or MIPS photometry since all corrections are much smaller than the uncertainties.

## 9. DECOMPOSING DUSTY GALAXIES

### 9.1. Spectral Decomposition Results

In Figures 9 and 10 we present our decompositions of the *nuclear* SEDs of the dusty galaxies in our sample. In these fits, the MIPS photometric points are used to constrain the nuclear far-IR SEDs, while the globally integrated *IRAS*, *ISO*, and submillimeter data provide upper limits to this nuclear emission. The entire ultraviolet to millimeter wavelength SEDs are presented in Figure 9, and enlarged views focusing on the IRS regions are shown in Figure 10. In Figure 9 we also show the *global* fitted flux densities obtained using the full values of the large-beam *IRAS*, *ISO*, and submillimeter data. The temperatures of the *cold* and *cool* dust components obtained in the global fits are held fixed to these values in the nuclear decompositions. Note that the *ISRF* component contributes minimally (only in Mrk 463) since the small-aperture near-IR photometry used to match the IRS slits is dominated by emission from young stellar populations and not evolved stars.

### 9.2. Decomposition Parameters and Constraints

The decomposition parameters obtained from the fits to the nuclear SEDs of the dusty galaxies in our sample are presented in Tables 6 and 7. There are a total of 17 free parameters. The *SB* source component has two free parameters:  $\tilde{\alpha}_{\text{SB}}$  and  $\tilde{\tau}_{\text{V}}^{\text{SB}}$  determine the fractional *SB* contribution to the total luminosity (see eq. [1]) and the 5500 Å optical depth (see eq. [6]). The *ISRF* source component has only a single free parameter:  $\tilde{\alpha}_{\text{ISRF}}$  (see eq. [5]). The *AGN* source component has a total of two free parameters:  $\tilde{\alpha}_{\text{AGN}}$  and  $\tilde{\epsilon}_{\text{AGN}}$ , where the latter determines the fraction of the *AGN* component covered by the obscuring screen (see eq. [9]). The optical depth through the obscuring clouds to the *AGN* component is fixed to  $\tilde{\tau}_{\text{V}}^{\text{AGN}} = 25$ . The *hot* and *warm* dust components each have three free parameters:  $\tilde{\alpha}_i$ ,  $\tilde{\tau}_{9.7}^i$ , and  $\tilde{U}_i$  determine the component luminosities, 9.7  $\mu\text{m}$  optical depths, and dust temperatures via  $\tilde{T}_i \equiv T(\tilde{U}_i)$  (see eq. [28]). The *cool* and *cold* components each have two free parameters:  $\tilde{\alpha}_i$  and  $\tilde{U}_i$  (see eq. [30]). Finally, there are two additional free parameters that control the water ice and HAC contributions to the total opacity:  $\tilde{\eta}_{\text{ice}}$  and  $\tilde{\eta}_{\text{HAC}}$  (see eqs. [23] and [24]).

We impose the following constraints to provide sensible limits over which the free parameters may range: (1) the magnitude of the radiation field energy density illuminating each dust component is constrained to give characteristic dust temperatures satisfying  $20 \text{ K} < \tilde{T}_{\text{cold}} < 50 \text{ K}$ ,  $50 \text{ K} < \tilde{T}_{\text{cool}} < 150 \text{ K}$ ,  $150 \text{ K} < \tilde{T}_{\text{warm}} < 500 \text{ K}$ , and  $500 \text{ K} < \tilde{T}_{\text{hot}} < 1500 \text{ K}$ ; (2) the maximum water ice and HAC contributions to the total opacity are constrained by their strengths in sources with very clean absorption spectra (see § 4.8); (3) the extinction to the *AGN* source component is fixed to  $\tau_{\text{V}} = 25$ ; (4) the extinction to the *SB* source component must satisfy  $\tau_{\text{V}} < 5$ ; (5) the optical depths through the screens obscuring the *hot* and *warm* components must not exceed the critical values beyond which their extinction-corrected luminosities would exceed the total dust luminosity; (6) the ratio of the unextinguished luminosity of the *SB* component to the luminosity of the *PAHs* component must be between the values obtained for our unobscured and obscured template starbursts NGC 7714 and NGC 2623; and (7) the *hot* dust covering fraction (i.e., the ratio of the unextinguished *hot* dust luminosity to the unextinguished *AGN* luminosity) must be  $>0.5$ , consistent

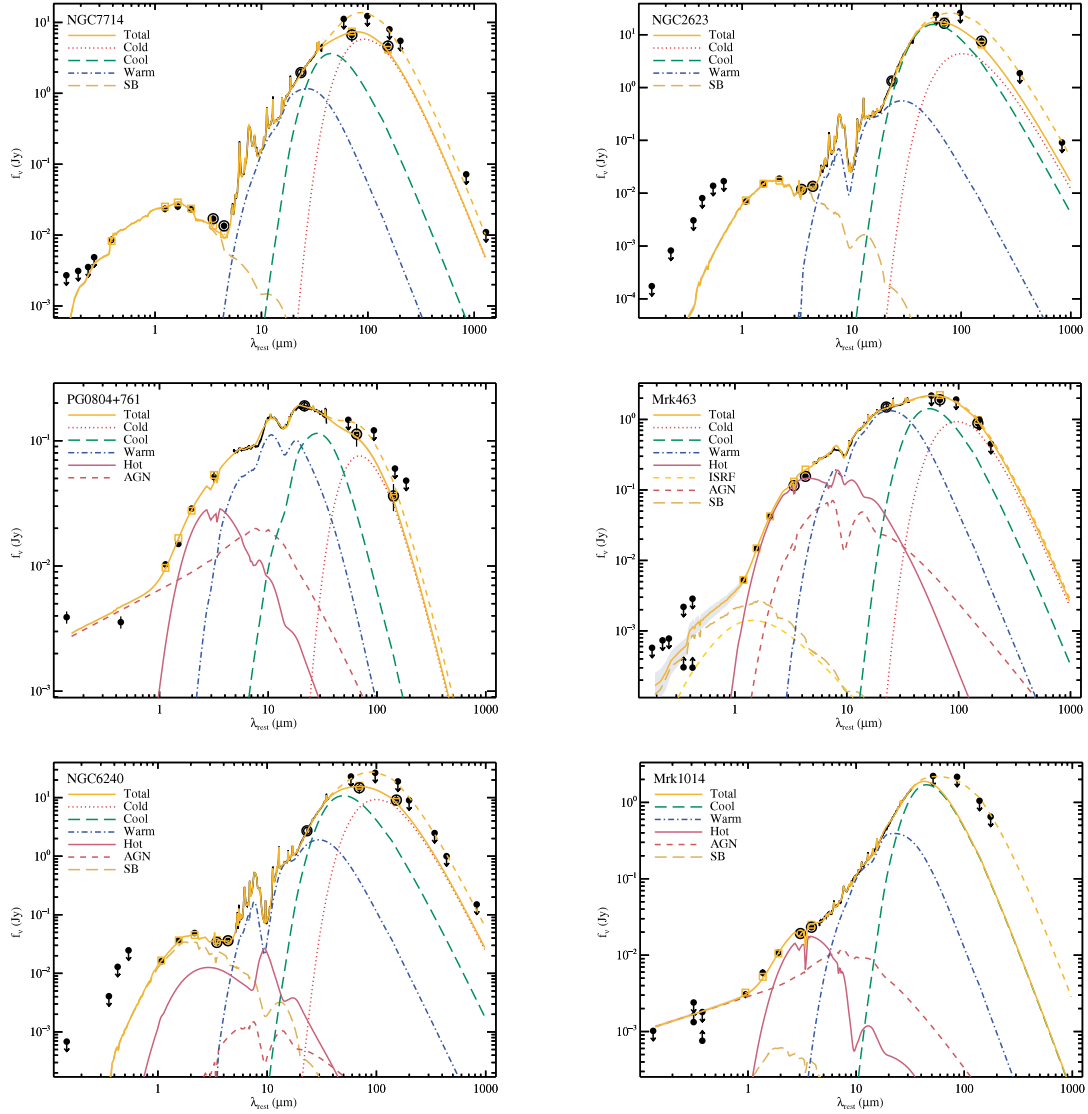

FIG. 9.— Spectral decompositions of the ultraviolet to millimeter wavelength SEDs (black solid lines and filled circles) of the nuclear regions of the dusty galaxies NGC 7714, NGC 2623, PG 0804+761, Mrk 463, NGC 6240, and Mrk 1014. Arrows indicate upper or lower limits (see § 8.3). Open circles indicate the position of the MIPS 24  $\mu\text{m}$  point to which the IRS spectra are scaled. IRAC and MIPS photometric points are circled. The various decomposition components are shown as indicated in the figure legend. In addition, the total fitted SEDs obtained using the globally integrated far-IR data (dashed “Total” line) are displayed.

with observations and corresponding to torus opening angles  $>30^\circ$ .

### 9.3. Derived Quantities

#### 9.3.1. Source and Dust Component Luminosities

Apparent and extinction-corrected source and dust component luminosities from the nuclear decompositions are presented in Table 7. The apparent luminosity of each component is calculated from

$$L_i = 4\pi D_L^2 \int f_\nu^i d\nu \equiv \begin{cases} \tilde{\alpha}_i L_{\text{source}}, & L_i \in L_{\text{source}}, \\ \tilde{\alpha}_i L_{\text{dust}}, & L_i \in L_{\text{dust}}, \end{cases} \quad (37)$$

where  $D_L$  is the luminosity distance to the galaxy (see Table 3) and  $L_{\text{source}}$  and  $L_{\text{dust}}$  are the sums of the luminosities of all source and dust components, respectively. Extinction-corrected luminosities are calculated from

$$L'_i = 4\pi D_L^2 \int \frac{f_\nu^i}{\Upsilon_i(\nu)} d\nu \equiv \begin{cases} \tilde{\alpha}'_i L_{\text{source}}, & L_i \in L_{\text{source}}, \\ \tilde{\alpha}'_i L_{\text{dust}}, & L_i \in L_{\text{dust}}, \end{cases} \quad (38)$$

where the  $\Upsilon_i$  are the extinction terms for each component [i.e.,  $\Upsilon_{\text{AGN}} = (1 - \tilde{\epsilon}_{\text{AGN}}) + \tilde{\epsilon}_{\text{AGN}} \exp(-\tau_{\text{AGN}})$  for the AGN component and  $\Upsilon_i = \exp(-\tau_i)$  for the warm, hot, and SB components].

#### 9.3.2. Dust Component Masses

The mass of dust in each of the cold, cool, warm, and hot nuclear decomposition components is provided in Table 8. We generalize the expression used to calculate dust masses for a single grain size and composition (see, e.g., eq. [4] of Klaas et al. 2001) to the case in which grains are distributed in both size and composition. The mass of dust in each component is therefore given by

$$M_i = D_L^2 \frac{f_\nu^i(\lambda_0)}{E_\nu^i(\lambda_0) e^{-\tau_i(\lambda_0)}} \sum_j \int \frac{4}{3} \pi a^3 \rho_j \frac{1}{n_H} \frac{dn_j}{da} da, \quad (39)$$

which is the product of the number of hydrogen nucleons required to power the fitted dust component and the total dust mass per hydrogen nucleon for the adopted dust model (summed over

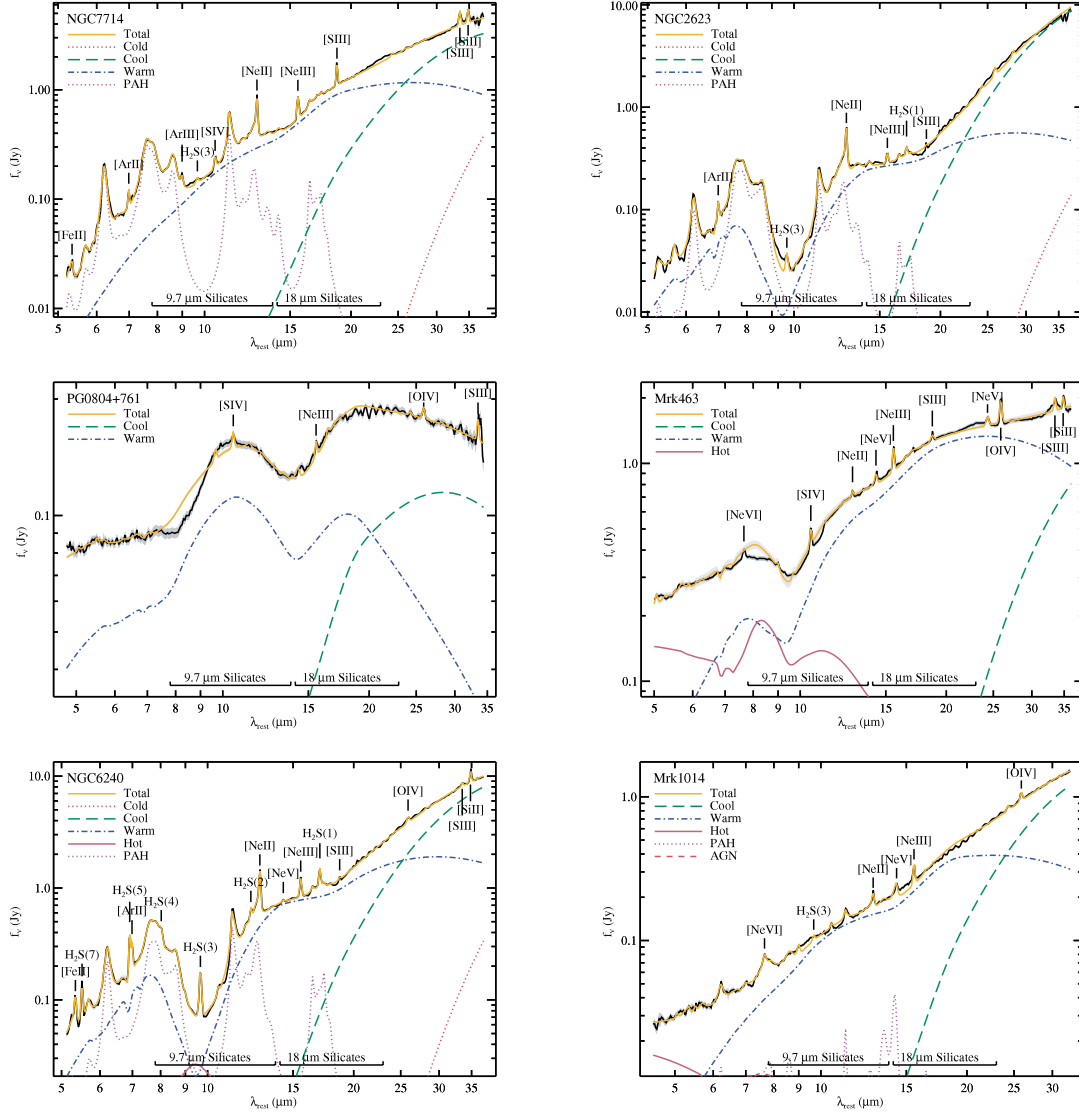

FIG. 10.—Close-up view of the IRS wavelength ranges for the nuclear decompositions presented in Fig. 9. The various decomposition components are shown as indicated in the figure legend. Also shown are the  $1\sigma$  uncertainties in the IRS spectra (dark shaded regions) and the formal  $1\sigma$  error contours for the total fit (light shaded regions). Emission lines and the wavelength ranges over which silicate emission and absorption are observed are also labeled.

NOTES.—Apparent and extinction-corrected luminosities of each source and dust component in the nuclear decompositions are given as fractions of  $L_{\text{source}}$  and  $L_{\text{dust}}$  (see eqs. [37] and [38]). Formal statistical uncertainties for the fitted luminosities are given beneath their values. The nuclear dust luminosity of Mrk 1014 is uncertain by  $\sim 20\%$  (i.e., the difference between its nuclear and global values), and its *cold* component luminosity is undetermined since no MIPS data are available to constrain its far-IR SED.

the graphite and silicate compositions). In this equation,  $\lambda_0$  is an arbitrary wavelength at which the terms are evaluated, and the densities of graphite and silicate are taken to be  $\rho_{\text{gra}} = 2.24$  and  $\rho_{\text{sil}} = 3.50 \text{ g cm}^{-3}$ . For comparison to the dust masses and luminosities obtained from the nuclear decompositions, we present the corresponding properties for the global decompositions in Table 9.

### 9.3.3. Comparison with Previous Results

Klaas et al. (2001) fit the far-IR to submillimeter wavelength SEDs of a sample of ULIRGs using dust-modified blackbodies with temperatures typically ranging between 28 and 50 K. Included among their sources are two galaxies that are also in our sample, Mrk 463 and NGC 6240, for which they fit single  $\beta = 2$  dust components with temperatures of 40 and 33 K, respectively. In a similar study of quasars presented in Haas et al. (2003) the far-IR SED of PG 0804+761 is fitted with a 47 K dust component. The temperatures we derive from our decompositions are all consistent with these values. Our decomposition of Mrk 463 includes contributions from 30 and 55 K dust components, while our fit to NGC 6240 includes emission from dust at 29 and 61 K. Finally, our decomposition of PG 0804+761 is dominated in the far-IR by emission from 42 K dust. For all three sources, the temperatures of the single-component fits in the literature fall between

the temperatures of the dust in our multicomponent fits. Klaas et al. (2001) also fit the  $\lambda > 60 \mu\text{m}$  SED of NGC 6240 with multiple  $\beta = 2$  dust components and obtain temperatures of 31 and 41 K (they also include a 10 K component to fit to submillimeter upper limits). Again, these temperatures are quite comparable to ours, noting that our warmer component is at a somewhat higher temperature in order to fit to the shorter wavelength data included in our fits.

As illustrated by these decompositions, multicomponent fits including dust at different temperatures are rarely unique since several components can usually be added together to approximate the SED of emission from a smaller number of components. In fact, dust in galaxies is likely to be distributed throughout many regions with various heating conditions and is therefore distributed over a continuum of temperatures. Any multicomponent decomposition therefore serves only to characterize these distributions of temperatures. In addition, if either or both of the restrictions that dust is optically thin to its own emission and that its far-IR emissivity index is characterized by  $\beta = 2$  imposed above are lifted, yet different dust temperatures may be obtained for the same SEDs. For example, Klaas et al. (2001) perform fits in which the dust optical depth and emissivity are free parameters and obtain much higher temperatures: 52 and 57 K for Mrk 463 and NGC 6240, respectively. Given the multiple factors determining the temperatures derived from spectral decompositions (e.g., fixed vs. variable  $\beta$ ), we emphasize that caution must be taken when comparing temperatures derived from different methods to ensure that they are in fact comparable.

The total far-IR luminosity from dust inferred from a multicomponent decomposition is largely independent of the number of components and the choice of their characteristic temperatures (since the luminosity is just the integral under the SED). The total mass of dust, however, depends on these choices (since the mass is a strong function of temperature). Since the total mass of dust in galaxies is dominated by low-temperature material, decompositions with multiple components (including very cold dust) produce much higher dust masses. For example, Klaas et al. (2001) estimate the mass of dust in Mrk 463 to be greater than  $5 \times 10^6 M_{\odot}$  and less than  $1.2 \times 10^7 M_{\odot}$  as derived from their single- and multicomponent fits, respectively. Similarly, they estimate that the mass of dust in NGC 6240 is between  $3.6 \times 10^7$  and

TABLE 8  
NUCLEAR SED DECOMPOSITION DUST MASSES

NOTES.—Global SED decomposition properties derived from fitting the total far-IR emission (see Fig. 9). All quantities are analogous to those in Tables 7 and 8. The temperatures of the *cold* and *cool* components are the same as given in Table 6. Formal statistical uncertainties for the fitted properties are given along with their values.

$5.8 \times 10^8 M_{\odot}$ . Our decompositions yield total globally integrated dust masses of  $2.8 \times 10^7$  and  $1.6 \times 10^8 M_{\odot}$  for the two sources, relatively consistent with the previously derived masses (within the uncertainties of the methods). Klaas et al. (2001) estimate the  $\text{H}_2$  mass of NGC 6240 to be  $3.7 \times 10^{10} M_{\odot}$  [assuming  $M(\text{H}_2) = 4.6 L_{\text{CO}}$ ]. This value, along with our estimate of the total dust mass in NGC 6240, gives a gas-to-dust ratio of  $\sim 230$ , in reasonable agreement with the canonical value of  $\sim 165$  from Li (2005).

#### 9.3.4. Diagnostic Ratios

In Table 10 we present several “diagnostic” ratios for each galaxy derived from the nuclear decomposition masses and luminosities presented in Tables 7 and 8. The first entry in this table gives the ratio of the total dust luminosity to the total gas mass. The total gas mass is calculated from the fitted value of the total dust mass and the gas-to-dust ratio of our adopted dust model:  $M_{\text{gas}}/M_{\text{dust}} = 1.4 M_{\text{H}}/M_{\text{dust}} = 124$  (Li & Draine 2001). The definition of this quantity is motivated by the fact that two sources with equivalent values of  $L_{\text{dust}}$  or  $L_{\text{IR}}$  may have completely different physical properties (e.g., a very massive but inactive system may have the same dust luminosity as a relatively small but highly active galaxy). The total dust luminosity is therefore a degenerate quantity that does not alone provide great insight into the nature of a galaxy. Normalizing the dust luminosity by the dust mass, however, does provide a means of breaking this degeneracy. This ratio characterizes the radiative efficiency of a galaxy, with smaller  $L_{\text{dust}}/M_{\text{gas}}$  ratios indicating lower efficiencies and cooler

dust temperatures and larger ratios indicating higher efficiencies and warmer dust temperatures.

Also included in Table 10 are the ratios of the extinction-corrected *SB* and *AGN* source component luminosities to the total nuclear dust luminosity. A ratio of unity or greater in these quantities indicates that the total observed dust emission could be heated by the fitted source component. A ratio significantly greater than unity indicates that either the source extinction correction was overpredicted or the dust covering fraction is less than unity. In the latter case, the fraction of the source that is covered by dust is obtained from the inverse of the source-to-dust ratio. A ratio significantly less than unity indicates that either the extinction to the source component is underpredicted or additional unmodeled source emission is present that has not been accounted for in the decomposition (e.g., the apparent near-IR luminosity of a deeply embedded source may be small in comparison to a relatively unextinguished source, even though the two may be intrinsically similar in strength). In addition to the source-to-dust *luminosity* ratios, we also calculate source-to-dust *mass* ratios, where the extinction-corrected *SB* and *AGN* luminosities are given as a fraction of the total gas mass. This quantity indicates the relative “dustiness” (in terms of mass) of a source compared to others of the same luminosity.

#### 9.3.5. PAH Feature Luminosities

The total apparent PAH luminosity of each source (integrated over all features), normalized to both the total dust luminosity and the total gas mass, is presented in Table 10. In addition, the

NOTES.—Formal statistical uncertainties for the diagnostic ratios are given along with their values. Mass-normalized values are not given for Mrk 1014 since no MIPS data are available to constrain its far-IR SED (and therefore  $M_{\text{gas}}$ ). This absence of data also results in a  $\sim 20\%$  uncertainty for the value of  $L_{\text{dust}}$  for Mrk 1014 (i.e., the difference between its nuclear and global values) and therefore in all quantities normalized by this total dust luminosity.

NOTES.—Ratios of the luminosities of each of the four main PAH complexes to the total PAH luminosity. Formal statistical uncertainties for the fitted properties are given along with their values. Also shown are the ratios for the mean starburst galaxy spectrum used to derive our PAH template (see Table 1) and the median values for the SINGS sample of star-forming galaxies presented in Smith et al. (2007).

fitted ratios of the luminosities of the four primary PAH complexes (see Table 1) to the total PAH luminosity are presented in Table 11. For reference, we also provide the corresponding ratios for the mean starburst galaxy spectrum from Brandl et al. (2006), used to create our PAH template, and the median ratios for the star-forming SINGS galaxies from Smith et al. (2007). With the exception of Mrk 1014, the fitted PAH luminosity ratios of the four sources in our sample with well-detected PAH emission are fairly consistent with the values of the mean starburst and SINGS templates (see § 10.1 for more on the PAH emission of Mrk 1014).

The apparent ratios of PAH emission from a galaxy may differ from those of the low-obscuration templates in Table 11 for several reasons. First, the size of a PAH (i.e., the number of carbon atoms) and its ionization state can alter the relative strengths of its emission features (see Draine & Li 2001). In addition, the apparent ratios may vary as a result of extinction from intervening dust. In Table 12 we present the ratios of the 6.2, 7.7, and 11.3  $\mu\text{m}$  PAH complexes to the total PAH luminosity for the mean starburst galaxy from Table 11 after passing through screens of dust with various values of  $\tau_{9.7}$ . In addition to the feature ratios, we also provide correction factors used to convert the total apparent PAH luminosity into the actual emitted PAH luminosity for a particular value of  $\tau_{9.7}$  estimated from the feature ratios.

## 10. DISCUSSION

### 10.1. Detailed Descriptions of Decompositions

**NGC 7714.**—Our low-obscuration template starburst is a massive barred spiral galaxy that makes up the western component of the interacting system Arp 284. The compact ultraviolet-luminous starburst nucleus of NGC 7714 has very low extinction, and there is no evidence at any wavelength for the presence of an AGN. The IRS spectrum of this galaxy (see Brandl et al. 2004) exhibits a rising continuum, strong PAH feature and line emission, and no

perceptible 9.7  $\mu\text{m}$  silicate absorption. As suggested by the relatively flat continuum near 10  $\mu\text{m}$ , all parameters from our fitting are consistent with this starburst galaxy being relatively unobscured at all wavelengths. The *warm* dust and *SB* source components have fitted values of  $\tau_{9.7} \approx 0.19$  and  $\tau_V = 0.97$ , respectively. Puxley & Brand (1994) estimate a screen extinction to the ionized gas within NGC 7714 of  $A_V \approx 0.86 \pm 0.13$  using optical and near-IR recombination lines, a value that is entirely consistent with our *SB* component optical depth. For our adopted dust model,  $A_V \approx 0.86$  corresponds to  $\tau_{9.7} \approx 0.07\text{--}0.22$ , depending on the influence of scattering in the total effective opacity (the latter value is for zero scattering contribution, as expected for spherical symmetry). This range is again completely consistent with the extinction we find for the *warm* dust component.

The extinction-corrected *SB*-to-dust ratio given in Table 10 is  $L'_{\text{SB}}/L_{\text{dust}} = 0.91$ , indicating that the fitted source component is capable of powering nearly all (i.e., 91%) of the total dust emission. Although we attempt to calculate the true far-IR dust luminosity of the nuclear point source, we may nonetheless overestimate this quantity since our MIPS photometry may still contain flux from outside the nucleus. Such an overestimate could give rise to the fitted slight source-luminosity deficit (i.e., there is not enough source emission to explain the observed dust emission). Given this possible explanation and the fact that the deficit is small (<10%), we conclude that the observed source-to-dust ratio of NGC 7714 is consistent with the total system being powered by star formation.

Our decomposition of this galaxy therefore indicates that the warmest dust in pure low-obscuration starbursts typically has a temperature  $\sim 165$  K and that emission from  $\sim 1000$  K dust is therefore negligible. Also, the observed PAH luminosity in NGC 7714 is  $\sim 5.2\%$  of its total nuclear dust luminosity, providing an estimate of the typical total PAH strength in low-obscuration starbursts. Smith et al. (2007) find a median PAH-to-dust luminosity ratio of  $\sim 10\%$  for the “normal” (i.e., nonstarburst) star-forming galaxies in the SINGS sample, with the ratio ranging between 3.2% and 16% for the sample. Thus, the ratio measured for NGC 7714 is consistent with this range, with the nearly factor of 2 difference from the median value likely indicating real differences in the emission from galaxies with different levels of star formation. Note also that the PAH ratio  $L_{11.3}/L_{7.7} \approx 0.28$  for NGC 7714 is very similar to the value of this ratio for the unobscured mean starburst template ( $\sim 0.27$ ). The PAH emission in NGC 7714 therefore appears to be relatively unobscured, consistent with the results from other extinction indicators.

The total global dust emission in our sample (i.e., obtained using *IRAS* and *ISO* far-IR data) ranges from  $\sim 1.0$  to 1.4 times

the nuclear emission (i.e., obtained using MIPS data). Lançon et al. (2001) estimate that only 10%–50% of the stellar emission in NGC 7714 emerges from the  $2'' \times 2''$  ( $\sim 0.37 \text{ pc}^2$ ) nucleus and therefore infer that 50%–90% of the far-IR *IRAS* emission likely emerges from the extended disk of the galaxy. They further reason that the strength of the extranuclear far-IR emission is likely to be toward the lower end of this range, since the ultraviolet observations used to quantify the stellar emission strength are prone to missing emission from extinguished populations. In comparing the results of our global and nuclear spectral decompositions of NGC 7714, we calculate that at least  $\sim 50\%$  of the *cold* dust component luminosity (and 30% of the total dust emission) emerges from extended regions, consistent with the Lançon et al. (2001) prediction.

**NGC 2623.**—Our extinguished template starburst galaxy is a late-stage merger with long tidal tails and an  $r^{1/4}$  nuclear stellar light profile (Wright et al. 1990; Scoville et al. 2000). The radio continuum (Condon et al. 1991) and mid-IR (Soifer et al. 2001) emission is similarly dominated by a compact nuclear source. The IRS spectrum of NGC 2623 is dominated by deep silicate absorption features at 9.7 and 18  $\mu\text{m}$  and a very steep continuum beyond 20  $\mu\text{m}$ . The fitted optical depths to the *warm* dust and *SB* source components of NGC 2623 are  $\tau_{9.7} \approx 3.5$  and  $\tau_V \approx 4.8$ , respectively. Note that Brandl et al. (2006) find an apparent 9.7  $\mu\text{m}$  optical depth of  $\sim 1.5$ , which is more than a factor of 2 lower than our fitted value. This difference occurs as a result of the method they employ to determine the *apparent* optical depth, namely, interpolating a smooth continuum above the silicate absorption feature and using the ratio of this “unextinguished” continuum to the observed value to infer  $\tau_{9.7}$ . In contrast, the unextinguished continuum in the dust model used in our decomposition method is not smooth at 9.7  $\mu\text{m}$ , but instead features a silicate *emission* feature (the presence of which is consistent with observations; see, e.g., the fit for PG 0804+761), therefore requiring a higher optical depth to obtain the same extinguished continuum.

We find no evidence for the presence of an AGN contribution to the SED of NGC 2623, consistent with the similar conclusion in Risaliti et al. (2000) based on hard X-ray observations. The extinction-corrected *SB*-to-dust ratio given in Table 10 is  $L'_{\text{SB}}/L_{\text{dust}} = 0.88$ , indicating that the fitted source component is capable of powering most of the total dust emission. As with NGC 7714, it is likely that this ratio is indicative of an entirely star formation-powered system (taking into account the likely small overprediction of the nuclear dust luminosity due to the MIPS resolution). Like NGC 7714, the mid-IR spectrum of NGC 2623 also exhibits significant emission from PAHs, albeit a factor of  $\sim 2.5$  weaker. The PAH ratio  $L_{11.3}/L_{7.7} \approx 0.18$  for NGC 2623 is also lower than the value for NGC 7714, with the lower ratio being consistent with PAH emission obscured by a screen of dust with  $\tau_{9.7} \approx 1$  (as determined by comparison with the obscured mean starburst template properties in Table 12). For this optical depth, the apparent PAH luminosity of the mean starburst template is only  $\sim 71\%$  its true emitted value. Using this correction factor, we estimate that the true PAH-to-dust luminosity ratio of NGC 2623 is  $L'_{\text{PAHs}}/L_{\text{dust}} \approx 0.029$ , a factor of  $\sim 1.8$  lower than NGC 7714. See § 10.2 for a detailed comparison of the properties of the low-obscuration system NGC 7714 and the obscured starburst NGC 2623.

**PG 0804+761.**—Our Type 1 template AGN is a variable source displaying  $\sim 40\%$  near-IR and 10.6  $\mu\text{m}$  brightness fluctuations over the course of a decade (Neugebauer & Matthews 1999). The first deep infrared observations of this source were obtained with *ISO* (Haas et al. 2003), which revealed a power-law spectral shape and a very warm infrared SED peaking at  $\sim 30 \mu\text{m}$ . Analysis of its IRS spectrum by Hao et al. (2005b) revealed the presence of

strong 9.7 and 18  $\mu\text{m}$  amorphous silicate emission features. In our decomposition, these emission features are produced by grains in the *warm* dust component. If we assume that the *warm* component is directly illuminated by the PG 0804+761 accretion disk ( $L_{\text{AGN}} = 1.26 \times 10^{12} L_{\odot}$ ), then equation (12) with  $\tilde{U}c\hat{u}_r \rightarrow L_{\nu}/4\pi r^2$  indicates that this dust is located  $\sim 19 \text{ pc}$  from the nucleus. Jaffe et al. (2004) analyze 10  $\mu\text{m}$  VLTI interferometric observations of the nucleus of the nearby Type 2 AGN NGC 1068 and conclude that its torus emission must be confined to a region  $\lesssim 2 \text{ pc}$  in size. Thus, some of the optically thin *warm* component emission from PG 0804+761 may emerge from regions beyond the torus, perhaps from clouds in the narrow-line region. Note that this distance to the *warm* dust is actually an upper limit to the true distance, since the emission may also originate from indirectly illuminated torus clouds (see Fig. 6) at  $r < 19 \text{ pc}$ .

The unextinguished *AGN*-to-dust ratio in the PG 0804+761 decomposition is  $\sim 2$  (see Table 10), indicating that the *AGN* source component is more than capable of heating the total observed dust emission. The inverse of this ratio provides an estimate of the total dust covering factor (i.e., the fraction of sky covered by the torus as seen from the nucleus), which is  $f_{\text{torus}} \approx 0.5$  (note that this value is at the constraint imposed during the fit; see § 9.2). This covering factor is consistent with a torus opening angle of  $\sim 30^\circ$  (i.e.,  $\sin \theta_{\text{torus}} = f_{\text{torus}}$ , where  $\theta_{\text{torus}}$  is the angle extending from the midplane to the top of the torus as viewed from the accretion disk). Based on the statistics of Seyfert galaxies (i.e., the relative numbers of Type 1 and 2 galaxies), Schmitt et al. (2001) find approximately twice as many Type 2 AGNs and hence estimate  $\theta_{\text{torus}} = 45^\circ$ . More recently, Hao et al. (2005a) study the AGNs in the Sloan Digital Sky Survey and conclude that  $\theta_{\text{torus}} \approx 30^\circ$ , consistent with the value obtained from our decomposition.

Jaffe et al. (2004) find that the 8–13  $\mu\text{m}$  VLTI spectrum of NGC 1068 can be decomposed into a  $\bar{T} > 800 \text{ K}$  dust component obscured by a  $\tau_{9.7} = 2.1 \pm 0.5$  screen and a  $\bar{T} = 320 \pm 30 \text{ K}$  component behind a  $\tau_{9.7} = 0.3 \pm 0.2$  screen. The temperatures and screen optical depths of these components are comparable to those obtained in our spectral decomposition (see also the properties of Mrk 463). PG 0804+761 has the worst reduced  $\chi^2$  of the galaxies in our sample, due primarily to the poor fit to its IRS spectrum between 7.5 and 10  $\mu\text{m}$  (although the fit to the rest of the SED is quite good).

Jaffe et al. (2004) report a similar problem in this wavelength range in their fit to the spectrum of NGC 1068 and conclude that the fit is improved using high-temperature calcium aluminum silicate dust instead of the standard olivine-type silicates (the opacity of the 9.7  $\mu\text{m}$  feature of the former species begins near 9  $\mu\text{m}$  as opposed to the  $\sim 8 \mu\text{m}$  onset for olivine). We finally note that our decomposition of the ultraviolet and optical emission is consistent with a largely uncovered *AGN* accretion disk (with only  $\sim 25\%$  covered) consistent with a Type 1 source.

**Mrk 463.**—Our Type 2 template AGN is a merging system with two nuclei separated by  $\sim 4''$  (Mazzarella et al. 1991). The portion of the IRS spectrum obtained with the short-low module is likely dominated by Mrk 463e (since the slit of this module is only  $\sim 3.6''$  wide and the observation targeted the eastern component), while the portion obtained with the wider slit of the long-low module likely contains emission from both nuclei (although the optically bright western component may not contribute significantly at these wavelengths). Mrk 463 has a luminous steep-spectrum radio core, and broad lines are seen in scattered optical (Miller & Goodrich 1990) and direct near-IR light (Goodrich et al. 1994; Veilleux et al. 1997). Like the quasar PG 0804+761, the mid-IR spectrum of this galaxy shows no discernible PAH emission features (Armus et al. 2004). Silicate absorption at 9.7  $\mu\text{m}$  is

clearly seen in the spectrum of Mrk 463, producing a mid-IR continuum dominated by a broad emission-like feature at  $\sim 8 \mu\text{m}$ , characteristic of self-absorbed silicate dust. In our decomposition, this feature is primarily produced by the *warm* component, which has a screen optical depth  $\tau_{9.7} \approx 1.3$ . Like the quasar PG 0804+761, Mrk 463 has a moderately obscured ( $\tau_{9.7} \approx 2.1$ ) *hot* dust component. The *hot* component optical depth and the deviations of the fit to the IRS spectrum from 7.5 to  $9 \mu\text{m}$  are both similar to the reported properties of PG 0804+761 and NGC 1068 described above. Unlike the fit to the quasar PG 0804+761, the *AGN* component of Mrk 463 is completely covered by obscuring clouds (i.e.,  $\epsilon_{\text{AGN}} = 1$ ) as is expected for a Type 2 source.

The *AGN*-to-dust ratio for Mrk 463 is 1.93 (similar to the value for PG 0804+761), consistent with the *AGN* source component powering the total observed dust emission, and implying a torus opening angle  $\theta_{\text{torus}} \approx 31^\circ$ . There is evidence for *ISRF* and *SB* contributions in the decomposition, although these are bolometrically weak compared to the power of the *AGN* ( $< 5\%$ ). Although Mrk 463 and PG 0804+761 have similar *AGN*-to-dust ratios, they have very different quantities of cooler dust. Mrk 463 has 16 times more *cold* dust by mass (see Table 8), and it also has a 14 times smaller dust luminosity-to-mass ratio (also indicative of cooler mean dust temperatures; see Table 10). Similarly, the ratio of the unextinguished *AGN* component luminosity to the total gas mass is 14 times smaller for Mrk 463 (i.e., it has 14 times more gas mass for the same accretion disk luminosity). In the standard *AGN* unification scenario, the only difference between a Type 1 source (such as PG 0804+761) and a Type 2 source (such as Mrk 463) is the orientation of the obscuring torus with respect to the observer. Thus, within this picture, Type 1 and Type 2 *AGNs* should have similar *cold* dust masses relative to their total masses, and they should therefore have similar *AGN* luminosity-to-mass ratios (since the accretion disk luminosity and the total mass of dust do not depend on orientation). In § 10.4 we suggest that the relative orientations of the accretion and host galaxy disks may explain why this simple consequence of the unification scenario does not hold for some galaxies. We therefore emphasize that the SEDs of individual *AGNs* may appear falsely inconsistent with the unification scenario due to local geometrical factors, even if unification holds for *AGNs* as a class.

**NGC 6240.**—The first of our two composite sources is an interacting system containing two nuclei separated by  $\sim 1''$  (so that both nuclei are contained within all IRS slits). With an  $L_{\text{IR}} \approx 6.5 \times 10^{11} L_\odot$  NGC 6240 is technically a LIRG, although it is often treated as a ULIRG since it shares most properties with other members of the class. Based on its optical nuclear spectrum, NGC 6240 is classified as a LINER (Armus et al. 1989), and X-ray observations (Komossa et al. 2003) provide clear evidence for the presence of a pair of *AGNs* located behind significant columns of absorbing neutral gas [ $N_{\text{H}} = (1-2) \times 10^{24} \text{ cm}^{-2}$ ]. The mid-IR spectrum of NGC 6240 is extremely rich, displaying strong PAH features, both low- and high-ionization lines (e.g., [Ne II]  $12.8 \mu\text{m}$  and [Ne V]  $14.3 \mu\text{m}$ ), and strong emission from molecular hydrogen (see Armus et al. 2006). Like NGC 2623, the mid-IR continuum of this galaxy is shaped by strong absorption from silicate grains at  $9.7$  and  $18 \mu\text{m}$ , as indicated by the *warm* component screen optical depth of  $\tau_{9.7} \approx 3.6$ . The near-IR continuum of NGC 6240 is well fitted by a combination of apparently unobscured weak *hot* dust and extinguished ( $\tau_{\text{V}} = 4.7$ ) *SB* component emission. The detection of [Ne V]  $14.3 \mu\text{m}$  in the high-resolution IRS spectrum of NGC 6240 presented in Armus et al. (2006) and the evidence for X-rays are both consistent with the presence of *hot* dust in our decomposition, indicating that a (perhaps small) fraction of the near-IR emission is powered by an *AGN*.

Based on *Chandra* X-ray observations, Lira et al. (2002) conclude that the *AGN* in NGC 6240 likely contributes between 30% and 50% of the bolometric luminosity. However, as reported in Armus et al. (2006), the small [Ne V]/[Ne II] and [Ne V]/ $L_{\text{IR}}$  flux ratios are both consistent with an *AGN* contribution of only 3%–5% of the bolometric luminosity. Similarly, the apparent *hot* dust emission in our decomposition makes up just  $\sim 2\%$  of the total dust luminosity (compared to  $> 36\%$  and  $30\%$  for PG 0804+761 and Mrk 463, respectively), so that any contribution to the observed near- and mid-IR from an *AGN* is very small. On the other hand, the *SB*-to-dust ratio for NGC 6240 is 1.43, indicating that the total observed dust emission could be powered by the observed *SB* component. This galaxy therefore presents quite a puzzle, whereby its appearance changes radically depending on where you look: although X-rays suggest powerful *AGNs*, data at optical and longer wavelengths do not require such a presence. We note that even though the *hot* component in the decomposition is unobscured, it could still be associated with a deeply obscured *AGN* in a clumpy geometry where most of the *hot* dust is too obscured to be seen, and we view only the most unobscured portions (see § 10.3). If this scenario is true, the actual *hot* dust contribution to the total bolometric luminosity could easily be pushed higher.

**Mrk 1014.**—Our second composite source is a radio-quiet infrared-luminous QSO with broad optical emission lines ( $\text{FWHM H}\beta > 4000 \text{ km s}^{-1}$ ). Mrk 1014 displays twin tidal tails, indicative of a recent interaction and merger (MacKenty & Stockton 1984). It is a relatively warm far-IR source, with the peak of its SED located around  $70 \mu\text{m}$ . Its mid-IR spectrum is characterized by a nearly power-law continuum, with no obvious silicate emission or absorption features, and weak PAH emission (see Armus et al. 2004). This power-law continuum is rather remarkable (assuming that the continuum is thermal in origin) since a nearly featureless SED must be constructed from emission components that are known to have significant features (i.e., silicates). The decomposition that provides a solution to this puzzle is consistent with Mrk 1014 being a composite source, containing a combination of dust components seen in both our template starbursts and *AGNs*. Like the *AGNs*, Mrk 1014 contains a moderately obscured ( $\tau_{9.7} \approx 2.7$ ) *hot* dust component and a much less obscured *warm* component ( $\tau_{9.7} \approx 0.14$ ). Like the starbursts (and unlike the quasar), Mrk 1014 also contains bolometrically significant emission from cooler dust, comprising  $\sim 60\%$  of its total dust luminosity (we argue in § 10.4 that some of this far-IR emission is likely powered by the *AGN*).

The extinction-corrected *AGN*-to-dust and *SB*-to-dust luminosity ratios of Mrk 1014 are 0.66 and 0.17, respectively, indicating that the *AGN* is capable of powering  $\sim 66\%$  of the observed dust emission from the galaxy. As fitted, the *AGN* and *SB* components are together capable of powering 83% of the observed dust emission, thereby requiring the presence of at least an additional 17% source luminosity to power the remaining dust emission (note also that the total nuclear dust luminosity from Mrk 1014 is uncertain by  $\sim 20\%$  since no MIPS data are available to constrain its far-IR SED). If all of this undetected source luminosity emerges from the *AGN* accretion disk (e.g., if we underpredict the *AGN* component luminosity as a result of too rigid a constraint on the *hot*-to-*AGN* luminosity ratio), the *AGN* would account for 83% of the bolometric luminosity of Mrk 1014. If, on the other hand, the remaining undetected source luminosity is entirely produced by a starburst (e.g., if we underpredict the *SB* component luminosity as a result of missing emission from highly embedded regions), then the *AGN* would account for 66% of the bolometric luminosity.

Armus et al. (2007) create diagnostic diagrams based on mid-IR spectral lines (see their Figs. 5–8) that are all consistent with an AGN fraction between 50% and 90% for Mrk 1014. In addition, Boller et al. (2002) conclude that Mrk 1014 is dominated by an AGN and not star formation based on X-ray observations. If we take the *PAHs*-to-dust luminosity fractions of the galaxies NGC 2623 and NGC 6240 to be representative of the range of values in obscured starbursts, then the *PAHs*-to-dust ratio of Mrk 1014 suggests that between  $\sim 38\%$  and  $57\%$  of its bolometric luminosity is powered by obscured star formation (assuming that all PAH emission comes from star formation). Given our conclusion above that the starburst contribution is between 17% and 34%, it is therefore likely either that we are underestimating the total starburst contribution based on the source components (which seems improbable given the corroborating X-ray and emission-line evidence) or that some of the observed PAH emission may actually be powered by the AGN (see § 10.4). We note as well that the PAH feature luminosity ratios for Mrk 1014 (see Table 11), in particular the  $7.7\ \mu\text{m}$  complex, differ significantly from the template starbursts, perhaps indicative of an AGN contribution giving rise to nonstandard PAH emission.

### 10.2. Comparison of Starburst SEDs

From our modest sample of two starburst galaxy decompositions, it is apparent that starburst SEDs do not form a homogeneous group. Comparing the fits of NGC 2623 and NGC 7714, noticeable differences include a 30% higher maximum dust temperature, a 20 times higher maximum optical depth, a 2.5 times weaker *PAHs*-to-dust luminosity ratio, and comparatively weaker [Ne III]  $15.56\ \mu\text{m}$ , [S III]  $18.71\ \mu\text{m}$ , [S III]  $33.48\ \mu\text{m}$ , and [Si II]  $34.82\ \mu\text{m}$  line emission. If the nuclear emission from each starburst emerges from distinct star-forming clouds consisting of embedded stars surrounded by cocoons of dust (see Fig. 1), then many of the observed variations in the SEDs of NGC 7714 and NGC 2623 can be understood as resulting from (1) differences in the total number of star-forming clouds (i.e., if individual cloud complexes in each galaxy have similar intrinsic luminosities, then the total luminosity of each galaxy is determined by the total number of clouds it contains) and (2) the mean optical depth through an individual cloud. There are, of course, many other factors shaping the SEDs of starbursts as well, e.g., age and metallicity. The simple model described in this section is therefore not intended to provide a comprehensive explanation of all starburst properties, but rather a structure within which to understand several general properties.

If we assume for simplicity that each cloud in a starburst has constant gas density, then the optical depth through a cloud is  $\tau(r) = \tau_{\text{cloud}}(r/r_{\text{cloud}})$ , where  $\tau_{\text{cloud}}$  and  $r_{\text{cloud}}$  are the total optical depth and radius of the cloud, respectively. As described in § 5.1, direct emission from stars heats a shell of dust out to a radius  $r_{\text{shell}}$ , corresponding to the optical depth  $\tau_{9.7}^{\text{shell}}$ , where the cloud becomes optically thick to the heating stellar photons (i.e., essentially the outer edge of the photodissociation region). Using the equation for the optical depth above, we obtain  $r_{\text{shell}}^{2623}/r_{\text{shell}}^{7714} = (\tau_{\text{cloud}}^{2623}/\tau_{\text{cloud}}^{7714})(r_{\text{cloud}}^{2623}/r_{\text{cloud}}^{7714})$ . Here we assume that  $\tau_{9.7}^{\text{shell}}$  is the same for all clouds since it depends only on the properties of dust and the illuminating radiation field. With  $\tau_{\text{cloud}} \rightarrow \tau_{\text{warm}}$  (i.e., using the *warm* component optical depth as a proxy for the total cloud optical depth), this gives  $r_{\text{shell}}^{2623}/r_{\text{shell}}^{7714} \approx 0.05(r_{\text{cloud}}^{2623}/r_{\text{cloud}}^{7714})$ . If the clouds in each galaxy are similar in size, this suggests that  $r_{\text{shell}}^{2623}/r_{\text{shell}}^{7714} < 1$  (i.e., the *warm* dust shell from Fig. 6 is geometrically more extended in NGC 7714 than NGC 2623), so that stellar photons penetrate to much larger radii in the star-forming clouds of NGC 7714. Furthermore, the fractional cloud volume containing dust at the temperature of the *warm* component should be smaller in NGC

2623 than NGC 7714, and consequently the mass of *warm* dust relative to the total mass should be smaller as well. Indeed, from Table 8 we find that  $(M_{\text{warm}}/M_{\text{dust}})_{7714} \approx 1.3 \times 10^{-4}$  and  $(M_{\text{warm}}/M_{\text{dust}})_{2623} \approx 4 \times 10^{-5}$ , consistent with this prediction.

For  $r < r_{\text{shell}}$ , energy conservation dictates that the temperatures of grains within a cloud scale roughly as  $T \propto r^{-1/2}$ . This, coupled with the fact that  $r_{\text{shell}}^{2623} < r_{\text{shell}}^{7714}$ , implies that the mean temperature of such grains should be higher in NGC 2623 than NGC 7714, a prediction that is consistent with its 25% higher *warm* component temperature. The luminosities per unit mass of dust at the temperatures of the *warm* components in the two galaxies scale approximately as  $(\bar{T}_{\text{warm}}^{2623}/\bar{T}_{\text{warm}}^{7714})^4 \approx (1.25)^4 \approx 2.4$  (i.e., a mass of *warm* dust from NGC 2623 will be  $\sim 2.4$  times more luminous than an equivalent mass from NGC 7714). This ratio, along with the absolute *warm* component dust masses for the two galaxies, suggests that the ratio of the *warm* component luminosities should be  $L_{\text{warm}}^{2623}/L_{\text{warm}}^{7714} \approx (\bar{T}_{\text{warm}}^{2623}/\bar{T}_{\text{warm}}^{7714})^4 (M_{\text{warm}}^{2623}/M_{\text{warm}}^{7714}) \approx 4$ . The actual fitted ratio is 4.7, in reasonable agreement with this prediction. Furthermore, the  $L_{\text{dust}}/M_{\text{H}}$  ratio from Table 10 is  $\sim 30\%$  higher in NGC 2623 than in NGC 7714. If the *warm* dust in NGC 7714 were at the temperature of the *warm* dust in NGC 2623, the total dust luminosity of NGC 7714 would increase by  $\sim 40\%$ , and the resulting dust luminosity-to-mass ratios of the two sources would differ by only  $\sim 7\%$ . Thus, the different values of  $L_{\text{dust}}/M_{\text{gas}}$  are directly related to the higher *warm* dust temperature in NGC 2623, which itself is likely directly related to the higher optical depth through the star-forming clouds in that galaxy.

The apparent *PAHs*-to-dust luminosity ratio is  $\sim 2.5$  times lower in NGC 2623 than in NGC 7714. We estimate that extinction to the *PAHs* component in NGC 2623 reduces its luminosity by a factor of 1.4 (see § 10.1), so that the unextinguished *PAHs*-to-dust luminosity ratios for the two galaxies differ by a factor of 1.8. With this correction, we also find that  $L_{\text{PAHs}}/M_{\text{gas}}$  is only a factor of 1.4 greater in NGC 7714, as opposed to the observed factor 1.9. As described above, the *warm*-to-total dust mass ratio is less in NGC 2623, so that the volume within which PAH molecules are heated is smaller for this source. Therefore, some portion of the reduced *PAHs* luminosity giving rise to the differences in ratios described above likely results from such a difference in heating geometries. Using the ratio of the extinction-corrected  $L_{\text{PAHs}}/M_{\text{gas}}$  values derived above, we estimate that this geometrical effect must decrease the observed *PAHs* luminosity of NGC 2623 by a factor of 1.4 (i.e., assuming that the full difference is caused by this geometrical effect). Note that this factor is similar to the value  $[(M_{\text{warm}}/M_{\text{dust}})_{2623}/(M_{\text{warm}}/M_{\text{dust}})_{7714}](L_{\text{warm}}^{2623}/L_{\text{warm}}^{7714}) \approx 1.4$ , where the first term accounts for the difference in volume within which PAHs are heated and the second term accounts for the difference in heating intensity. With these two correction factors of 1.4, the *PAHs*-to-dust luminosity ratio of NGC 2623 differs by only  $\sim 30\%$  from that of NGC 7714. Recalling that the dust luminosity of NGC 7714 would increase by  $\sim 40\%$  if its *warm* dust were at the same temperature of the dust in NGC 2623, the *PAHs*-to-dust luminosity ratios of the two galaxies differ by less than 10%.

The differences in the apparent PAH emission from our two starburst templates may therefore be understood as resulting from a combination of (1) extinction to the PAHs, (2) the geometry of the PAH-emitting regions, and (3) the method of normalizing the *PAHs* component luminosity. We suggest that the ratio  $L_{\text{PAHs}}/M_{\text{gas}}$  is a somewhat better tracer of the true strength of PAH emission than  $L_{\text{PAHs}}/L_{\text{dust}}$ , since it is less affected by temperature effects. The latter ratio, or a related quantity such as  $L_{6.2}/L_{\text{FIR}}$ , is often used to quantify the amount of star formation in galaxies (e.g., Peeters et al. 2004). Given that both our template starbursts are believed to be entirely powered by star formation, it is clear that there is

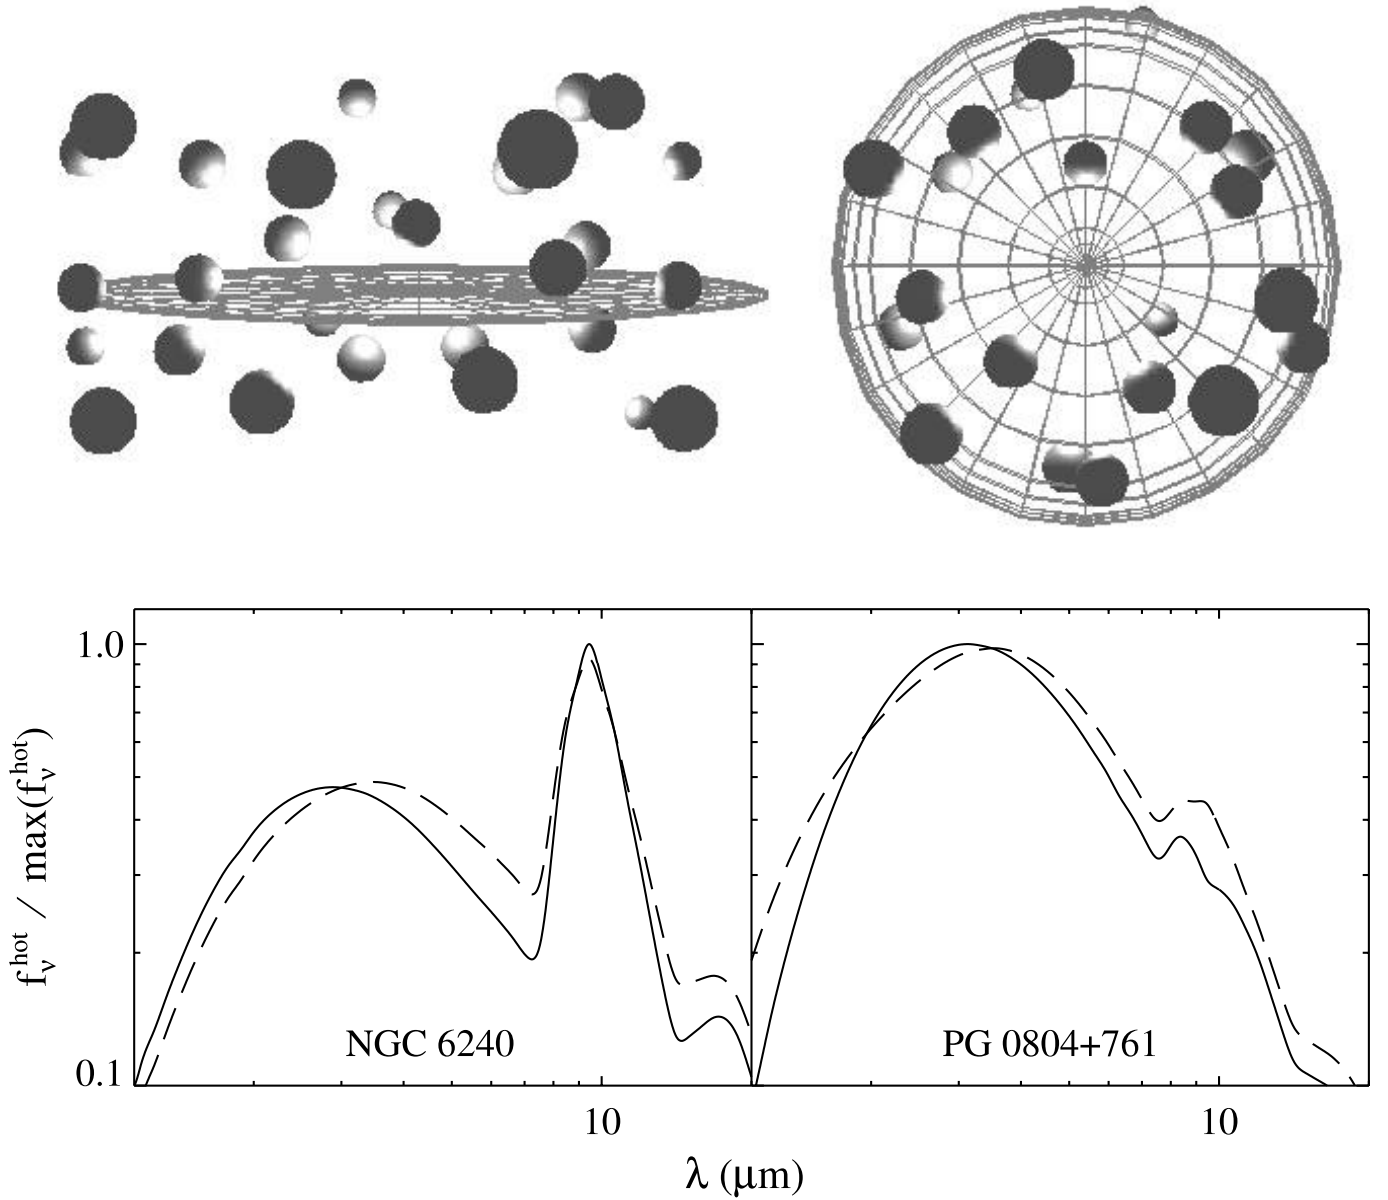

FIG. 11.— Edge-on (*top left*) and face-on (*top right*) views of a clumpy torus comprised of a toroidal distribution of discrete clouds. Directly illuminated cloud faces (i.e., the sources of *hot* emission) are obscured from most viewpoints by dust on the shaded side of each cloud. SEDs of the fitted NGC 6240 and PG 0804+761 *hot* components are shown beneath the schematic torus model representing their geometry (*solid lines*), along with model SEDs derived assuming that a fraction of the *hot* component emission (50% for NGC 6240 and 75% for PG 0804+761) is obscured by a  $\tau_V = 25$  screen, with the remainder emerging unobscured (*dashed lines*).

significant variation in the relative strength of PAH emission in pure starbursts. We therefore caution that great care must be taken when using any of these metrics to derive absolute quantities of star formation, since both extinction and geometrical effects may result in different ratios for pure starburst galaxies.

### 10.3. Hot Dust Emission from Clumpy AGN Tori

If the obscuring dust surrounding an AGN accretion disk is arranged in a smooth (i.e., nonclumpy) toroidal distribution, then the  $\sim 3\text{--}8\ \mu\text{m}$  SEDs of Type 1 sources should be dominated by emission from relatively unobscured *hot* dust (since this *hot* dust is viewed directly by the observer, with no intervening material from the torus along the line of sight to obscure it). If, however, the obscuring structure is instead composed of discrete clouds distributed in a roughly toroidal shape (i.e., a clumpy torus), then *hot* dust emission is not expected to emerge unobscured. As illustrated in Figure 11, the directly illuminated (and therefore

hotter) faces of clouds in a clumpy torus always point radially toward the nucleus, and therefore away from the observer. Thus, emission from these hot cloud faces, and therefore *hot* component emission from such sources, is obscured by cooler dust on the shaded sides of clouds. Our decomposition of the quasar PG 0804+761 includes a moderately obscured ( $\tau_{9.7} \approx 1.2$ ) *hot* dust component, consistent with such a clumpy obscuring torus.

The SED of the *hot* dust component from the PG 0804+761 decomposition is shown in the bottom right panel of Figure 11. Also shown is a curve representing emission from dust at the temperature of the PG 0804+761 *hot* component, with 75% obscured by a  $\tau_V = 25$  screen (i.e., equivalent to the screen obscuring the AGN component), and the remaining 25% emerging unobscured. While this model with nonuniform coverage does not exactly reproduce the SED from the fully covered model (in particular at shorter wavelengths), it nonetheless produces a very similar spectrum that would also provide an adequate fit to the PG 0804+761 SED (with

suitable small adjustments to the *AGN* and *warm* components). Thus, the SED of *hot* component emission from a highly obscured geometry with a few clear lines of sight may appear similar to the emission from a fully covered but less obscured geometry. For a traditional torus made from a smooth dust distribution, *hot* dust emission from a face-on source would emerge unobscured with strong silicate emission features (since there are no shaded sides of clouds to obscure the *hot* emission). Our decomposition of PG 0804+761 does not show such strong features from the *hot* component, suggesting that its *hot* dust, and possibly that of most Type 1 sources, may therefore be significantly obscured by the shadowed sides of clumpy torus clouds.

The bottom left panel of Figure 11 depicts the fitted NGC 6240 *hot* dust component SED (unobscured in the decomposition), along with a model in which 50% of its *hot* dust is covered by a screen with  $\tau_V = 25$  and the remainder emerges unobscured. As with PG 0804+761, this partially covered model does not precisely reproduce the fitted *hot* dust component. It is, however, similar enough to the fitted component to provide a reasonably good fit (i.e., since the *hot* component of NGC 6240 contributes in a region with strong contributions from several other components, the small deviations between the two models would not affect the decomposition greatly). The near equivalence of these two models demonstrates that emission from a highly obscured, but only partially covered, geometry may appear quite similar to emission from a fully covered geometry at much lower levels of obscuration. Therefore, despite the small apparent optical depth derived from the fit to NGC 6240, it is possible that the *hot* component in this source is actually much more significantly obscured (i.e., we may only see direct emission from a few clear lines of sight, while the majority of the *hot* dust is completely obscured).

#### 10.4. Origin of the Far-IR Emission in AGNs

Since emission from dust at far-IR ( $\lambda > 50 \mu\text{m}$ ) wavelengths is likely to emerge unobscured from galaxies, the average properties of the far-IR SEDs of AGNs (e.g., their relative cold dust luminosities and masses) should be similar for all sources (assuming that their nuclei are similarly structured), independent of their orientation-based (i.e., Type 1 vs. Type 2) classification. As described in § 10.1, the two template AGNs in our sample have very different far-IR properties (e.g., Mrk 463 has a dust luminosity-to-mass ratio  $\sim 15$  times that of PG 0804+761), in sharp contrast to these expectations. Farrah et al. (2003) use a two-component (starburst+AGN) template decomposition to conclude that some optically classified AGNs with strong far-IR emission likely have significant contributions from starbursts. While this is likely true for many AGNs with cool far-IR SEDs, it does not appear to hold for Mrk 463 (see § 10.1). As illustrated in Figure 12, we instead suggest that the far-IR emission from *some* AGNs (including Mrk 463) is powered by the AGN itself and originates from cool dust in the disk of the host galaxy. We note here that this suggestion is based on the SEDs of only two AGNs, so further study using a much larger sample (to be presented in a subsequent paper) is needed before conclusions are drawn about the origin of far-IR emission from the class of AGNs.

While it is often assumed that an AGN accretion disk and the disk of the galaxy hosting the AGN are coplanar (as in the top of Fig. 12), this geometrical assumption is not necessarily always true. After the merger of two galaxies, the resulting accretion and host galaxy disks may eventually come to rest in the same plane (e.g., due to torques), but there is a period of time after the merger during which their relative orientation is essentially random. If the two disks are tilted with respect to each other, a significant quantity of dust in the disk of the host galaxy may be heated by the

FIG. 12.—If the disk of the host galaxy and the AGN accretion disk are coplanar (*top*), very little dust in the disk of the galaxy is illuminated by the AGN (i.e., the radiation cones from the accretion disk do not intersect the host galaxy disk). In contrast, if the host galaxy and AGN accretion disks are orthogonal (*bottom*), the AGN heats dust over a large area of the galaxy disk (i.e., the radiation cones *do* intersect the host galaxy disk), resulting in far-IR and possibly PAH emission. Broad arrows label the lines of sight giving rise to the indicated properties of the emergent SEDs for the various geometries.

AGN out to large radial distances (see the bottom of Fig. 12). Assuming that the galaxy disk is not a significant source of opacity, a galaxy therefore appears as a Type 1 or Type 2 AGN depending on the relative orientation of the obscuring torus with respect to the observer (i.e., the standard AGN unification scenario). In addition, depending on the relative orientation of the host galaxy and AGN accretion disks (but independent of the orientation of the observer), the source may exhibit weak or strong far-IR emission (i.e., “Warm” or “Cold” far-IR SEDs as labeled in Fig. 12). In this model, Mrk 463 and PG 0804+761 are therefore “Cold” and “Warm” far-IR sources, respectively, with emission arising from geometries similar to those in the bottom and top of Figure 12, respectively. We note that the geometry suggested here has a similar impact on the SEDs of galaxies as the “warped disk” geometry from Sanders et al. (1989).

As described in § 10.1, we estimate that  $\sim 35\%$  of the bolometric luminosity of Mrk 1014 is powered by star formation. If all of this luminosity emerges in the form of *cool* dust, this still leaves  $\sim 30\%$  of its 70 K emission component to be powered by its AGN. We therefore suggest that the geometry of Mrk 1014 is likely to be similar to that of Mrk 463 (i.e., the bottom of Fig. 12). In addition, the luminosity of the Mrk 1014 *PAHs* component compared to its inferred starburst fraction suggests that between  $\sim 20\%$  and  $50\%$  of its PAH emission is powered by its AGN (i.e., derived by comparison with the properties of the obscured starbursts NGC 2623 and NGC 6240; see § 10.1). Schweitzer et al. (2006) argue against AGN-powered far-IR emission in a sample of QSOs observed with *Spitzer* based largely on the fact that PAHs are destroyed in a hard AGN radiation field. However, in the geometry of Figure 12, the radiation field gradually softens as the photons propagate through the galaxy disk, so that at some radius PAH molecules illuminated by the AGN may survive. Clearly, more work is required (e.g., radiative transfer calculations with realistic PAH destruction models) to verify if this scenario is indeed realistic, and we do not dispute that some far-IR emission in AGNs is powered by starbursts, but the suggested mechanism to generate far-IR and PAH emission in AGNs as a result of the interaction of the accretion disk with its host galaxy should be considered as well. Furthermore, we warn against the blanket assumption that all PAH and far-IR emission is directly associated with star formation, as this could result in an overestimation of the true level of star formation activity in galaxies.

## 11. SUMMARY

We have presented a new multicomponent SED decomposition method. Our principal goal for this paper is to demonstrate the effectiveness of the method for studying composite dusty galaxies, although we note that the method is quite general and may be applicable to much broader selections of galaxies. To demonstrate the efficacy of the method, we have applied it to the ultraviolet through millimeter wavelength SEDs of the nuclei of the unobscured and obscured template starbursts NGC 7714 and NGC 2623, as well as the template Type 1 and Type 2 AGNs PG 0804+761 and Mrk 463. We find that the pan-spectral SEDs of these sources are all consistent with being entirely powered by star formation and accretion, respectively. We compare the SEDs of the two starburst galaxies and demonstrate that the differences in their properties (including the luminosities and masses of their dust components and the strength of their PAH emission) can largely be explained in terms of the different mean optical depths through the dusty cocoons surrounding their newly formed stars. In comparing the template AGNs, we find that the far-IR SEDs of the two sources differ significantly, which we suggest may result from variations in the relative orientation of their host galaxy and AGN accretion disks.

We also decompose the nuclear SEDs of the composite sources NGC 6240 and Mrk 1014. Our decomposition finds very little evidence for an AGN contribution in NGC 6240 ( $\sim 2\%$ ), with the total dust emission in that galaxy being powered by a starburst with mean optical depth  $\tau_V \approx 5$ . We note, however, that we cannot rule out a larger contribution from a deeply embedded AGN visible only in X-rays. The SED of Mrk 1014 is consistent with a

galaxy that is  $\sim 65\%$  AGN powered, with a  $\sim 35\%$  contribution from star formation. Like Mrk 463, we find that Mrk 1014 has a far-IR excess (compared to the Type 1 AGN PG 0804+761) and attribute this to cold dust in the disk of its host galaxy, which is heated directly by its AGN. We also estimate that up to 50% of the detected PAH emission in Mrk 1014 may be powered by radiation from the AGN that has softened as it propagates through the galaxy disk (and therefore does not destroy the fragile PAH molecules). In a future paper, we will apply this decomposition method to a much larger sample of starbursts, AGNs, LIRGs, and ULIRGs observed as part of the *Spitzer* GTO program in order to provide a suite of templates to aid in understanding both the local dusty galaxy population and the high-redshift LIRGs and ULIRGs now being uncovered by *Spitzer*.

We would like to thank Moshe Elitzur, Vandana Desai, and Kieran Cleary for many helpful discussions. We also wish to acknowledge the assistance of the anonymous referee, whose review has resulted in a much improved paper. This work is based (in part) on observations made with the *Spitzer Space Telescope*, which is operated by the Jet Propulsion Laboratory, California Institute of Technology under NASA contract 1407. Support for this work was provided by NASA through contract 1257184 issued by JPL/Caltech. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

## APPENDIX A

## WEIGHTING OF NONUNIFORMLY SAMPLED DATA

The sampling term,  $\hat{\Lambda}$ , in equation (3) is required to produce sensible and fair fits of nonuniformly sampled data, as is the case when coarsely sampled photometry is joined together with spectral data. If such a term is excluded (i.e.,  $\hat{\Lambda}_k = 1$  for all  $\lambda_k$ ), then  $\chi^2$  will be dominated by the more finely sampled spectral data, simply because it contains many more data points. To establish a weighting scheme for nonuniformly sampled data, we define the quantity

$$n_{\text{IRS}} \equiv N_{\text{IRS}} / \log(\lambda_{\text{max}}^{\text{IRS}} / \lambda_{\text{min}}^{\text{IRS}}), \quad (\text{A1})$$

which is the number of spectral samples per logarithmic wavelength interval in an IRS spectrum. Here  $N_{\text{IRS}}$  is the total number of spectral samples in the IRS spectrum, and  $\lambda_{\text{min}}^{\text{IRS}} \equiv \min(\lambda_{\text{IRS}})$  and  $\lambda_{\text{max}}^{\text{IRS}} \equiv \max(\lambda_{\text{IRS}})$ , where  $\lambda_{\text{IRS}}$  is the array of wavelength points in the IRS spectrum. We then divide the full SED into  $N_{\text{bins}}$  wavelength bins (typically 10), distributed in even logarithmic wavelength intervals, with each bin  $l \in [0, 1, \dots, N_{\text{bins}} - 1]$  containing minimum and maximum wavelengths

$$\lambda_{\text{min}}^l \equiv \min(\lambda_l) = \lambda_{\text{min}} \left( \frac{\lambda_{\text{max}}}{\lambda_{\text{min}}} \right)^{l/N_{\text{bins}}}, \quad \lambda_{\text{max}}^l \equiv \max(\lambda_l) = \lambda_{\text{min}} \left( \frac{\lambda_{\text{max}}}{\lambda_{\text{min}}} \right)^{(l+1)/N_{\text{bins}}}, \quad (\text{A2})$$

where  $\lambda_{\text{min}} \equiv \min(\lambda)$  and  $\lambda_{\text{max}} \equiv \max(\lambda)$  are the minimum and maximum wavelength in the SED having wavelength array  $\lambda$ . Each bin is then assigned a total weight based on the sampling of the IRS spectrum

$$\Lambda_{\text{bins}}^l = n_{\text{IRS}} \log \left( \frac{\lambda_{\text{max}}^l}{\lambda_{\text{min}}^l} \right) = \frac{N_{\text{IRS}}}{N_{\text{bins}}} \frac{\log(\lambda_{\text{max}} / \lambda_{\text{min}})}{\log(\lambda_{\text{max}}^{\text{IRS}} / \lambda_{\text{min}}^{\text{IRS}})}. \quad (\text{A3})$$

The weight of bins containing no data points is redistributed to the nearest bins containing data above and below, with the weight going to each bin being a linear function of the proximity to the bin with no data; i.e., for a bin  $l'$  containing no data, the weight distributed to the bins  $l'_+$  and  $l'_-$  above and below is

$$\delta \Lambda_{\text{bins}}^{l' \rightarrow l'_+} = \Lambda_{\text{bins}}^{l'_+} \frac{l'_+ - l'}{l'_+ - l'_-}, \quad \delta \Lambda_{\text{bins}}^{l' \rightarrow l'_-} = \Lambda_{\text{bins}}^{l'_-} \frac{l' - l'_-}{l'_+ - l'_-}. \quad (\text{A4})$$

The weighting in each bin is then distributed to the data points within that bin, so that for a data point at wavelength  $k$  that is in bin  $l$ ,

$$\Lambda_{k \in l} = \frac{\Lambda_{\text{bins}}^l}{N_l}, \quad (\text{A5})$$

where  $N_l$  is the number of data points in bin  $l$ . Thus, the  $\Lambda_k$  represent the number of effective spectral samples that each data point represents so that the sampling over the entire SED is equivalent to the IRS sampling. Finally, we normalize and scale the weighting function

$$\hat{\Lambda}_k = N_{\text{tot}} \frac{\Lambda_k}{\sum_k \Lambda_k}, \quad (\text{A6})$$

so that  $\sum_k \hat{\Lambda}_k = N_{\text{tot}} = N_{\text{phot}} + N_{\text{IRS}}$ , the total number of data points in the spectral energy distribution, as would be the case if the weighting function were taken to be unity at all wavelengths (i.e.,  $\hat{\Lambda}_k = 1$  for all  $\lambda_k$ ).

## APPENDIX B

### IRS STATISTICAL FLUX DENSITY UNCERTAINTIES

We derive the statistical flux density uncertainty at each wavelength element of an IRS spectrum by differencing two spectra obtained at different nod positions of each slit. The initial estimate of the uncertainty at each wavelength is

$$\delta f_k = \frac{f_1(\lambda_k) - f_2(\lambda_k)}{(\sqrt{2})^2}, \quad (\text{B1})$$

where  $f_1$  and  $f_2$  are the observed flux densities in nod positions 1 and 2, and the two factors of  $\sqrt{2}$  both correct for the introduction of noise resulting from the subtraction and account for the reduction in noise of the final flux densities resulting from averaging the two nods. At each wavelength, this array contains a single sample of the true uncertainty drawn from the probability distribution function having standard deviation  $\sigma(\lambda_k)$ . We estimate the true value of the statistical uncertainty at each wavelength by calculating the standard deviation of the points in a window of width  $W$  (typically around 20 wavelength bins, with the window size decreasing near the edges of the spectrum) and assigning this value as the standard deviation of the central wavelength, i.e.,

$$\sigma^2(\lambda_k) = \frac{1}{W+1} \sum_{i=k-W/2}^{k+W/2} (\delta f_i - \langle \delta f \rangle)^2, \quad (\text{B2})$$

where  $\langle \delta f \rangle \approx 0$  is the mean value of  $\delta f$  for the points within the window. Since we are approximating a function that in principle should be sampled on an infinitely fine grid, our estimated  $\sigma$  array will always show some residuals from our finite grid size. As a result, the  $\sigma$  array does not always have the expected property that  $\sim 68\%$  of the  $\delta f_k$  are enveloped by the  $1\sigma$  contour. We therefore perform one final step, smoothing our estimated  $\sigma$  array with a window of width  $W$  and scaling the entire array until it has the expected behavior that the  $1\sigma$  error contour envelops  $68\%$  of the  $\delta f_k$ .
