In this paper, we compare the relative sensitivities of gamma-ray and neutrino observations to the dark matter annihilation cross section in leptophilic models such as have been designed to explain PAMELA data. We investigate whether the high energy neutrino telescope IceCube will be competitive with current and upcoming searches by gamma-ray telescopes, such as the Atmospheric Čerenkov Telescopes (H.E.S.S., VERITAS, and MAGIC), or the Fermi Gamma-Ray Space Telescope, in detecting or constraining dark matter particles annihilating in dwarf spheroidal galaxies. We find that after 10 years of observation of the most promising nearby dwarfs, IceCube will have sensitivity comparable to the current sensitivity of gamma-ray telescopes only for very heavy ($m_X \gtrsim 7$ TeV) or relatively light ($m_X \lesssim 200$ GeV) dark matter particles which annihilate primarily to $\mu^+ \mu^-$. If dark matter particles annihilate primarily to $\tau^+ \tau^-$, IceCube will have superior sensitivity only for dark matter particle masses below the 200 GeV threshold of current Atmospheric Čerenkov Telescopes. If dark matter annihilations proceed directly to neutrino-antineutrino pairs a substantial fraction of the time, IceCube will be competitive with gamma-ray telescopes for a much wider range of dark matter masses.

I. INTRODUCTION

Of the many dark matter candidates to have been proposed, those within the classification of weakly interacting massive particles (WIMPs) are often considered to be the best motivated (for reviews, see Refs. [1,2]). In particular, if a stable particle with an electroweak-scale mass and electroweak-scale interactions exists, such particles would have annihilated among themselves at a rate in the early universe that naturally led them to freezeout with a relic density similar to the measured dark matter abundance. This process of dark matter annihilation is also predicted to be taking place in the present universe, providing the basis for dark matter indirect detection experiments. Such experiments search for the annihilation products of dark matter particles, including electrons and/or positrons, anti-protons, photons, and neutrinos. Promising sites for the observation of dark matter annihilation products include the core of the Sun [3], the Earth [4], our Galactic halo [5], Galactic center [6], and dwarf satellite galaxies [7]. Here, we examine the sensitivity of the IceCube neutrino detector to dark matter annihilations taking place in dwarf satellite galaxies in the Milky Way.

In the case of dark matter candidates that annihilate primarily to gauge bosons or hadronic final states, gamma-ray telescopes provide a more sensitive test of dark matter annihilations taking place in dwarf spheroidals than can be accomplished with existing or planned neutrino telescopes. This is not necessarily the case, however,

if the dark matter annihilates largely to leptons. Dark matter annihilating to leptonic final states has become increasingly well motivated by the anomalous observations recently reported by several cosmic ray experiments, including PAMELA, which has observed an excess of cosmic ray positrons (relative to electrons) between 10 and 100 GeV [8] (along with previous experiments, including HEAT [9] and AMS-01 [10], which also reported evidence for such an excess). A surplus of cosmic ray electrons and/or positrons has also been reported by the Fermi Gamma-Ray Space Telescope (FGST) [11], however this excess is less than that previously reported by ATIC [12].

Although an excess of cosmic ray positrons/electrons may come from more conventional sources such as pulsars [13], a great deal of interest has been generated in the possibility that these signals might result from dark matter particles annihilating in the local halo of the Milky Way. Efforts to produce such signals with dark matter, however, have faced some model-building challenges. First, as there is no observed excess of cosmic ray antiprotons, the annihilation channels must be “leptophilic,” i.e. the WIMPs must annihilate preferentially to leptons. Many models have been proposed with this property [14]. Second, the local halo density of dark matter is insufficient to explain the signals unless the annihilation rate is supplemented by a large factor $\sim 10 - 10^3$ relative to that predicted for a typical smoothly distributed thermal relic. Such a boost may arise due to the properties of the dark matter candidate

itself; for example, via a nonperturbative Sommerfeld enhancement to the low-velocity cross section resulting from the exchange of a light state [15], or a Breit-Wigner enhancement [16,17]. Because of the smaller velocity dispersion of dark matter particles in smaller halos, the annihilation cross section in a dwarf galaxy may be even higher than that in the halo of the Milky Way [15,18–20]. Alternatively, an enhancement to the annihilation rate over the standard prediction can result if the dark matter is not distributed smoothly. In this paper, we examine bounds on the observed WIMP annihilation cross section, $\langle\sigma v\rangle$, including any relevant enhancements or boost factors, the origin of which we leave unspecified.

The prospects for IceCube observations of high energy neutrinos from dark matter annihilations or decays in the Galactic halo have been considered in [21–24]. It was found that IceCube will be sensitive to WIMP annihilation cross sections of order 10^{-24} to 10^{-23} $\text{cm}^3 \text{s}^{-1}$, depending on the WIMP mass. As Super-Kamiokande is located in the Northern Hemisphere, and therefore is subject to significantly reduced atmospheric backgrounds from the direction of the Galactic center, its sensitivity to the neutrino flux from dark matter annihilations in the inner Milky Way has been studied in [25,26] and found to be roughly an order of magnitude less sensitive than the IceCube projections. Nonetheless, Ref. [25] finds that Super-Kamiokande already constrains annihilations to $\tau^+\tau^-$ as the explanation for the cosmic ray anomalies (though this channel is also disfavored by the large expected γ flux), while Ref. [26] finds that Super-Kamiokande may also constrain the scenario in which neutrinos are directly produced in the annihilations as frequently as charged leptons. While these studies are concerned with the signature of annihilations occurring in the Galactic center, here we focus instead on the annihilations taking place in satellite dwarf spheroidal galaxies of the Milky Way. In particular, we estimate the neutrino fluxes from WIMP annihilation in the dwarf galaxies Draco, Willman 1, and Segue 1, and examine the prospects for their observation with the IceCube neutrino telescope located at the South Pole.

II. DARK MATTER ANNIHILATION IN DWARF SPHEROIDAL GALAXIES

In general, the differential flux of particles of type j from the annihilation of dark matter particles of mass m_χ is given by

$$\frac{d\Phi_j(\Delta\Omega, E_j)}{dE_j} = \frac{\langle\sigma v\rangle}{8\pi m_\chi^2} \sum_F f_F \frac{dN_{j,F}}{dE_{j,F}} \times \bar{J}(\Delta\Omega)\Delta\Omega, \quad (1)$$

where f_F is the fraction of annihilations which produce a final state F , and $dN_{j,F}/dE_{j,F}$ is the differential spectrum of particles j from an annihilation to final state F . $\bar{J}(\Delta\Omega)$ is the square of the dark matter density integrated along the line of sight, averaged over the solid angle $\Delta\Omega$:

$$\bar{J}(\Delta\Omega) = \frac{1}{\Delta\Omega} \int_{\Delta\Omega} d\Omega \int_{l.o.s.} \rho_\chi^2(s) ds. \quad (2)$$

Dwarf spheroidal galaxies are promising sources for indirect dark matter searches for a number of reasons. First, they contain relatively large dark matter densities, and thus may produce sizable fluxes of annihilation products. Furthermore, dwarf spheroidals contain relatively little in the way of baryonic material (stars, gas, etc.) and are astrophysically simple. The typical mass of known dwarf spheroidal galaxies is $\sim 10^7 M_\odot$, which is distributed over a volume on the order of a cubic kiloparsec. Dwarfs are largely devoid of astrophysical activity, and have very large mass to light ratios, Segue 1 being a particularly extreme example [27]. The systems therefore lack astrophysical sources which could potentially mimic a signal of dark matter annihilation. Although simulations suggest that many more are likely to exist, approximately 25 dwarf galaxies within the local group have been discovered thus far.

The dark matter distribution $\rho(r)$ within a dwarf spheroid can be fit with a five parameter density profile [28]

$$\rho(r) = \frac{\rho_0}{\left(\frac{r}{r_s}\right)^a \left(1 + \left(\frac{r}{r_s}\right)^b\right)^{(c-a)/b}}, \quad (3)$$

where r is the distance from the dynamical center of the dwarf galaxy, r_s is the scale radius, and ρ_0 is the central core density. Typical ranges for the parameters a , c , and b , which determine the inner slope, outer slope, and transition between the two, respectively, are: $a = [0.0 - 1.5]$, $b = [0.5 - 1.5]$, and $c = [2 - 5]$. N -body simulations find cusped inner profiles with $a = [1.0 - 1.5]$. The profile of each individual halo can vary, however, depending upon its own merger history. Given this uncertainty, we follow Ref. [28] which marginalized over these five parameters, including r_s and ρ_0 , over the ranges specified above with flat priors. Although the parameter ranges are generous, Ref. [28] finds that the velocity dispersion data fix the line-of-sight integral, $\bar{J}(\Delta\Omega)$, to lie in a relatively small range. For details, see Ref. [29].

Presently, more than half a dozen dwarf galaxies are known which could potentially provide an observable flux of neutrinos. These dwarfs are relatively near the Solar System (tens of kpc) and, importantly, are in the northern hemisphere. This enables IceCube's background of atmospheric muons to be largely avoided by looking through the Earth, towards the northern hemisphere. We have selected three nearby dwarfs as sources of interest for IceCube; Draco, Willman 1, and Segue 1. In Table I, we display the relevant properties of these satellite galaxies [30], with $\bar{J}(\Delta\Omega)\Delta\Omega$ and errors representing the 2σ range taken from Ref. [31]. We note that there is some uncertainty in the observational status of Willman 1; it is currently unclear whether it is a dwarf galaxy or a globular cluster. It follows that there is considerably more uncertainty in the value of $\bar{J}(\Delta\Omega)\Delta\Omega$.

TABLE I. Properties of selected Milky Way dwarf galaxies.

Galaxy	Distance (kpc)	$\text{Log}_{10}\bar{J}(\Delta\Omega)\Delta\Omega$	Declination
Draco	80	18.63 ± 0.73	$+57^\circ 54'55''$
Willman 1	38	19.55 ± 1.19	$+51^\circ 03'00''$
Segue 1	23	19.88 ± 0.82	$+16^\circ 04'55''$

IceCube is designed to have an angular resolution of approximately 1° for muon tracks [32]. Given this resolution, the dwarf galaxies in Table I are sufficiently small and distant that we can treat them as point sources. Atmospheric Čerenkov Telescopes (ACTs) and the Fermi Gamma-Ray Space Telescope have angular resolutions much smaller than IceCube. For example, VERITAS has observed Draco, Ursa Minor, and Willman 1 over regions within 0.15° of each galaxy's center [33].

Several dwarf galaxies have been observed by ACTs as potential sources of gamma rays: Draco by MAGIC [34] and STACEE [35], Sagittarius (which is visible from the Southern Hemisphere) by H.E.S.S. [36], and Draco, Willman 1, and Ursa Minor by VERITAS [33]. None of these telescopes have observed any significant signal and, therefore, have placed upper limits on the flux of gamma rays coming from these sources. The strongest constraints on the annihilation rate of WIMPs in dwarf galaxies come from H.E.S.S. and VERITAS [28]. H.E.S.S. observations of the center of the Sagittarius dwarf yield an upper limit on the gamma-ray flux above 250 GeV of $\Phi(E_\gamma > 250 \text{ GeV}) \lesssim 3.6 \times 10^{-12} \text{ cm}^{-2} \text{ s}^{-1}$ at the 95% confidence level [36]. VERITAS observations of Draco, Ursa Minor, and Willman 1 bound the gamma-ray flux from each of these objects above 200 GeV to be $\Phi(E_\gamma > 200 \text{ GeV}) \lesssim 2.4 \times 10^{-12} \text{ cm}^{-2} \text{ s}^{-1}$ [33].

III. MUON NEUTRINOS FROM DWARF SPHEROIDAL GALAXIES

In this study, we consider three leptophilic scenarios: WIMPs which annihilate solely to $\tau^+\tau^-$, solely $\mu^+\mu^-$, or to both $\mu^+\mu^-$ and $\nu_\mu\bar{\nu}_\mu$, each with branching fractions of 50%. The differential flux of neutrinos from annihilations directly to neutrino-antineutrino pairs in a dwarf galaxy is given by Eq. (1), and the ν_μ differential spectrum at production takes the very simple form

$$\frac{dN_{\nu_\mu}}{dE_{\nu_\mu}} = \frac{dN_{\bar{\nu}_\mu}}{dE_{\bar{\nu}_\mu}} = \delta(E_{\nu_\mu} - m_X). \quad (4)$$

In the cases in which the WIMPs annihilate to $\tau^+\tau^-$ or $\mu^+\mu^-$, we use PYTHIA [37] to calculate the resulting neutrino spectra. In all cases, we include the effects of three-flavor vacuum oscillations [38].

Atmospheric muon neutrinos constitute the most serious background for detection of ν_μ from dark matter annihilation products from northern hemisphere dwarf spheroidal

galaxies. This background is a function of the zenith angle observed [39]. We use Ref. [40] to calculate the atmospheric neutrino background specific to the direction of each of the three source dwarfs. We note that the predicted background spectra are in agreement with the observations of Amanda-II [41].

The rate of muon tracks from charged current neutrino interactions observed at IceCube is calculated by combining the incoming spectrum of muon neutrinos with the probability of those neutrinos being converted to muons above the energy threshold of the telescope [42], which is given by

$$P(E_\nu, E_\mu^{\text{thr}})_\mu = \rho N_A \int_0^1 dy \frac{d\sigma_{\nu N}}{dy}(E_\nu, y) \times [R_\mu(E_\nu(1-y), E_\mu^{\text{thr}}) + L]. \quad (5)$$

Here, $\rho = \rho_{\text{ice}} \approx 0.9 \text{ g cm}^{-3}$ is the density of the target medium (ice) and $N_A = 6.022 \times 10^{23}$ is Avogadro's number. The total charged current cross section for neutrino nucleon scattering, $\sigma_{\nu N}$, can be taken as

$$\frac{\sigma_{\nu N}(E_\nu) + \sigma_{\bar{\nu} N}(E_\nu)}{2} = 3.06 \times 10^{-36} \left(\frac{E_\nu}{600 \text{ GeV}} \right)^{0.96} \text{ cm}^2 \quad (6)$$

for $100 \text{ GeV} < E_\nu < 1 \text{ TeV}$, and is approximately flatly distributed in y [43]. Finally, $R_\mu + L$ is the effective detector size, the sum of the physical length of the detector, L , and the distance a muon travels before its energy falls below the threshold of the experiment, R_μ . The muon range in ice is

$$R_\mu \approx 2.4 \text{ km} \times \ln \left[\frac{2.0 + 4.2(E_\mu/\text{TeV})}{2.0 + 4.2(E_\mu^{\text{thr}}/\text{TeV})} \right]. \quad (7)$$

The event rate for both the background and the signal is given by the integral

$$N = \int A_{\text{eff}} P(E_\nu, E_\mu^{\text{thr}}) \frac{d\Phi}{dE_\nu} dE_\nu. \quad (8)$$

The effective area, A_{eff} , in IceCube is approximately one square kilometer. The DeepCore supplement to the IceCube detector is designed to increase the sensitivity to low energy neutrino-induced muons with $10 \text{ GeV} \lesssim E_\mu \lesssim 100 \text{ GeV}$, with the improvement most substantial at the lowest energies [44]. However, the dark matter annihilation signal in IceCube and DeepCore is dominated by muons with energies close to the dark matter mass: for the lowest WIMP masses considered here, $m_X = 100 \text{ GeV}$, the signal comes primarily from neutrinos with $50 \text{ GeV} \lesssim E_\nu \lesssim 100 \text{ GeV}$. In this case, considering only the IceCube and DeepCore sensitivities reported in Fig. 4 of Ref. [44], we expect an improvement of roughly 20% over IceCube alone.

WIMP masses below $\sim 100 \text{ GeV}$ are not compatible with the anomalous cosmic ray excesses. However, the

sensitivity to neutrinos with $E_\nu \sim 10$ GeV is improved by including the DeepCore addition by more than an order of magnitude over that of IceCube alone [44]. At the same time, since the maximal angle between a muon track and the primary neutrino increases at low neutrino energies as $1/\sqrt{E_\nu}$, the angular resolution is significantly degraded at low energies, resulting in a decreased signal to background ratio for localized objects such as the dwarf satellite galaxies in Table I. We therefore estimate that the DeepCore addition would improve the sensitivity to low-mass dark matter annihilating in dwarf satellite galaxies by, at most, a factor of a few. However, as the cosmic ray anomalies do not favor light leptophilic dark matter, we report only on the sensitivity of the IceCube neutrino detector to dark matter annihilations in dwarf galaxies for WIMPs with $m_X > 100$ GeV.

In comparing the event rate to that predicted from the background of atmospheric neutrinos, we include events with energy up to 25% greater than the WIMP mass, which conservatively accounts for the finite energy resolution of IceCube [32]. We can now calculate the exposure time, T , necessary to achieve a detection with a given level of statistical significance over the background of atmospheric neutrinos. Since the background is essentially isotropic over the angular window of interest we follow the analysis of Ref. [45] to find the minimum exposure time,

$$T = \sigma_{\text{stat}}^2 \frac{N_{\text{atm}} + N_{\text{DMA}}}{N_{\text{DMA}}^2}, \quad (9)$$

where N_{DMA} is the event rate from dark matter annihilations in the dwarf and N_{atm} is the event rate from the atmospheric background. In the following section, we use this approach to determine the sensitivity of IceCube to dark matter annihilations taking place in the dwarf galaxies Draco, Willman 1, and Segue 1.

IV. PROSPECTS FOR ICECUBE AND COMPARISON TO GAMMA-RAY SEARCHES

We now compare the relative merits of gamma-ray and neutrino observations in their ability to place limits on the dark matter annihilation cross section in leptophilic models. In Fig. 1, we present IceCube's sensitivity to neutrinos from dark matter annihilations in Draco, after 10 years of observation. In the left panel, we show results for the annihilation channels $XX \rightarrow \mu^+ \mu^-$ in red (lower contours) and $XX \rightarrow \tau^+ \tau^-$ in blue (upper contours). As a consequence of neutrino oscillations, red and blue contours are distinct only at low m_X . The thick dashed lines denote the projected 2σ upper limit on the annihilation cross section as a function of mass (using the 2σ low value for $\bar{J}(\Delta\Omega)\Delta\Omega$), whereas the shaded regions bounded by thin solid lines denote the minimal cross sections necessary for a 5σ discovery, given the $\pm 2\sigma$ range of values for $\bar{J}(\Delta\Omega)\Delta\Omega$. In the right panel, results are shown for the case in which $XX \rightarrow \mu^+ \mu^-$ and $XX \rightarrow \nu_\mu \bar{\nu}_\mu$ each occur with branching fractions of 50%. One can see that, due to the uncertainty in the dark matter halo properties, the potential discovery regions extend well below the exclusion contours.

For comparison, in each frame we also show the corresponding upper limits on the dark matter annihilation cross section from VERITAS observations of Draco, as found in Ref. [28]. In the left panel, the grey and black dotted curves represent the upper limits on $\langle\sigma v\rangle$ assuming annihilations to $\mu^+ \mu^-$ and $\tau^+ \tau^-$, respectively, while in the right panel, the grey dotted curve is the VERITAS upper limit assuming $XX \rightarrow \mu^+ \mu^-$ and $XX \rightarrow \nu_\mu \bar{\nu}_\mu$ with equal branching fractions. We note that Ref. [28] uses the 90% confidence level lower limit on $\bar{J}(\Delta\Omega)\Delta\Omega$, while we consider the slightly more generous 2σ lower limit. Our projected sensitivities are therefore slightly more conservative. As

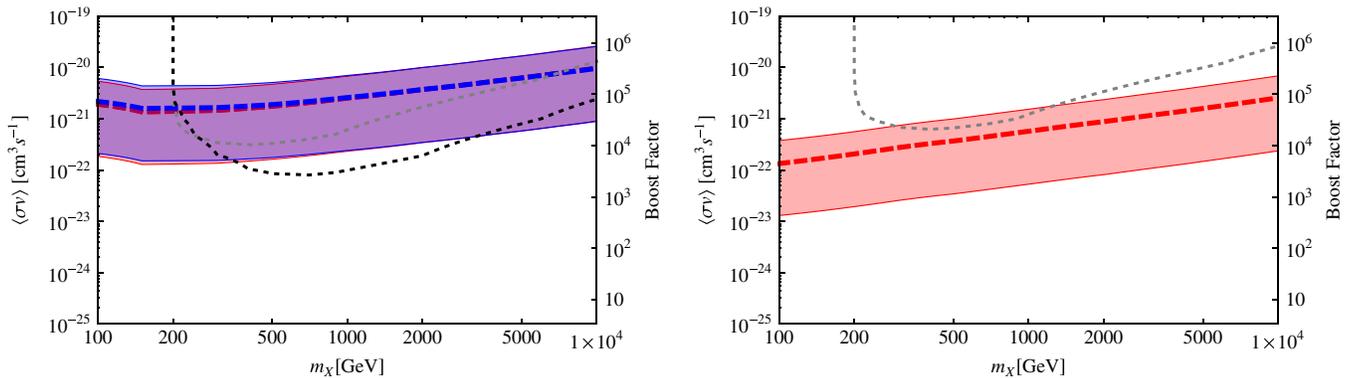

FIG. 1 (color online). Projected upper limits on the dark matter annihilation cross section, $\langle\sigma v\rangle$ (alternatively, boost factor), at 95% confidence level as a function of mass (thick dashed) from neutrino observations of the dwarf spheroidal galaxy Draco. Also shown are the 5σ discovery regions (shaded). In the left frame, the red (lower) region and lines denote the case in which dark matter annihilates to $\mu^+ \mu^-$, whereas the blue (upper) regions and lines denote annihilations to $\tau^+ \tau^-$. The right frame is for the case in which dark matter annihilates to both $\mu^+ \mu^-$ and $\nu_\mu \bar{\nu}_\mu$ with equal probability. In each frame, the dotted lines denote the current limits from gamma-ray observations by VERITAS. See text for more details.

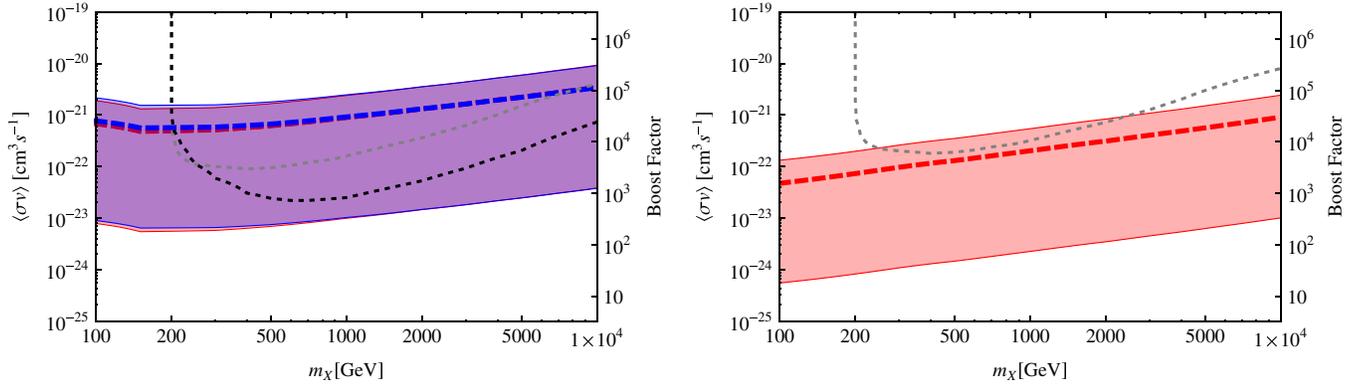

FIG. 2 (color online). The same as Fig. 1, but for observations of the dwarf spheroidal galaxy Willman 1.

Draco is the least bright of the dwarf galaxies considered here, we find that for WIMP masses ≥ 200 GeV, VERITAS has already constrained the annihilation cross section roughly as tightly as IceCube will with 10 years of data for annihilation purely to $\mu^+\mu^-$ or $\tau^+\tau^-$. In the case of annihilations to $\mu^+\mu^-$, IceCube may place competitive limits on the WIMP annihilation cross section only for $m_\chi \geq 5$ TeV or $m_\chi \leq 200$ GeV. For annihilation to $\tau^+\tau^-$ the current constraints on $\langle\sigma v\rangle$ from VERITAS observations of Draco are stronger than any IceCube will be able to achieve in the next 10 years for $m_\chi > 200$ GeV. This stems from the fact that taus often decay hadronically, resulting in many more high energy photons than in the purely leptonic decays of muons. For annihilation to taus, a substantial portion of IceCube’s discovery reach has already been excluded by VERITAS.

Instead of presenting our results as limits (or discovery reach) on the dark matter annihilation cross section, we can alternatively describe them in terms of the boost factor to the annihilation rate in a given dwarf spheroidal galaxy. Along the right side of each frame, the constraints and discovery prospects are given in terms of this quantity, which we define as the annihilation rate divided by that predicted for dark matter with $\langle\sigma v\rangle = 3 \times 10^{-26} \text{ cm}^3/\text{s}$

and distributed smoothly over the halo. This definition allows us to leave the origin of the boost factor unspecified.

Turning to the right panel, we find that if neutrinos and muons are each are directly produced in 50% of annihilations, IceCube will have comparable or better sensitivity than VERITAS for all WIMP masses. In fact, in this case IceCube’s discovery reach is largely untested by ACTs. We note that if the branching fraction to neutrinos is larger than 50%, IceCube’s sensitivity will be further increased, while that of ACTs and other gamma-ray telescopes will be reduced.

In Fig. 2 we present the same information as Fig. 1, but for the dwarf galaxy Willman 1. Willman 1 is somewhat brighter than Draco, and therefore we expect all sensitivities to improve. However, there is also considerably more uncertainty in the halo profile, leading to large discovery regions and inflated prospective limits. For annihilations to charged leptons only, boost factors of $\mathcal{O}(10^2)$ may be accessible at IceCube if $\bar{J}(\Delta\Omega)\Delta\Omega$ is near its 2σ upper limit. For low m_χ , these annihilation cross sections have not yet been probed by ACTs. For annihilation to $\mu^+\mu^-$ and $\nu_\mu\bar{\nu}_\mu$, shown in the right panel, boost factors as low as $\mathcal{O}(10)$ may be accessible in the most optimistic case.

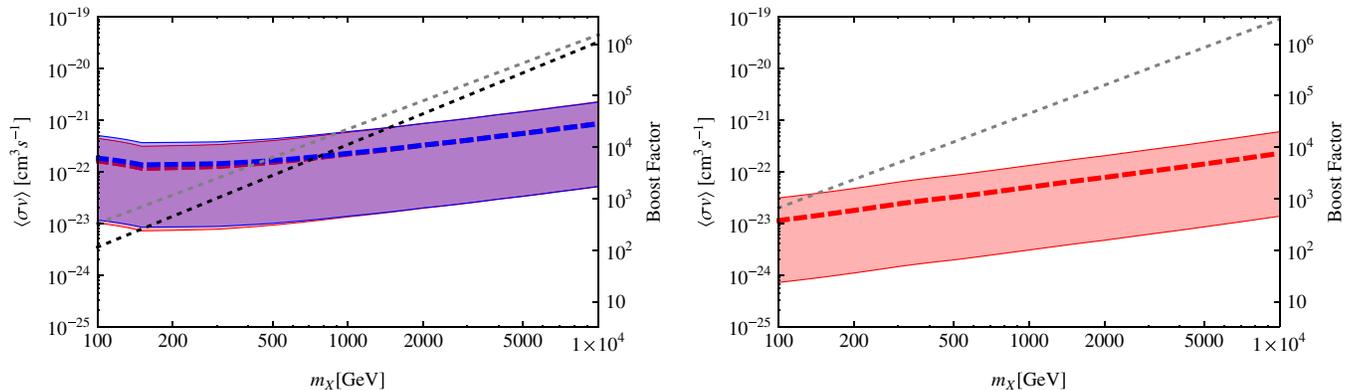

FIG. 3 (color online). The same as Fig. 1, but for observations of the dwarf spheroidal galaxy Segue 1. In this figure, the dotted lines denote the preliminary limits from the FGST [46].

Finally, we examine the closest of the three dwarfs we have considered, Segue 1. In Fig. 3, we present IceCube's projected sensitivity to dark matter annihilations in Segue 1, along with the current upper limits on the annihilation cross section from FGST measurements [46]. For annihilation to muons (taus), IceCube may eventually set stronger exclusion limits for $m_X > 450(750)$ GeV. If there is a 50% branching fraction to neutrinos, IceCube will do better for all WIMP masses shown. As Segue 1 is newly discovered, we expect that ACTs will observe this galaxy in the near future.

V. DISCUSSION AND CONCLUSIONS

In this article, we have considered the prospects for the kilometer-scale neutrino telescope IceCube to detect neutrinos from dark matter annihilating in dwarf spheroidal galaxies, and have compared these to the constraints placed by gamma-ray telescopes. We find that if dark matter annihilates primarily to muons, taus, and/or neutrinos, IceCube can potentially provide constraints comparable to or even stronger than those obtained by current gamma-ray telescopes.

Other dwarf spheroidal galaxies, such as Ursa Minor, which yield weaker gamma-ray limits on the dark matter annihilation cross section will also be less promising to be observed by IceCube. An analysis of the neutrino flux from all dwarf galaxies accessible to IceCube could potentially improve the sensitivity to the annihilation cross section, however, the maximal improvement assuming all dwarfs are equal is proportional to $1/\sqrt{N}$, where N is the number

of dwarfs in the sample. All dwarfs, of course, are not equal. In order to carry out such an analysis, one must assume that the mechanism responsible for the boosted (relative to thermal) annihilation cross section results in the same observed cross section in each dwarf galaxy. As the velocity dispersion in each dwarf is independent and the clumpiness of each dwarf is unknown, there is no reason to expect that the observed annihilation cross section in any two dwarfs should be the same, thus, at this point, the only appropriately model-independent interpretation is to view the annihilation signal from each dwarf independently. Given the velocity dispersion in each dwarf, one could derive limits on particular dark matter models assuming a specific velocity-dependent enhancement to the annihilation cross section. Such a study may be useful in the near future.
