

On the Capacity of Frequency-Selective Channels in Training-Based Transmission Schemes

Haris Vikalo, Babak Hassibi, Bertrand Hochwald, and Thomas Kailath, *Life Fellow, IEEE*

Abstract—Communication systems transmitting over frequency-selective channels generally employ an equalizer to recover the transmitted sequence corrupted by intersymbol interference (ISI). Most practical systems use a training sequence to learn the channel impulse response and thereby design the equalizer. An important issue is determining the optimal amount of training: too little training and the channel is not learned properly, too much training and there is not enough time available to transmit data before the channel changes and must be learned anew. We use an information-theoretic approach to find the optimal parameters in training-based transmission schemes for channels described by a block-fading model. The optimal length of the training interval is found by maximizing a lower bound on the training-based channel capacity. When the transmitter is capable of providing two distinct transmission power levels (one for training and one for data transmission), the optimal length of the training interval is shown to be equal to the length of the channel. Further, we show that at high SNR, training-based schemes achieve the capacity of block-fading frequency selective channels, whereas at low SNR, they are highly suboptimal.

Index Terms—Block fading, frequency-selective channels, intersymbol interference.

I. INTRODUCTION

FREQUENCY-selective fading multipath channels are often encountered in wireless communication systems (see the review of fading channels [1] and the references therein). To combat intersymbol interference (ISI) on such channels, receivers use various equalization techniques. Most practical communication systems learn the channel impulse response by means of training. They devote a portion of the transmission time to the training sequence that is known to the receiver. This training sequence, and its transmitted version corrupted by ISI and additive noise, which is received at the other end, are then used to estimate the channel. Alternatively, the channel may be identified blindly, using available information about the channel and input signals.

The most important parameter in any training-based scheme is the length of training interval or, equivalently, the amount of training. Clearly, if there is too little training, the channel will not be learned properly; if there is too much training, there will not be enough time to transmit information before the channel changes

and must be relearned. One can conceive of different criteria to determine the optimal amount of training, but we believe that the most natural criterion is an information-theoretic one based on maximizing capacity. The reason for this is that in most communication systems, one is concerned with reliably transmitting data at the highest possible rate: a concern that is well captured by capacity. Computing the capacity for frequency-selective fading channels in training-based schemes is a formidable task, and so, as a compromise, we find a lower bound on this capacity. The channel is assumed to be discrete-time finite-impulse response (FIR), subject to block-fading, i.e., the channel impulse response is constant over an interval (the so-called *coherence interval*) after which, it is changed to an independent value. The capacity lower bound is then maximized to find the optimal portion of the coherence interval that should be devoted to training. If the transmitter is capable of providing two distinct transmission power levels for training and for data transmission, then the optimal length of the training interval is shown to be equal to the length of the channel. If the transmitter cannot vary transmission power over the training and data transmission intervals, then the optimal length of the training interval can be found numerically and may be longer than the length of the channel (up to one half of the coherence interval).

A natural question to ask follows: How good are training-based schemes? In other words, can one obtain significant improvement in performance by employing other methods, such as noncoherent detection or blind equalization? Our analysis allows us to give a qualitative answer to the above question. At high SNR, we show that our training-based capacity lower bounds coincide with the actual Shannon capacity of a block-fading FIR channel (this statement is true insofar as the leading order terms are concerned). Therefore, at high SNR, training-based schemes achieve the leading order term of the actual Shannon capacity, and so, we lose very little by considering a training-based scheme, as opposed to a more general scheme. On the other hand, at low SNR, we show that training-based schemes are highly suboptimal, in the sense that they can only deliver a diminishing factor of the actual Shannon capacity. Therefore, at low SNR, alternative methods to training must be sought.

Using a lower bound on the capacity of training-based schemes first developed in [2] and later extended to frequency-selective channels in [8], related work [9] finds power allocation and optimal placement for the training symbols. Similar techniques were also used for analysis of channel capacity in [3].

The remainder of the paper is organized as follows: In Section II, we describe the block-fading model for FIR channels. The procedure for finding the optimal parameters of the transmission scheme is presented in Section III. The optimization

Note that compared to the training phase, the roles of the transmitted symbols and channel coefficients are reversed: In the data transmission phase, the former are the unknowns and the latter the knowns. Therefore, unlike (1), we have gathered the channel coefficients into a Toeplitz matrix and the transmitted symbols into a vector.

The following points are worthy of mention. First, the term $H_\tau \boldsymbol{\theta}_\tau$ in (3) represents the terms that “trickle down” from the training phase into the data transmission phase. Second, the receiver collects data even after the transmission ends and until the FIR channel is “emptied” (which is why the length of \mathbf{y}_d is $T_d + L - 1$, rather than T_d). Finally, to allow for block-by-block processing, we assume that the data transmission phase is followed by a guard period of $L - 1$ zeros. [Alternatively, one can think of the guard period as preceding the training phase.] The guard period protects from interblock-interference.

Analysis of the transmission scheme requires knowledge of the covariance matrix of \mathbf{h} . We assume that the channel coefficients are independent complex Gaussian with covariance matrix

$$R_{\mathbf{h}} = E\mathbf{h}\mathbf{h}^* = \text{diag}(\sigma_{h_1}^2, \sigma_{h_2}^2, \dots, \sigma_{h_L}^2).$$

The estimate of the channel $\hat{\mathbf{h}}$ is (indirectly, through \hat{H}_d and \hat{H}_τ) used to detect \mathbf{s}_d from

$$\underbrace{\mathbf{y}_d - \sigma_\tau \hat{H}_\tau \boldsymbol{\theta}_\tau}_{\mathbf{y}'_d} = \sigma_d \hat{H}_d \mathbf{s}_d + \underbrace{\sigma_d \tilde{H}_d \mathbf{s}_d + \sigma_\tau \tilde{H}_\tau \boldsymbol{\theta}_\tau}_{\mathbf{v}'_d} + \mathbf{v}_d \quad (4)$$

where \mathbf{v}'_d is the effective noise comprised of the additive noise and residual channel estimation error, and \mathbf{y}'_d denotes the combination of the measured and known signals during the data transmission phase.

We note that the following relations hold due to conservation of time and energy:

$$T = T_\tau + T_d, \quad \sigma^2 T = \sigma_\tau^2 T_\tau + \sigma_d^2 T_d$$

where $\sigma^2 T$ is the total transmit energy, and $\sigma_\tau^2 T_\tau$ and $\sigma_d^2 T_d$ are the total transmit energies in the training and data phase, respectively.

Clearly, increasing T_τ improves the channel estimate, but that is achieved at the expense of the length of data transmission interval T_d . A similar tradeoff holds between σ_τ^2 and σ_d^2 . We are interested in finding optimal values for the parameters $(T_\tau, T_d, \sigma_\tau^2, \sigma_d^2)$, along with the optimal training sequence $\boldsymbol{\theta}_\tau$. Of course, we must specify what we mean by optimal. In the communications context we are studying, the most natural objective appears to be channel capacity, since it determines the maximum amount of information that can be reliably transmitted. Therefore, in what follows, we will attempt to find the parameters $(T_\tau, T_d, \sigma_\tau^2, \sigma_d^2, \boldsymbol{\theta}_\tau)$ that maximize the capacity of a training-based scheme.

In what follows, we will find it convenient to make use of the MMSE estimate of the channel \mathbf{h} . The MMSE estimate $\hat{\mathbf{h}}$ is the conditional mean of \mathbf{h} given $\boldsymbol{\theta}_\tau$ and \mathbf{y}_τ , meaning that $\hat{\mathbf{h}}$ and $\tilde{\mathbf{h}}$, and so, \hat{H} and \tilde{H} are uncorrelated. This implies that when the

channel estimate is MMSE, conditioned on the observations, the effective noise \mathbf{v}'_d in (4) is uncorrelated with the signal \mathbf{s}_d :

$$\begin{aligned} E_{|\mathbf{y}_\tau} \mathbf{s}_d \mathbf{v}'_d{}^* &= E_{|\mathbf{y}_\tau} \mathbf{s}_d \left(\sigma_d \tilde{H}_d \mathbf{s}_d + \sigma_\tau \tilde{H}_\tau \boldsymbol{\theta}_\tau + \mathbf{v}_d \right)^* \\ &= \sigma_d E_{|\mathbf{y}_\tau} (\mathbf{s}_d \mathbf{s}_d^* \tilde{H}_d^*) + \sigma_\tau E_{|\mathbf{y}_\tau} (\mathbf{s}_d \boldsymbol{\theta}_\tau^* \tilde{H}_\tau^*) + \underbrace{E_{|\mathbf{y}_\tau} (\mathbf{s}_d \mathbf{v}_d^*)}_{=0} \\ &= \sigma_d E_{|\mathbf{y}_\tau} (\mathbf{s}_d \mathbf{s}_d^*) E_{|\mathbf{y}_\tau} (\tilde{H}_d^*) + \sigma_\tau E_{|\mathbf{y}_\tau} (\mathbf{s}_d \boldsymbol{\theta}_\tau^*) E_{|\mathbf{y}_\tau} (\tilde{H}_\tau^*) \\ &= 0 \end{aligned}$$

since $E_{|\mathbf{y}_\tau} (\mathbf{h} - \hat{\mathbf{h}}) = 0$, and thus, $E_{|\mathbf{y}_\tau} (\tilde{H}_d) = E_{|\mathbf{y}_\tau} (H_d - \hat{H}_d) = 0$, and $E_{|\mathbf{y}_\tau} (\tilde{H}_\tau) = E_{|\mathbf{y}_\tau} (H_\tau - \hat{H}_\tau) = 0$. It is the property that \mathbf{v}'_d and \mathbf{s}_d are uncorrelated that makes the MMSE estimate useful in the sequel. We remark that no other estimate has this property.

III. LOWER BOUND ON THE TRAINING-BASED CAPACITY

The capacity of any training-based scheme is given by the supremum of the mutual information between the transmitted signal \mathbf{s}_d and the known and observed signals $\{\mathbf{y}_\tau, \boldsymbol{\theta}_\tau, \mathbf{y}_d\}$. To be precise

$$C_\tau = \sup_{p_{\mathbf{s}_d}, \text{tr} E \mathbf{s}_d \mathbf{s}_d^* \leq T_d, \boldsymbol{\theta}_\tau} I(\mathbf{y}_\tau, \boldsymbol{\theta}_\tau, \mathbf{y}_d; \mathbf{s}_d).$$

The above expression can be rewritten as

$$\begin{aligned} C_\tau &= \sup_{p_{\mathbf{s}_d}, \text{tr} E \mathbf{s}_d \mathbf{s}_d^* \leq T_d, \boldsymbol{\theta}_\tau} \left[I(\mathbf{y}_d; \mathbf{s}_d | \mathbf{y}_\tau, \boldsymbol{\theta}_\tau) + \underbrace{I(\mathbf{y}_\tau, \boldsymbol{\theta}_\tau; \mathbf{s}_d)}_{=0} \right] \\ &= \sup_{p_{\mathbf{s}_d}, \text{tr} E \mathbf{s}_d \mathbf{s}_d^* \leq T_d, \boldsymbol{\theta}_\tau} I(\mathbf{y}_d; \mathbf{s}_d | \mathbf{y}_\tau, \boldsymbol{\theta}_\tau) \quad (5) \end{aligned}$$

where we have used the fact that \mathbf{s}_d and $\{\mathbf{y}_\tau, \boldsymbol{\theta}_\tau\}$ are independent. This implies that the capacity in a training-based scheme is the supremum of the mutual information between the transmitted and received signals during the data transmission phase, given the transmitted and received signals during the training phase.

In general, finding the capacity in (5) is a hard problem. Instead, we find a lower bound on the capacity for a particular choice of the channel estimate. From (4)

$$\mathbf{y}'_d = \sigma_d \hat{H}_d \mathbf{s}_d + \mathbf{v}'_d. \quad (6)$$

We assume that \hat{H} in (6) is the MMSE estimate of the channel \mathbf{h} . As mentioned earlier, this choice of the channel estimate guarantees that the signal \mathbf{s}_d and the additive noise \mathbf{v}'_d are uncorrelated. The reason explicit computation of the capacity in a training-based scheme is difficult is that the signals \mathbf{s}_d and \mathbf{v}'_d , although uncorrelated, are dependent and that the distribution of \mathbf{v}'_d is complicated to describe. Nonetheless, the covariance matrix of \mathbf{v}'_d is easy to compute and has the following form:

$$\begin{aligned} R_{\mathbf{v}'_d} &= E \mathbf{v}'_d \mathbf{v}'_d{}^* = E \left[\sigma_d^2 \tilde{H}_d \mathbf{s}_d \mathbf{s}_d^* \tilde{H}_d^* + \sigma_\tau^2 \tilde{H}_\tau \boldsymbol{\theta}_\tau \boldsymbol{\theta}_\tau^* \tilde{H}_\tau^* + \mathbf{v}_d \mathbf{v}_d^* \right] \\ &= E \left[\sigma_d^2 \tilde{H}_d \mathbf{s}_d \mathbf{s}_d^* \tilde{H}_d^* + \sigma_\tau^2 \tilde{H}_\tau \boldsymbol{\theta}_\tau \boldsymbol{\theta}_\tau^* \tilde{H}_\tau^* \right] + I. \quad (7) \end{aligned}$$

In [2], it has been shown that among all additive noises that are uncorrelated with the signal \mathbf{s}_d and have a given covariance matrix $R_{\mathbf{v}'_d}$, the worst-case noise (from a capacity point of view) is zero-mean independent Gaussian noise with the same covariance matrix. This allows us to lower bound the training-based capacity C_τ by the capacity of an additive Gaussian noise channel with the same noise covariance matrix. The capacity for such a channel, when the channel matrix is known at the receiver, has been computed in [4] (see also [5]), and so, we may write

$$C_\tau \geq \max_{R_{\mathbf{s}_d}, \text{tr} R_{\mathbf{s}_d} = T_d, \boldsymbol{\theta}_\tau} E \log \det \left(I + \sigma_d^2 R_{\mathbf{v}'_d}^{-1} \hat{H}_d R_{\mathbf{s}_d} \hat{H}_d^* \right)$$

where $R_{\mathbf{s}_d} = E \mathbf{s}_d \mathbf{s}_d^*$. Maximization of the above expression over $R_{\mathbf{s}_d}$ appears to be formidable. A choice that makes practical sense, since the transmitter does not know the channel, is $R_{\mathbf{s}_d} = I_{T_d}$. Since this choice will not necessarily maximize the right-hand side of the above inequality, it yields the following lower bound:

$$C_\tau \geq E \log \det \left(I + \sigma_d^2 R_{\mathbf{v}'_d}^{-1} \hat{H}_d \hat{H}_d^* \right).$$

Further, when $R_{\mathbf{s}} = I_{T_d}$, from (7), we obtain

$$R_{\mathbf{v}'_d} = I + \sigma_d^2 \underbrace{E(\hat{H}_d \hat{H}_d^*)}_{R_{\mathbf{v}_1}} + \sigma_\tau^2 \underbrace{E(\hat{H}_\tau \boldsymbol{\theta}_\tau \boldsymbol{\theta}_\tau^* \hat{H}_\tau^*)}_{R_{\mathbf{v}_2}}. \quad (8)$$

It is also useful to define the normalized channel \bar{H}_d as

$$\bar{H}_d = \sqrt{\frac{LT_d}{\text{tr} E(\hat{H}_d^* \hat{H}_d)}} \hat{H}_d$$

defined so that the nonzero entries of \bar{H}_d have, on the average, unit variance. With this normalization, we write the capacity bound as

$$\begin{aligned} C_\tau &\geq E \log \det \left(I + \sigma_d^2 \frac{\text{tr} E(\hat{H}_d \hat{H}_d^*)}{LT_d} R_{\mathbf{v}'_d}^{-1} \bar{H}_d \bar{H}_d^* \right) \\ &= E \log \det \left(I + \sigma_d^2 \frac{T_d \sum_{i=1}^L \sigma_{\hat{h}_i}^2}{LT_d} R_{\mathbf{v}'_d}^{-1} \bar{H}_d \bar{H}_d^* \right) \end{aligned} \quad (9)$$

where $\sigma_{\hat{h}_i}^2 = E|\hat{h}_i|^2$. We are interested in finding the parameters of the transmission scheme such that the capacity lower bound in (9) is maximized. In particular, we will attempt to maximize this lower bound with respect to the training data sequence $\boldsymbol{\theta}_\tau$, the training power σ_d^2 , and the length of the training interval T_τ .

IV. OPTIMAL TRAINING-BASED PARAMETERS

Maximization of the lower bound over the parameters $\{\boldsymbol{\theta}_\tau, \sigma_d^2, T_\tau\}$ can be done in any order. We will find it most convenient to begin with determining the optimal training sequence $\boldsymbol{\theta}_\tau$.

A. Maximizing Over $\boldsymbol{\theta}_\tau$

From the orthogonality property of the MMSE estimate, we may write

$$\sigma_{\hat{h}_i}^2 = \sigma_{h_i}^2 - \sigma_{\tilde{h}_i}^2$$

where we have defined $\sigma_{\tilde{h}_i}^2 = E|\tilde{h}_i|^2 = E|h_i - \hat{h}_i|^2$. Thus, (9) can be written as

$$C_\tau \geq E \log \det \left(I + \sigma_d^2 \frac{\sum_{i=1}^L (\sigma_{h_i}^2 - \sigma_{\tilde{h}_i}^2)}{L} R_{\mathbf{v}'_d}^{-1} \bar{H}_d \bar{H}_d^* \right). \quad (10)$$

Note that the right-hand side in (10) depends on $\boldsymbol{\theta}_\tau$ through $\sigma_{\tilde{h}_i}^2$, $R_{\mathbf{v}'_d}$, and \bar{H}_d . However, we expect the dependence of \bar{H}_d on $\boldsymbol{\theta}_\tau$ to be the mildest, since the entries of \bar{H}_d have been normalized. Exactly maximizing the right-hand side over $\boldsymbol{\theta}_\tau$ appears to be analytically intractable, and so, we propose to approximately maximize the right-hand side by considering only the dependence of $\sigma_{\tilde{h}_i}^2$ and $R_{\mathbf{v}'_d}$ of $\boldsymbol{\theta}_\tau$ and ignoring the dependence on \bar{H}_d . In particular, we will choose $\boldsymbol{\theta}_\tau$ to maximize the effective power

$$\bar{\rho}_{\text{eff}} = \frac{\sigma_d^2}{L} \sum_{i=1}^L (\sigma_{h_i}^2 - \sigma_{\tilde{h}_i}^2). \quad (11)$$

From (11), this is equivalent to minimizing $\sum \sigma_{\tilde{h}_i}^2 = \text{tr} R_{\tilde{\mathbf{h}}}$. As we will see below, this results in $R_{\mathbf{v}_2} = 0$ and minimizes the trace of $R_{\mathbf{v}_1}$. Therefore, it clearly minimizes the trace of $R_{\mathbf{v}'_d}$; therefore, the eigenvalues of $R_{\mathbf{v}'_d}^{-1}$, which is what appears in the capacity lower bound, will be large. Thus, we conclude that minimizing $\text{tr} R_{\tilde{\mathbf{h}}}$ makes a lot of sense.

To this end, consider the MMSE estimation error covariance matrix

$$\begin{aligned} R_{\tilde{\mathbf{h}}} &= R_{\mathbf{h}} - R_{\mathbf{h}\mathbf{y}} R_{\mathbf{y}}^{-1} R_{\mathbf{y}\mathbf{h}} \\ &= R_{\mathbf{h}} - R_{\mathbf{h}} (\sigma_\tau \Theta_\tau^*) (I + \sigma_\tau^2 \Theta_\tau R_{\mathbf{h}} \Theta_\tau^*) (\sigma_\tau \Theta_\tau) R_{\mathbf{h}} \\ &= (R_{\mathbf{h}}^{-1} + \sigma_\tau^2 \Theta_\tau^* \Theta_\tau)^{-1}. \end{aligned}$$

Hence, to minimize $\text{tr} R_{\tilde{\mathbf{h}}}$, we need to solve the optimization problem

$$\min_{\boldsymbol{\theta}_\tau, \text{tr} \boldsymbol{\theta}_\tau \boldsymbol{\theta}_\tau^* = T_\tau} \text{tr} (R_{\mathbf{h}}^{-1} + \sigma_\tau^2 \Theta_\tau^* \Theta_\tau)^{-1}. \quad (12)$$

The optimization problem (12) is convex and can be solved numerically as a semi-definite program. However, besides the optimal training sequence, in this paper, we are interested in finding the optimal power allocation and the optimal length of the training interval. To carry out these optimization procedures, we need to obtain a closed-form expression of the training sequence. This can be facilitated if we assume that $\{h_1, \dots, h_L\}$ are independent, identically distributed (iid) (that is, $R_{\mathbf{h}}$ is a multiple of the identity matrix).

Assume that $R_{\mathbf{h}} = I$. Then, the optimization problem (12) can be expressed in terms of $\lambda_1, \lambda_2, \dots, \lambda_L$, which are the eigenvalues of $\Theta_\tau^* \Theta_\tau$, as

$$\min_{\lambda_1, \dots, \lambda_L} \sum_{i=1}^L \frac{1}{1 + \sigma_\tau^2 \lambda_i}$$

which is minimized when $\lambda_1 = \lambda_2 = \dots = \lambda_L$ and, thus, when $\Theta_\tau^* \Theta_\tau$ is a multiple of identity. Since Θ_τ has a Toeplitz structure, this can only be achieved by an impulse-like training sequence, where the impulse should be sent no later than $T_\tau - L + 1$ from the beginning of the training interval. To be more explicit, we have the following result.

Optimal Training Sequence: In MMSE estimation of iid complex Gaussian channel coefficients, the training sequence that solves optimization problem (12) is given by

$$\begin{aligned} \theta_{T_\tau - L + 2} &= \dots = \theta_{T_\tau} = 0 \\ \theta_i &= \sqrt{T_\tau}, \text{ for some } i, 1 \leq i \leq T_\tau - L + 1 \\ \theta_j &= 0 \text{ for } 1 \leq j \leq T_\tau - L + 1, j \neq i. \end{aligned} \quad (13)$$

Note that the optimal training sequence is an impulse and that therefore the optimal Θ_τ consists of a single diagonal. Since the duration of this diagonal is L , it may at first appear counterintuitive that such a diagonal matrix should be optimal for $T_\tau > L$ since in this case, the matrix Θ_τ will have $T_\tau - L$ zero rows. However, adding extra nonzero elements to Θ_τ reduces the magnitude of these entries (since we have the constraint $\Theta_\tau^* \Theta_\tau = T_\tau$); therefore, the above calculations show that we do not gain anything by doing so.

As promised earlier, it follows that for the optimal choice of the training sequence, $R_{\mathbf{v}_2} = 0$. This is a consequence of the readily verified fact that $\tilde{H}_\tau \theta_\tau = 0$. Moreover, since trace $R_{\mathbf{v}_1} = E \text{ trace} \left(\tilde{H}_d \tilde{H}_d^* \right) = T_d \text{ trace} R_{\mathbf{h}}$, we conclude that this choice of training sequence also minimizes the trace of $R_{\mathbf{v}'_d}$.

Inserting the optimal value of the training matrix Θ_τ into (13) yields

$$R_{\mathbf{h}} = \frac{1}{1 + T_\tau \sigma_\tau^2} I \quad (14)$$

or, in other words, $\sigma_{\tilde{h}_i}^2 = \sigma_h^2 = 1/(1 + T_\tau \sigma_\tau^2)$, for all i . Moreover, the matrix $R_{\mathbf{v}'_1}$ in (8) is now diagonal

$$R_{\mathbf{v}'_1} = \text{diag} \left(\sigma_h^2, 2\sigma_h^2, \dots, L\sigma_h^2, \dots, L\sigma_h^2, \dots, 2\sigma_h^2, \sigma_h^2 \right).$$

It is therefore quite clear that

$$R_{\mathbf{v}'_1} \leq L\sigma_h^2 I_{T_d - L + 1}$$

so that $R_{\mathbf{v}'_d} \leq (1 + L\sigma_d^2 \sigma_h^2) I$, and

$$R_{\mathbf{v}'_d}^{-1} \geq \frac{1}{1 + L\sigma_d^2 \sigma_h^2} I_{T_d - L + 1}.$$

Now, for positive definite matrices $A \geq B > 0$, we have $\log \det A \geq \log \det B$.¹ Therefore, we may write

$$\begin{aligned} E \log \det \left(I + \bar{\rho}_{\text{eff}} R_{\mathbf{v}'_d}^{-1} \tilde{H}_d \tilde{H}_d^* \right) \\ \geq E \log \det \left(I + \frac{\bar{\rho}_{\text{eff}}}{1 + L\sigma_d^2 \sigma_h^2} \tilde{H}_d \tilde{H}_d^* \right). \end{aligned} \quad (15)$$

We thus obtain the following lower bound on the capacity of training-based schemes:

$$C_\tau \geq E \log \det \left(I + \frac{\bar{\rho}_{\text{eff}}}{1 + L\sigma_d^2 \sigma_h^2} \tilde{H}_d \tilde{H}_d^* \right).$$

Using $\sigma_h^2 = 1/(1 + T_\tau \sigma_\tau^2)$ and $\bar{\rho}_{\text{eff}} = \sigma_d^2(1 - \sigma_h^2)$ allows us to write

$$C_\tau \geq E \log \det(I + \rho_{\text{eff}} \tilde{H}_d \tilde{H}_d^*) \quad (16)$$

where

$$\rho_{\text{eff}} = \frac{\bar{\rho}_{\text{eff}}}{1 + \sigma_d^2 \sum_{i=1}^L \sigma_{\tilde{h}_i}^2} = \frac{\sigma_d^2 \sigma_\tau^2 T_\tau}{1 + \sigma_\tau^2 T_\tau + \sigma_d^2 L}$$

can be treated as the effective SNR.

The expectation in (16) is taken over the random matrix \tilde{H}_d , which is just a scaled version of $\tilde{H}_d = H_d - \hat{H}_d$. Note that the entries of \tilde{H}_d , the $\{\tilde{h}_i\}$, are iid $\mathcal{CN}(0, \sigma_{\tilde{h}_i}^2)$ random variables. Therefore, the entries of \tilde{H}_d , the $\{\tilde{h}_i\}$, are iid $\mathcal{CN}(0, 1)$ random variables. This is a crucial result. The distribution of the elements of \tilde{H}_d does not depend on the training-based parameters $\{\sigma_\tau^2, \sigma_d^2, T_\tau, T_d\}$. Therefore, one can ignore the distribution on \tilde{H}_d when maximizing the capacity lower bound over the remaining parameters.

The question that remains is how do the remaining parameters influence the capacity lower bound? The quantities σ_τ^2 and σ_d^2 clearly only have an influence through ρ_{eff} . The parameters T_τ and T_d , on the other hand, influence both the effective SNR ρ_{eff} and the dimension of the matrix \tilde{H}_d , which is $(T_d + L - 1) \times T_d$.

Optimizing over the power allocations $\{\sigma_\tau^2, \sigma_d^2\}$ therefore appears to be easier and is what we do next.

B. Optimizing the Power Allocation

Clearly, maximizing the lower bound on the capacity over the power allocation is equivalent to maximizing ρ_{eff} with respect to $\{\sigma_\tau^2, \sigma_d^2\}$. This is the following optimization problem:

$$\max_{\sigma_\tau^2, \sigma_d^2} \rho_{\text{eff}} \text{ s.t. } T_\tau + T_d = T, \quad \sigma_\tau^2 T_\tau + \sigma_d^2 T_d = \sigma^2 T. \quad (17)$$

Solving (17) is what we do in this section. To this end, let us denote the fraction of the total transmit energy used in the data transmission phase by α so that

$$\sigma_d^2 T_d = \alpha \sigma^2 T, \quad \sigma_\tau^2 T_\tau = (1 - \alpha) \sigma^2 T, \quad 0 < \alpha < 1.$$

¹ $A \geq B > 0$ implies that $B^{-*/2} A B^{1/2} \geq I$, which in turn implies that $\log \det B^{-*/2} A B^{1/2} \geq 0$, which further implies that $\log \det A \geq \log \det B$.

Then, we can write

$$\begin{aligned}\rho_{\text{eff}} &= \frac{\sigma_d^2 \sigma_\tau^2 T_\tau}{1 + \sigma_\tau^2 T_\tau + \sigma_d^2 L} \\ &= \frac{(\sigma^2 T)^2 \alpha (1 - \alpha)}{T_d + (1 - \alpha) \sigma^2 T T_d + \alpha \sigma^2 T L} \\ &= \frac{\sigma^2 T}{T_d - L} \cdot \frac{\alpha (1 - \alpha)}{-\alpha + \gamma}\end{aligned}\quad (18)$$

where

$$\gamma = \frac{T_d(1 + \sigma^2 T)}{\sigma^2 T(T_d - L)}.$$

The maximum ρ_{eff} in (18) depends on γ and, consequently, the sign of $T_d - L$. We consider the three possible cases:

1) $T_d = L$:

Here, we can write

$$\rho_{\text{eff}} = \frac{(\sigma^2 T)^2}{L(1 + \sigma^2 T)} \cdot \alpha(1 - \alpha)$$

and clearly

$$\max_{\alpha} \rho_{\text{eff}} = \frac{(\sigma^2 T)^2}{4L(1 + \sigma^2 T)}, \text{ achieved for } \alpha = \frac{1}{2}.$$

2) $T_d > L$:

Differentiating ρ_{eff} with respect to α yields

$$\frac{d\rho_{\text{eff}}}{d\alpha} = \frac{\sigma^2 T}{T_d - L} \frac{(1 - 2\alpha)(-\alpha + \gamma) + \alpha(1 - \alpha)}{(-\alpha + \gamma)^2}.$$

Since $\gamma < 0$ here, the optimal α is given by

$$\alpha = \gamma - \sqrt{\gamma(\gamma - 1)}$$

and the maximum effective power

$$\max_{\alpha} \rho_{\text{eff}} = \frac{\sigma^2 T}{T_d - L} (\sqrt{\gamma} - \sqrt{\gamma - 1})^2.$$

3) $T_d < L$:

In this case, $\gamma > 1$, and hence, the optimal α is given by

$$\alpha = \gamma + \sqrt{\gamma(\gamma - 1)}$$

achieving the maximum effective power

$$\max_{\alpha} \rho_{\text{eff}} = \frac{\sigma^2 T}{L - T_d} (\sqrt{-\gamma} - \sqrt{-\gamma + 1})^2.$$

We can summarize the previous results as follows:

Optimal Power Distribution: Given the total transmit energy in a training-based transmission scheme $\sigma^2 T$, the power allocation to the data transmission over an interval T_d that maximizes the lower bound on the capacity of training-based schemes (16) is given by

$$\sigma_d^2 = \begin{cases} (\gamma - \sqrt{\gamma(\gamma - 1)}) \sigma^2 \frac{T}{T_d}, & \text{for } T_d > L \\ \frac{1}{2} \sigma^2 \frac{T}{T_d}, & \text{for } T_d = L \\ (\gamma + \sqrt{\gamma(\gamma - 1)}) \sigma^2 \frac{T}{T_d}, & \text{for } T_d < L \end{cases}$$

where $\gamma = (T_d(1 + \sigma^2 T))/(\sigma^2 T(T_d - L))$. The corresponding lower bound on capacity is

$$C_\tau \geq E \log \det(I + \rho_{\text{eff}} \bar{H}_d \bar{H}_d^*)$$

where

$$\rho_{\text{eff}} = \begin{cases} \frac{\sigma^2 T}{T_d - L} (\sqrt{\gamma} - \sqrt{\gamma - 1})^2, & \text{for } T_d > L \\ \frac{(\sigma^2 T)^2}{4L(1 + \sigma^2 T)}, & \text{for } T_d = L \\ \frac{\sigma^2 T}{L - T_d} (\sqrt{-\gamma} - \sqrt{-\gamma + 1})^2, & \text{for } T_d < L \end{cases}. \quad (19)$$

We can further simplify these expressions for the special cases of low and high SNR. In particular, at high SNR, we have

$$\lim_{\sigma^2 \rightarrow \infty} \gamma = \frac{T_d}{T_d - L}$$

and at low SNR

$$\gamma = \frac{T_d}{T(T_d - L)} O\left(\frac{1}{\sigma^2}\right), \text{ as } \sigma^2 \rightarrow 0.$$

1) *High SNR:*

At high SNR, the lower bound on capacity is given by

$$C_\tau \geq E \log \det \left(I + \frac{\sigma^2 T}{(\sqrt{T_d} + \sqrt{L})^2} \bar{H}_d \bar{H}_d^* \right)$$

while the optimal power allocation is

$$\sigma_d^2 = \frac{\sqrt{T_d}}{\sqrt{T_d} + \sqrt{L}} \cdot \sigma^2 \frac{T}{T_d}.$$

2) *Low SNR:*

At low SNR, the optimal power allocation is

$$\sigma_d^2 = \frac{1}{2} \cdot \sigma^2 \frac{T}{T_d}$$

while the lower bound on the capacity is given by

$$\begin{aligned} C_\tau &\geq E \log \det \left(I + \frac{(\sigma^2 T)^2}{4T_d} \bar{H}_d \bar{H}_d^* \right) \\ &\approx \frac{(\sigma^2 T)^2}{4T_d} E \text{trace} (\bar{H}_d \bar{H}_d^*) = \frac{(\sigma^2 T)^2 L}{4} \end{aligned}$$

where to find the low SNR approximations, we used $\log \det(\cdot) = \text{trace} \log(\cdot)$ and the Taylor series expansion of $\log(\cdot)$. Note that the low SNR capacity is quadratic in σ^2 and independent of T_d .

C. Optimizing Over T_τ

The final step in the optimization procedure is to maximize the capacity bound in (16) over the length of the training interval T_τ (equivalently, $T_d = T - T_\tau$). To this end, let us write the training-based capacity lower bound as

$$\begin{aligned} C_B(\rho_{\text{eff}}(T_d), T_d) &= E \log \det (I + \rho_{\text{eff}}(T_d) \bar{H}_d \bar{H}_d^*) \\ &= E \log \det R(\rho_{\text{eff}}(T_d), T_d) \end{aligned}$$

where, from the Toeplitz structure of \bar{H}_d , $R(\rho_{\text{eff}}(T_d), T_d)$ is the $T_d \times T_d$ Toeplitz matrix given by

$$R(\rho_{\text{eff}}(T_d), T_d)_{ij} = \begin{cases} 1 + \rho_{\text{eff}}(T_d) \sum_k |h_k|^2 & i = j \\ \rho_{\text{eff}}(T_d) \sum_k h_{k+i-j}^* h_k & i \neq j. \end{cases}$$

Note that T_d affects the capacity lower bound C_B in two ways: one through the effective SNR ρ_{eff} and the other through the dimension of the Toeplitz matrix R . This is why we have explicitly written $C_B = C_B(\rho_{\text{eff}}(T_d), T_d)$.

For brevity, here, we will treat only the case when $T_d > L$. (Other cases are treated similarly.) Using some cumbersome algebra, it can be shown that the effective SNR, as given by (19), satisfies

$$\rho_{\text{eff}}(T_d) \geq \left(1 - \frac{1}{T_d}\right) \rho_{\text{eff}}(T_d - 1). \quad (20)$$

Thus, the rate of decrease of the SNR as we increase the training interval is no greater than $1/T_d$. Now, note that

$$\begin{aligned} C_B(\rho_{\text{eff}}(T_d), T_d) &= E \log \det (I + \rho_{\text{eff}}(T_d) \bar{H}_d^* \bar{H}_d) \\ &\geq E \log \det \left(I + \left(1 - \frac{1}{T_d}\right) \rho_{\text{eff}}(T_d - 1) \bar{H}_d^* \bar{H}_d \right) \\ &= C_B(\rho_{\text{eff}}(T_d - 1), T_d) \\ &\quad + E \log \det \left(I - \frac{\rho_{\text{eff}}(T_d - 1)}{T_d} \bar{H}_d^* \bar{H}_d R^{-1}(\rho_{\text{eff}}(T_d - 1), T_d) \right) \\ &= C_B(\rho_{\text{eff}}(T_d - 1), T_d) \\ &\quad + E \log \det \left[I - \frac{1}{T_d} \left(I + \frac{1}{\rho_{\text{eff}}(T_d - 1)} (\bar{H}_d^* \bar{H}_d)^{-1} \right)^{-1} \right] \\ &= C_B(\rho_{\text{eff}}(T_d - 1), T_d) \\ &\quad + E \sum_{i=1}^{T_d} \log \left(1 - \frac{\frac{1}{T_d}}{1 + \frac{1}{\lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}} \right) \\ &= C_B(\rho_{\text{eff}}(T_d - 1), T_d) \\ &\quad + E \sum_{i=1}^{T_d} \log \frac{1 + \left(1 - \frac{1}{T_d}\right) \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}{1 + \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)} \end{aligned}$$

where $\lambda_i(\bar{H}_d^* \bar{H}_d)$ denotes eigenvalues of $\bar{H}_d^* \bar{H}_d$.

Let us now further identify the first term on the right-hand side of the above inequality. Note that by the Toeplitz property of $R(\rho_{\text{eff}}(T_d - 1), T_d)$, we may write

$$R(\rho_{\text{eff}}(T_d - 1), T_d) = \begin{bmatrix} R(\rho_{\text{eff}}(T_d - 1), T_d - 1) & \times \\ \times & \times \end{bmatrix}$$

and that

$$\det R(\rho_{\text{eff}}(T_d - 1), T_d) = \frac{\det R(\rho_{\text{eff}}(T_d - 1), T_d - 1)}{[R^{-1}(\rho_{\text{eff}}(T_d - 1), T_d)]_{T_d, T_d}}$$

since $1/[R^{-1}(\rho_{\text{eff}}(T_d - 1), T_d)]_{T_d, T_d}$ is the corresponding Schur complement. Inserting this last expression into the bound for $C_B(\rho_{\text{eff}}(T_d), T_d)$ yields

$$C_B(\rho_{\text{eff}}(T_d), T_d) \geq C_B(\rho_{\text{eff}}(T_d - 1), T_d - 1) + \delta \quad (21)$$

where

$$\begin{aligned} \delta &= -E \log [R^{-1}(\rho_{\text{eff}}(T_d - 1), T_d)]_{T_d, T_d} \\ &\quad + E \sum_{i=1}^{T_d} \log \frac{1 + \left(1 - \frac{1}{T_d}\right) \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}{1 + \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}. \quad (22) \end{aligned}$$

The quantity $C_B(\rho_{\text{eff}}(T_d), T_d)$ is the training-based capacity lower bound for a data interval of length T_d , and likewise, $C_B(\rho_{\text{eff}}(T_d - 1), T_d - 1)$ is the training-based capacity lower bound for a data interval of length $T_d - 1$. Clearly, if $\delta \geq 0$ for all T_d , then the capacity lower bound is an increasing function of T_d ; therefore, the optimal choice of the data interval is its largest possible value $T_d = T - L$.

This is certainly true at high SNR. To see that, note that the second term in (22) is bounded below by

$$\begin{aligned} E \sum_{i=1}^{T_d} \log \frac{1 + \left(1 - \frac{1}{T_d}\right) \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}{1 + \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)} \\ \geq \sum_{i=1}^{T_d} \log \left(1 - \frac{1}{T_d}\right) = T_d \log \left(1 - \frac{1}{T_d}\right) \end{aligned}$$

which is increasing in T_d , and thus, since $T_d > L \geq 1$, is bounded below by $-2 \log 2$. On the other hand, the first term in (22) behaves as $\log \sigma^2$ at high SNRs. We therefore have the following result.

Optimal Training Interval at High SNR: For any T and sufficiently high transmit power σ^2 , the optimal length of the training interval is equal to the length of the channel $T_\tau = L$.

Showing that the above result holds for all SNR requires one to verify that $\delta \geq 0$ at all SNR. Based on extensive simulations, we conjecture that the expected value of the first diagonal entry of $R^{-1}(\rho_{\text{eff}}(T_d - 1), T_d)$ is bounded by

$$\begin{aligned} E \log [R^{-1}(\rho_{\text{eff}}(T_d - 1), T_d)]_{T_d, T_d} \\ \leq E \sum_{i=1}^{T_d} \log \frac{1 + \left(1 - \frac{1}{T_d}\right) \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}{1 + \lambda_i(\bar{H}_d^* \bar{H}_d) \rho_{\text{eff}}(T_d - 1)}. \end{aligned}$$

We therefore propose the following.

Conjecture: For any T and any transmit power σ^2 , the optimal length of the training interval is equal to the length of the channel $T_\tau = L$.

Although we have not yet been able to prove this conjecture, based on extensive study and simulation, we believe it to be true. We therefore formalize the result in the following theorem.

Theorem 1 (Optimal Parameters of Training-Based Scheme): The optimal length of the training interval for a training-based transmission scheme over a block-fading frequency-selective FIR channel of length L is given by $T_\tau = L$, and the lower bound on the capacity is given by

$$C_\tau \geq E \log \det (I + \rho_{\text{eff}} \bar{H}_d^* \bar{H}_d) \quad (23)$$

where

$$\rho_{\text{eff}} = \begin{cases} \frac{\sigma^2 T}{T-2L}(\sqrt{\gamma} - \sqrt{\gamma-1})^2, & \text{for } T > 2L \\ \frac{(\sigma^2 T)^2}{4L(1+\sigma^2 T)}, & \text{for } T = 2L \\ \frac{\sigma^2 T}{2L-T}(\sqrt{-\gamma} - \sqrt{-\gamma+1})^2, & \text{for } T < 2L \end{cases}$$

and $\gamma = (T-L)(1+\sigma^2 T)/(\sigma^2 T(T-2L))$.

The optimal power allocation is given by

$$\sigma_d^2 = \begin{cases} (\gamma - \sqrt{\gamma(\gamma-1)})\sigma^2 \frac{T}{T-L}, & \text{for } T > 2L \\ \frac{1}{2}\sigma^2 \frac{T}{T-L}, & \text{for } T = 2L \\ (\gamma + \sqrt{\gamma(\gamma-1)})\sigma^2 \frac{T}{T-L}, & \text{for } T < 2L \end{cases}$$

$$\sigma_\tau^2 = \sigma_d^2 + (\sigma^2 - \sigma_d^2) \frac{T}{L}.$$

At high SNR, the optimal power distribution can be approximated by

$$\sigma_d^2 = \frac{T}{T-L+\sqrt{L(T-L)}}\sigma^2, \quad \sigma_\tau^2 = \frac{T}{L+\sqrt{L(T-L)}}\sigma^2$$

and the corresponding effective SNR becomes

$$\rho_{\text{eff}} = \frac{\sigma^2 T}{(\sqrt{T-L} + \sqrt{L})^2}.$$

Some comments regarding Theorem 1 are in place. Intuitively, the longer the training interval, the better estimate of the channel, and thus, the larger the effective SNR. However, a longer training interval means less time for the data transmission. Theorem 1 implies that the significance of the data transmission interval outweighs that of the training interval, as the optimal training interval is set to its minimum meaningful length, that is, the length of the channel. Although it would appear that this stems from the fact that increasing the length of the training interval is associated with the tendencies of logarithmic decrease and linear increase of the capacity lower bound, we should re-emphasize that this result is valid only when the optimal power allocation has been performed and not, for example, when $\sigma_\tau^2 = \sigma_d^2 = \sigma^2$.

From Theorem 1, we can draw some further conclusions about the general behavior of the power allocation. In particular, one can show that the following inequalities hold for all SNR σ^2 :

$$\begin{aligned} \sigma_d^2 &< \sigma^2 < \sigma_\tau^2, & \text{for } T > 2L \\ \sigma_\tau^2 &< \sigma^2 < \sigma_d^2, & \text{for } T < 2L \\ \sigma_d^2 &= \sigma^2 = \sigma_\tau^2, & \text{for } T = 2L. \end{aligned}$$

Hence, we need to spend more power for training than for transmission when $T > 2L$, more power for transmission than for training when $T < 2L$, and the same power for both when $T = 2L$.

D. Equal Powers

The assumption made throughout the paper is that the communication system can provide two different transmission power levels, which are then allocated to the training and data transmission phases. However, this may not always be the case. If the practical constraints impose equal power in the

training and transmission phases, i.e., if $\sigma_\tau^2 = \sigma_d^2 = \sigma^2$, then the capacity lower bound of (16) can be expressed as

$$C_\tau \geq E \log \det \left(I + \frac{\sigma^4 T_\tau}{1 + \sigma^2(T_\tau + L)} \bar{H}_d^* \bar{H}_d \right).$$

The tradeoff between the training interval T_τ and the data transmission interval T_d here is obvious. The capacity lower bound increases logarithmically with T_τ through $\log \det(\cdot)$ but decreases linearly through the dimension of $\bar{H}_d^* \bar{H}_d$.

Further simplifications of the capacity lower bound expressions are possible for the special cases of high and low SNR.

1) High SNR:

At high SNR, we can write the capacity lower bound as

$$C_\tau \geq E \log \det \left(I + \frac{\sigma^2 T_\tau}{T_\tau + L} \bar{H}_d^* \bar{H}_d \right). \quad (24)$$

The optimum length of the training interval can be obtained by evaluating (24) for various T_τ , $L \leq T_\tau < T$.

2) Low SNR:

At low SNR, using $\log(I+A) = A - A^2/2 + A^3/3 \dots$, we obtain following expression for the capacity lower bound

$$\begin{aligned} C_\tau &\geq E \log \det (I + \sigma^4 T_\tau \bar{H}_d^* \bar{H}_d) \\ &\approx \text{Etr} \sigma^4 T_\tau \bar{H}_d^* \bar{H}_d \\ &= \sigma^4 L T_\tau (T - T_\tau). \end{aligned}$$

Upon taking the derivative with respect to T_τ , one can notice that the capacity bound is maximized for $T_\tau = T/2$, i.e., that half of the coherence interval must be devoted to training. This matches the multiantenna results of [2].

V. COMPARING CAPACITY BOUNDS WITH ACTUAL CAPACITY AT HIGH AND LOW SNR

Having determined the optimal amount of training for any training-based communication system, the question that remains is *how good are training-based schemes?* To answer this, one would need to compute the actual capacity of a block-fading frequency-selective channel and to compare it with the training-based capacity lower bounds that we have obtained. Unfortunately, computing this capacity, in the general case, is an open problem. However, we can obtain the expression for the capacity at high and low SNR ($\sigma \rightarrow \infty$ and $\sigma \rightarrow 0$).

We begin with the high SNR result, for which the following lemma is useful.

Lemma 1: The $(T+L-1) \times L$ matrix

$$S = \begin{bmatrix} s_1 & 0 & 0 & \dots & 0 \\ s_2 & s_1 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ s_L & s_{L-1} & s_{L-2} & \dots & s_1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ s_T & s_{T-1} & s_{T-2} & \dots & s_{T-L+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & s_T \end{bmatrix}$$

is rank-deficient if, and only if, $s_1 = s_2 = \dots = s_T = 0$.

The entropy of the random vector \mathbf{y}_1 is upper bounded by the entropy of a zero-mean Gaussian random vector of the same variance, and thus

$$h(\mathbf{y}|S \neq 0) \leq T \log \pi(1 + L\sigma^2) + O(1) = T \log \sigma^2 + O(1).$$

Therefore

$$h(\mathbf{y}) \leq (1 - q)T \log \sigma^2 + O(1).$$

To find $h(\mathbf{y}|\mathbf{s})$, we note that $\mathbf{y}|\mathbf{s}$ is a Gaussian random vector with covariance matrix $R_{\mathbf{y}} = I_{T+L-1} + \sigma^2 S S^*$, and so

$$\begin{aligned} h(\mathbf{y}|\mathbf{s}) &= E \log \det \pi (I_{T+L-1} + \sigma^2 S S^*) \\ &= \log \pi^{T+L-1} + E \log \det (I_L + \sigma^2 S^* S) \\ &= (1 - q)E \log \det (I_L + \sigma^2 S^* S) + O(1) \\ &= (1 - q) \log \det(\sigma^2 I_L) \\ &\quad + (1 - q)E \log \det \left(S^* S + \frac{1}{\sigma^2} I_L \right) + O(1) \\ &= (1 - q)L \log \sigma^2 + O(1). \end{aligned}$$

We therefore obtain

$$I(\mathbf{y}; \mathbf{s}) \leq (1 - q)(T - L) \log \sigma^2 + O(1).$$

The following upper bound is clearly maximized by choosing $q = 0$, i.e., by assuming that the transmitted matrix is generically nonsingular (nonzero). Thus, for any such distribution on S , we obtain $I(\mathbf{y}; \mathbf{s}) \leq (T - L) \log \sigma^2 + O(1)$, from which it follows that

$$C \leq (T - L) \log \sigma^2 + O(1). \quad (30)$$

On the other hand, Theorem 1 at high SNR yields $\rho_{\text{eff}} = \sigma^2 T / (\sqrt{T - L} + \sqrt{L})^2$. Thus, since $\bar{H}_d^* \bar{H}_d$ is generically nonsingular

$$\begin{aligned} C &\geq E \log \det \left(I + \frac{\sigma^2 T}{(\sqrt{T - L} + \sqrt{L})^2} \bar{H}_d^* \bar{H}_d \right) \\ &\geq E \log \det \left(\frac{\sigma^2 T}{(\sqrt{T - L} + \sqrt{L})^2} \bar{H}_d^* \bar{H}_d \right) \\ &= \log \det \sigma^2 I_{T-L} + O(1) \\ &= (T - L) \log \sigma^2 + O(1) \end{aligned} \quad (31)$$

where, in the progression from the first to the second line, we have used a well-known fact that for $A \geq 0$, $\det(I + A) \geq \det A$.

The inequalities (30) and (31) yield the desired result. \square

Remark: The above result shows that training-based schemes achieve the leading order term in the capacity at high SNR (a similar result for narrowband flat-fading channels is given in [2] and [7]). We may therefore claim that

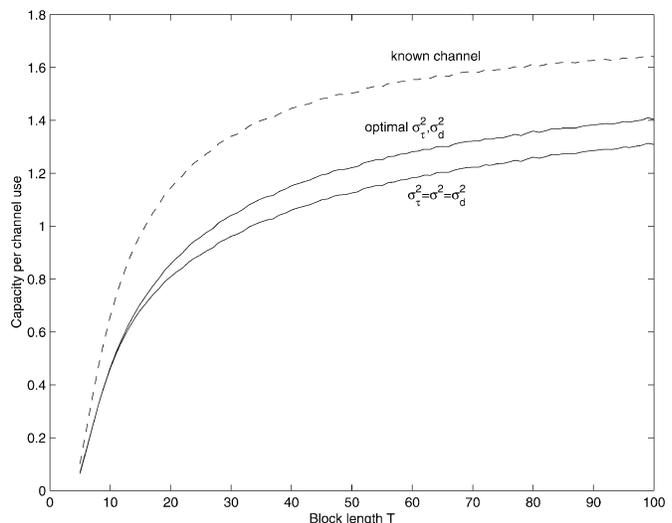

Fig. 1. C/T_d versus T .

training-based schemes are optimal at high SNR. We should further mention that although the results derived in this paper assumed that the channel coefficients are iid $\mathcal{CN}(0, 1)$, this assumption can be considerably relaxed for the high SNR results. In fact, all that is needed is that

$$E \log \det \sigma^2 \bar{H}^* \bar{H} = (T - L) \log \sigma^2 + O(1).$$

Low SNR: At low SNR, the issue is somewhat more tricky. It is well known (see, e.g., [1] and the references therein) that at low SNR, we have $C = O(\sigma^2)$. Examination of Theorem 1, on the other hand, yields

$$C_{\tau} \geq O(\sigma^4). \quad (32)$$

At first glance, it may appear that the above lower bound on the training-based capacity is tight since the effective noise term $\mathbf{v}'_d = \sigma_d \bar{H}_d \mathbf{s}_d + \sigma_{\tau} \bar{H}_{\tau} \boldsymbol{\theta}_{\tau} + \mathbf{v}_d$ in (4) approaches Gaussian noise as $\sigma \rightarrow 0$; therefore, our lower bound obtained by replacing the effective noise by independent Gaussian noise should be tight. However, this claim cannot be true since in any scheme that uses training symbols, one can always ignore the fact that training was employed, and for the remaining $T_d = T - T_{\tau}$ channel uses, assume that the channel is unknown, and obtain the (now scaled) low SNR bound $C = (T_d/T)O(\sigma^2) = O(\sigma^2)$. Of course, this is not what training schemes do: They assume that the channel estimate is perfect and ignore the correlation between the signal and effective additive noise.

Therefore, insofar as the *capacity* of any scheme that transmits training symbols goes, the bound in (32) is extremely loose at low SNR. However, if one considers the fact that training-based detection schemes assume perfect channel estimates and ignore the correlation between the signal and effective noise, then one realizes that training-based detectors are mismatched to the channel and that (32) is an indication of the mutual information obtainable from any such mismatch scheme. We therefore can claim that at low SNR, training-based schemes are

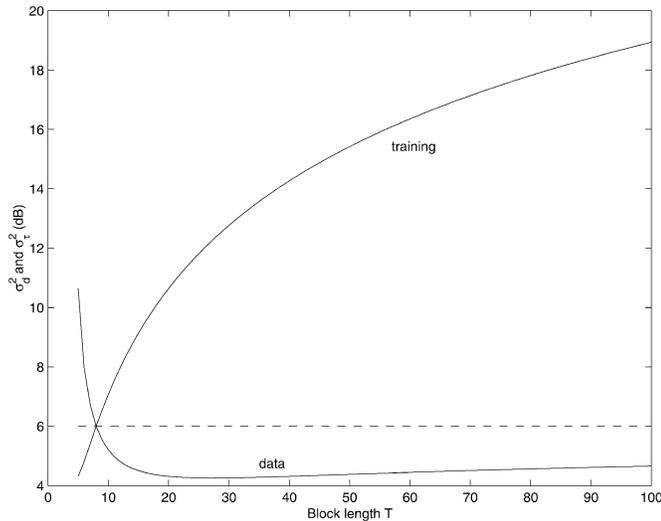

Fig. 2. σ_d^2, σ_r^2 versus T .

highly suboptimal since they can only deliver $O(\sigma^4)$ mutual information, as opposed to the true channel capacity $O(\sigma^2)$.²

VI. PLOTS OF CAPACITIES

Fig. 1 shows the training-based lower bounds on capacity as a function of the block length T for $\sigma^2 = 6$ db and the channel length $L = 4$. By allowing the training and data transmission powers to vary, we achieve an approximately 5–10% increase in capacity. At $T = 50$, achieved capacity is approximately 20% below the (unrealistic) capacity achieved when the receiver knows the channel perfectly.

In Fig. 2, the optimal transmit power allocation σ_d^2 and σ_r^2 is plotted as a function of the block length. The dashed line in Fig. 2 denotes the case of equal training and data transmission powers $\sigma_d^2 = \sigma_r^2$. Fig. 2 illustrates what is implied by Theorem 1 — we need to spend more power for training than for transmission when $T > 2L$, more power for transmission than for training when $T < 2L$, and the same power for both when $T = 2L$.

Haris Vikalo was born in Tuzla, Bosnia and Herzegovina. He received the B.S. degree from the University of Zagreb, Zagreb, Croatia, in 1995, the M.S. degree from Lehigh University, Bethlehem, PA, in 1997, and the Ph.D. degree from Stanford University, Stanford, CA, in 2003, all in electrical engineering.

He held a short-term appointment at Bell Laboratories, Murray Hill, NJ, in the summer of 1999. From November 2002 to July 2003, he was a Postdoctoral Researcher, and since July 2003, he has been an Associate Scientist at the California Institute of

Technology, Pasadena. His research interests include wireless communications, signal processing, and estimation.

Babak Hassibi was born in Tehran, Iran, in 1967. He received the B.S. degree from the University of Tehran in 1989 and the M.S. and Ph.D. degrees from Stanford University, Stanford, CA, in 1993 and 1996, respectively, all in electrical engineering.

From October 1996 to October 1998, he was a research associate with the Information Systems Laboratory, Stanford University, and from November 1998 to December 2000, he was a Member of the Technical Staff with the Mathematical Sciences Research Center, Bell Laboratories, Murray Hill, NJ.

Since January 2001, he has been an assistant professor of electrical engineering at the California Institute of Technology, Pasadena. He has also held short-term appointments at Ricoh California Research Center, Menlo Park, CA, the Indian Institute of Science, Bangalore, India, and Linköping University, Linköping, Sweden. His research interests include wireless communications, robust estimation and control, adaptive signal processing and linear algebra. He is the coauthor of the books *Indefinite Quadratic Estimation and Control: A Unified Approach to H^2 and H^∞ Theories* (New York: SIAM, 1999) and *Linear Estimation* (Englewood Cliffs, NJ: Prentice Hall, 2000). He is a recipient of the 1999 Hugo Schuck Best Paper Award of the American Automatic Control Council, the 2002 National Science Foundation Career Award, and the 2003 Okawa Foundation Research Grant for Information and Telecommunications.

Bertrand Hochwald was born in New York, NY. He received the undergraduate degree from Swarthmore College, Swarthmore, PA, and the M.S. degree in electrical engineering from Duke University, Durham, NC. In 1989, he enrolled at Yale University, New Haven, CT, where he received the M.A. degree in statistics and the Ph.D. degree in electrical engineering.

From 1986 to 1989, he worked for the United States Department of Defense, Fort Meade, MD. From 1995 to 1996, he was a Research Associate and

Visiting Assistant Professor at the Coordinated Science Laboratory, University of Illinois, Urbana-Champaign. He joined the Mathematics of Communications Research Department, Lucent Technologies Bell Laboratories, Murray Hill, NJ, in 1996, where he is now a Distinguished Member of the Technical Staff. He holds several patents in the field of multiantenna wireless communications.

Dr. Hochwald received several achievement awards while with the Department of Defense and the Prize Teaching Fellowship at Yale.

Thomas Kailath (LF'97) received the B.E. (Telecom) degree from the College of Engineering, Pune, India, in June 1956 and the S.M. and Sc.D. degrees in electrical engineering from the Massachusetts Institute of Technology, Cambridge, in June 1959 and June 1961, respectively. He has also received honorary degrees from Linköping University, Linköping, Sweden; Strathclyde University, Glasgow, U.K.; the University of Carlos III, Madrid, Spain; and the University of Bordeaux, Bordeaux, France.

From October 1961 to December 1962, he worked in the Communications Research Division, Jet Propulsion Laboratories, California Institute of Technology Pasadena, where he also taught part-time. Since then, he has been at Stanford University, Stanford, CA, where he is currently Hitachi America Professor of Engineering, Emeritus. He has also held shorter-term appointments at several institutions around the world. His research has spanned a large number of disciplines, emphasizing information theory and communications in the 1960s, linear systems, estimation, and control in the 1970s, VLSI design and sensor array signal processing in the 1980s, and applications to semiconductor manufacturing and digital communications in the 1990s. Concurrently, he contributed to several fields of mathematics, especially stochastic processes, operator theory, and linear algebra. He has authored, edited, and coauthored several books; including *Linear Systems* (Englewood Cliffs, NJ: Prentice-Hall, 1980), *Indefinite Quadratic Estimation and Control* (with B. Hassibi and A. H. Sayed) (New York: SIAM, 1999), and *Linear Estimation* (with A. H. Sayed and B. Hassibi) (Englewood Cliffs, NJ: Prentice-Hall, 2000). In the course of his research and teaching, He has mentored over 100 doctoral and postdoctoral students and authored or co-authored over 300 journal papers.

Prof. Kailath has received outstanding paper prizes from the IEEE Information Theory Society, the IEEE Signal Processing Society, the European Signal Processing Society, and the IEEE TRANSACTIONS ON SEMICONDUCTOR MANUFACTURING. He has held Guggenheim, Churchill, and Humboldt fellowships, among others. He served as President of the IEEE Information Theory Society in 1975 and received its Shannon Award in 2000. Among other awards, he has received the Technical Achievement (in 1989) and Society (in 1991) Awards of the IEEE Signal Processing Society, the 1995 IEEE Education Medal, and (with A. Sayed), and the 1996 IEEE Donald G. Fink Prize Award. He is a member of the National Academy of Engineering, the National Academy of Sciences, the American Academy of Arts and Sciences, the Third World Academy of Sciences, the Indian National Academy of Engineering, and the Royal Spanish Academy of Engineering.
