ABSTRACT

The young binary system T Tauri was observed with the Owens Valley Millimeter Array in the 267 GHz continuum and HCO^+ $J = 3$–2 emission at 0.″8 resolution, with the single-baseline interferometer of the James Clerk Maxwell Telescope–Caltech Submillimeter Observatory in the 357 GHz continuum and with the W. M. Keck Telescope at $\lambda = 4$ μm. The 267 GHz emission is unresolved, with a flux of 397 ± 35 mJy, located close to the position of the optical star T Tau N. An upper limit of 100 mJy is obtained toward the infrared companion T Tau S. The 357 GHz continuum emission is unresolved, with a flux of 1.35 ± 0.68 Jy. HCO^+ $J = 3$–2 was detected from a 2″ diameter core surrounding T Tau N and S. Both stars are detected at 4 μm, but there is no evidence of the radio source T Tau R.

We propose a model in which T Tau S is intrinsically similar to T Tau N but is obscured by the outer parts of T Tau N's disk. A fit to the spectral energy distribution (SED) between 21 cm and 1.22 μm is constructed on this basis. Adopting an r^{-1} surface density distribution and an exponentially truncated edge, disk masses of 0.04 ± 0.01 and 6×10^{-5} to 3×10^{-3} $M_\odot$ are inferred for T Tau N and T Tau S, respectively. A 0.005–0.03 $M_\odot$ circumbinary envelope is also required to fit the millimeter to mid-infrared SED.

Subject headings: binaries: close — ISM: molecules — stars: formation — stars: low-mass, brown dwarfs — stars: pre–main-sequence

1. INTRODUCTION

Many low-mass stars form in multiple systems (see Ghez, Neugebauer, & Matthews 1993), through capture, fragmentation of the collapsing core, or condensation from the primary's disk (e.g., Bodenheimer, Ruzmaikina, & Mathieu 1993). The presence of a close companion must influence the evolution of the star and the possible development of an accretion disk (see, e.g., Jensen, Mathieu, & Fuller 1996). Observations of the distribution of the bulk of the gas and dust in young and forming multiple systems are needed to better understand their evolution, which may be very different from that of a single star. This Letter presents high-resolution continuum and spectral line observations of one such close multiple system: T Tauri.

A prototypical low-mass young stellar object, T Tau is a 0.″7 separation binary (projected distance of 100 AU at 140 pc), consisting of an optically visible star, T Tau N, and an infrared companion, T Tau S (Dyck, Simon, & Zuckerman 1982). Ray et al. (1997) report the presence at $\lambda = 6$ cm of a third source, possibly a star, T Tau R. The system is surrounded by 0.03–0.3 $M_\odot$ of gas and dust distributed on 3000 to 10^4 AU scales (see, e.g., Schuster, Harris, & Russell 1997; Hogerheijde et al. 1997). Both stars appear to drive outflows, at least one of which is directed close to the line of sight (Edwards & Snell 1982; Beckwith et al. 1978; van Langevelde et al. 1994; Herbst, Robberto, & Beckwith 1997). Stellar light curves indicate that the rotation axis of T Tau N is inclined by only ~19° (Herbst et al. 1997). From the strength and variability of its free-free radio emission, T Tau S appears to be a more active outflow source than T Tau N (Skinner & Brown 1994; Ray et al. 1997).

The infrared nature and activity of T Tau S have been explained in a number of ways: through obscuration by a remnant protostellar envelope surrounding T Tau S (Dyck et al. 1982) or around the binary system (Calvet et al. 1994), or through obscuration caused by periodic perturbation of circumstellar material in the binary orbit (Koresko, Herbst, & Leinert 1997). Until recently, the T Tau binary has been resolved only at centimeter and near-infrared wavelengths. All information on the gas and dust in the system has been derived from (sub)millimeter and far-infrared measurements, which did not separate the pair. In this Letter we present subarcsecond resolution 267 and 357 GHz continuum observations showing that the compact dust emission from the system is confined to the surroundings of T Tau N (see also van Langevelde, van Dishoeck, & Blake 1997). In addition, 0.″4 resolution imaging confirms that T Tau S is brighter than T Tau N at $\lambda = 4$ μm. The spatially resolved (sub)millimeter fluxes, and literature values for centimeter and infrared observations, allow a fit to the spectral energy distributions (SEDs) of the individual sources, constraining the mass and size of the disk around T Tau N and the circumstellar material around T Tau S.

2. OBSERVATIONS

Continuum emission at 267 GHz and HCO^+ $J = 3$–2 line emission were imaged with the millimeter array at the Owens Valley Radio Observatory (OVRO) on 1994 December 1. Baselines between 20 and 200 kλ were sampled, resulting in a 0.″77 × 0.″96 synthesized beam for a robust weighting of +1. The continuum data were integrated over a 1 GHz bandwidth, yielding a 1 σ rms noise level of 30 mJy beam^{-1}. The HCO^+ 3–2 data were recorded in a 64 channel correlator with a resolution of 0.5 MHz, or 0.56 km s^{-1}; the 1 σ rms noise in a channel is 1.3 Jy beam^{-1}, or 19 K km s^{-1} for natural weighting. The antenna-based complex gains of the OVRO instrument were derived with the MMA package, using PKS 0528+134 as the phase calibrator and 3C 454.3 as the flux calibrator, for

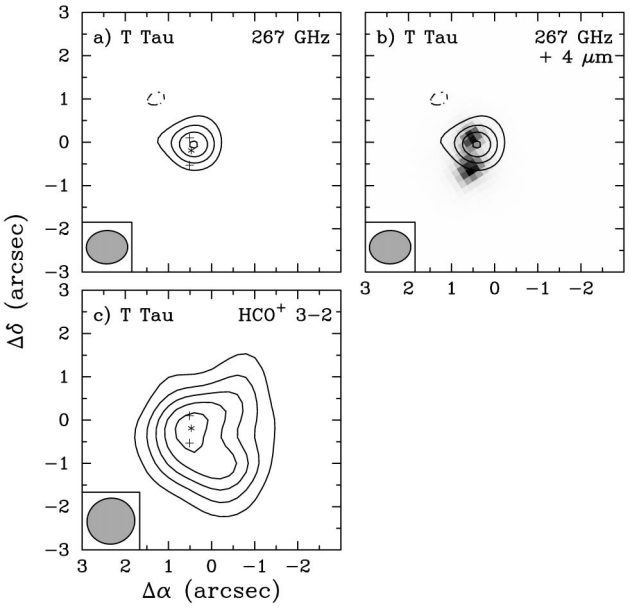

FIG. 1.—(*a*) Cleaned image of 267 GHz continuum emission of T Tau using robust weighting of +1. Contours are drawn at 3 σ intervals of 90 mJy beam^{-1}. T Tau N and S are indicated by crosses and T Tau R by an asterisk. (*b*) Same 267 GHz contours overlaid on the 4 μm image (gray scale), which has been aligned with the radio positions of T Tau N and S. (*c*) Velocity-integrated HCO^+ 3–2 emission on baselines less than 120 kλ. Contours are drawn at 3 σ intervals of 9.2 Jy beam^{-1} km s^{-1} (134 K km s^{-1}).

which a flux of 6.50 Jy was derived from observations of planets. The data were mapped and analyzed with the MIRIAD software package. Like the radio positions of T Tau N and S, the coordinates of the 267 GHz emission are tied to the radio reference frame; the estimated uncertainty in the absolute positions of 0.″2 is dominated by the accuracy of the array baselines.

The 357 GHz continuum emission was observed together with HCO^+ 4–3 line emission using the single-baseline interferometer (SBI) of the James Clerk Maxwell Telescope (JCMT) and the Caltech Submillimeter Observatory (CSO), on 1994 October 28. Projected baselines ranged between 140 and 195 kλ, resulting in an effective resolution of ~0.″7. The data were recorded in a 500 MHz wide band with 400 channels and vector averaged over 100 s intervals. The gain of the instrument was ~135 Jy K^{-1}, derived from PKS 0528+134. Since the phase variations on the JCMT-CSO baseline cannot be tracked, only the 100 s vector-averaged visibility amplitudes are used (cf. Lay et al. 1994).

Imaging at $\lambda = 4$ μm was acquired with the W. M. Keck Telescope on 1997 February 7, using the near-infrared camera and Brα-continuum filter (3.97–4.02 μm). The detector array has 0.″15 pixels. The final image contains 2000 integrations of 45 ms each. Atmospheric conditions were good, with a seeing of 0.″3–0.″4. The image was processed with the IRAF package.

3. RESULTS

The 267 GHz continuum emission, shown in Figure 1*a*, is unresolved with a peak flux of 369 ± 30 mJy beam^{-1}. A point-source fit to the visibilities yields a flux of 397 ± 35 mJy and a position within 1 σ (0.″2) of both T Tau N and T Tau R (Table 1). The 3 σ upper limit on the flux toward T Tau S is 100 mJy. Although T Tau R, at 0.″13, is slightly closer to the continuum peak than T Tau N (0.″20), we attribute the 267 GHz emission to T Tau N, because of the uncertain nature of T Tau R. On the basis of the compactness of the source and the emission at infrared and submillimeter wavelengths (Herbst et al. 1997; Beckwith et al. 1990), we interpret the 267 GHz emission as arising from a disk of radius less than 0.″45 ≈70 AU around the optical star.

TABLE 1

SOURCE POSITIONS AND 267 GHz FLUXES[a]

Source	α(1950.0)	δ(1950.0)	F_ν (Jy)
T Tau N	04 19 04.24	+19 25 04.92	0.397 ± 0.035
T Tau S	...	...	<0.10
HCO^+ 3–2	04 19 04.23	+19 25 04.46	29.5 ± 2.8
Radio Positions			
T Tau N[b]	04 19 04.245	+19 25 05.20	
T Tau S[b]	04 19 04.250	+19 25 04.58	
T Tau R[c]	04 19 04.243	+19 25 04.88	

NOTE.—Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds.

[a] Absolute positional accuracy at 267 GHz ~0.″2.

[b] 3.6 cm coordinates from Skinner & Brown 1994.

[c] 6.0 cm coordinates from Ray et al. 1997.

The $\lambda = 4$ μm Keck image of the T Tau system is shown in Figure 1*b* in gray scale, with contours of the 267 GHz emission superposed. The binary is clearly resolved and is consistent with two individual point sources. The 4 μm flux from T Tau S is 1.5 times that from T Tau N. No absolute positional information is available for the Keck data, so the image has been aligned with the radio positions of T Tau. The binary separation at 4 μm is 0.″70, consistent with measurements at centimeter wavelengths. No evidence is found for emission from T Tau R.

The 357 GHz continuum SBI data are consistent with emission from a single point source and yield a vector-averaged flux of 1350 ± 675 mJy, where the uncertainty is dominated by the flux calibration. The observed emission at 267 and 357 GHz accounts for 60%–80% of the single-dish fluxes at these wavelengths on 19″ and 13″ scales, respectively (Moriarty-Schieven et al. 1994). Including the 2.7 mm point-source flux from Hogerheijde et al. (1997), a spectral index of 2.6 ± 0.2 is found for the compact emission.

Emission in the HCO^+ 3–2 line is detected only on baselines less than 70 kλ and over 3–11 km s^{-1}. The naturally weighted image (Fig. 1*c*) shows a 2″ core, centered between T Tau N and S, with a peak flux of 6.1 ± 0.4 Jy beam^{-1}, or 745 K km s^{-1}. This is 25% of the 19″ single-dish line flux, comparable to the 10% recovered at HCO^+ 1–0 by OVRO (Hogerheijde et al. 1997). No emission from HCO^+ 4–3 was detected in the SBI data with a statistical upper limit of ~0.35 Jy, or ~7 K, for a 1″ source size, consistent with the nondetection of HCO^+ 3–2 emission on baselines greater than 70 kλ.

4. UNDERSTANDING THE NATURE OF T TAU S AND T TAU N

Our observations of 267 GHz continuum emission show that most of the material on 100 AU scales is associated with T Tau N, most likely in a disk. Although the near-infrared SED of T Tau S also indicates the presence of a disk, the 267 GHz upper limit strictly constrains the mass. Bate & Bonnell (1997) found that material infalling toward a binary system preferably forms a disk around the more massive primary, which our observations show to be T Tau N. How does the difference in disk mass for T Tau N and S impact our

understanding of the T Tau system, especially the obscured, infrared nature of T Tau S?

Of the many scenarios that have been proposed to explain the infrared nature of T Tau S (see § 1), that of dynamical interaction is particularly interesting because it links the obscuration of infrared companions in binary systems with their observed variability (Koresko et al. 1997). On the basis of our new data for T Tau, we propose a variation on this model wherein T Tau S is obscured directly by the disk around T Tau N. This requires the disk to extend to $\gtrsim$100 AU, at a modest inclination with respect to the binary orbital plane. For the assumed dust properties (Ossenkopf & Henning 1994; their model "thin 6"), a surface density of 0.12 g cm^{-2} is required to obscure an assumed stellar photosphere for T Tau S of ~5000 K.

To further investigate this model and derive mass estimates for the disks around T Tau N and S and for the circumbinary envelope, a fit to the SED between 21 cm and 1.22 μm is constructed (Fig. 2). The model for T Tau N is based on a stellar photosphere of 5250 K (K0 star) and a temperature distribution in the disk characterized by a radial power law with index $-q$ with an intrinsic luminosity L_d (Adams, Lada, & Shu 1987; their eq. [A22]). From the optically thick 1.22–20 μm range, estimates are obtained of the stellar radius, $R_* = 3.4\ R_\odot$, the inner radius of the disk, $R_{\rm in} = 5.1\ R_\odot$, the disk luminosity, $L_d = 3.0\ L_\odot$, and the index, $q = 0.51$ (cf. Herbst et al. 1997).

At longer wavelengths, where the disk is largely optically thin, the surface density is important. The density distribution depends on angular momentum transport processes like viscosity and disk wind (cf. Adams & Lin 1993). The gravitational interaction with the binary companion is expected to truncate the disk at some radius (cf. Lin & Papaloizou 1993). The surface density is approximated here by a radial power law $\Sigma \propto r^{-1}$, which is truncated at radii $r > R_{\rm trunc}$ by an exponential taper, $\exp(-[r - R_{\rm trunc}]/r_e)$. It is found that this exponential falloff is required to permit the low surface density of 0.12 g cm^{-2} needed for the obscuration of T Tau S while still fitting the flux of T Tau N. The exact functional form of the truncation or the adopted outer radius is not important for the derived masses for $R_{\rm trunc} \gtrsim 50$ AU. Assuming that $R_{\rm trunc} = 70$ AU, the only free model parameter left is the 1/*e* radius r_e. The 267 GHz flux constrains r_e to 7–8 AU, with a corresponding disk mass of $0.04 \pm 0.01\ M_\odot$.

The SED of T Tau S is fitted with the same model and parameters, plus obscuration by the disk of T Tau N. The only differences are the disk mass, along with the luminosity of 15 $L_\odot$ and the index of $q = 0.54$ required to fit the higher infrared fluxes. An interstellar extinction of $A_V = 1.44$ mag is applied to the whole system (Cohen & Kuhi 1979), and free-free spectral indices of 0.6 and 0.2 are used for T Tau N and S, respectively. The assumed stellar temperature is unimportant since the disk luminosity dominates the SED at $\lambda > 2$ μm. The disk mass is constrained by the 20 μm flux and the 267 GHz upper limit to lie between 6×10^{-5} and $3 \times 10^{-3}\ M_\odot$.

To fit the unresolved (sub)millimeter and infrared observations, a circumbinary envelope of 0.005–0.03 $M_\odot$ is also required, depending on the disk mass of T Tau S. This envelope is modeled with a power law for the density with slope $p = -1.5$ and for the temperature with slope $q = -0.4$. At the inner radius of 100 AU, a temperature of 63 K provides a good fit to the peak of the SED. An outer radius of 3000 AU is used, corresponding to the typical beam size of the (sub)millimeter observations. The presence of this power-law envelope is consistent with the nondetection of extended 267 GHz continuum emission on 16–200 kλ baselines at the obtained noise level. The HCO^+ 3–2 emission on 16–70 kλ baselines can be explained by the sensitivity of this line to density, which results in a more peaked brightness distribution, although additional emission from, e.g., material in the walls of the outflow cavity (cf. Hogerheijde et al. 1997) is required to fit its absolute flux.

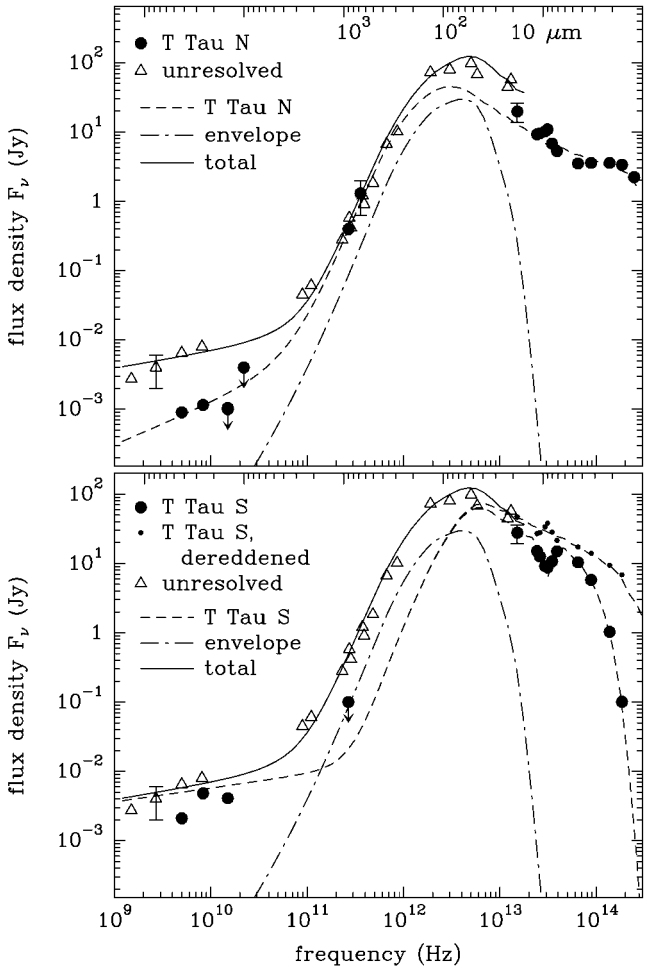

FIG. 2.—Spectral energy distribution of T Tau N (*top panel*) and S (*lower panel*) and model curves for T Tau S with $M_d = 5 \times 10^{-4}\ M_\odot$ and envelope of $M = 0.02\ M_\odot$. The data points include our 267 and 357 GHz measurements and literature data (Beckwith et al. 1990; Beckwith & Sargent 1991; Herbst, Robberto, & Beckwith 1997; Hogerheijde et al. 1997; Ray et al. 1997; Skinner & Brown 1994; Weintraub, Sandell, & Duncan 1989; Weintraub, Masson, & Zuckerman 1987). The model is discussed in the text.

The nondetection of HCO^+ 3–2 on baselines greater than 70 kλ with an upper limit of ~1.4 Jy beam^{-1}, or ~171 K km s^{-1}, sets a rough upper limit to the HCO^+ abundance in the disk. Assuming an excitation temperature of 60 K and neglecting any optical depth effects, we find an upper limit to the abundance of 1×10^{-8}.

The limit placed on the amount of circumstellar material around T Tau S by our 267 GHz measurements places constraints on the nature of the obscuration. While a small edge-on disk around T Tau S could provide the observed extinction, the disk around T Tau N is a more likely candidate. In either case, it is implied that the binary orbit and the respective disks are not coplanar. A circumstellar envelope around T Tau S alone is unlikely as obscuring agent, since it implies that either the current projected binary separation is a chance close pro-

jection or that the envelope is less than 50 AU and hence dynamically short-lived. An envelope around both T Tau N and S requires a special geometry that allows T Tau N to suffer little extinction while heavily obscuring T Tau S.

To test the hypothesis that T Tau N's disk is obscuring T Tau S, subarcsecond resolution observations at submillimeter wavelengths and at 10–20 μm are needed to place firmer limits on the distribution of the circumstellar material around T Tau S. For example, monitoring of the near-infrared variability and the shape of the 10 μm silicate absorption could distinguish intrinsic variations in T Tau S from inhomogeneities in the obscuring disk or changes in the star-disk geometry. Observation of the 20–200 μm spectrum planned for the *Infrared Space Observatory* will help to further constrain the SED model, since the emission from the disks and the envelope peak at these wavelengths. Some of the other infrared companions to T Tauri stars might be explained by disk obscuration as well (e.g., Haro 6–10 at 1.″2 separation, Leinert & Haas 1989; XZ Tau at 0.″3, Haas et al. 1990; UY Aur at 0.″9, Herbst et al. 1995). Millimeter observations at subarcsecond resolution are needed to determine the material distributions in these systems.

The authors wish to thank O. Lay for a critical reading of the manuscript and him and J. Carlstrom for assistance in the observation and reduction of the SBI data. The telescope staffs are thanked for support during the observations. E. v. D. acknowledges support by NWO/NFRA, G. A. B. by NASA (NAGW-2297, NAGW-1955), L. G. M. by NASA (NAG 5-4429), and H. J. v. L. by the European Union (CHGECT920011). The OVRO Millimeter Array and the CSO are operated by the Caltech under funding from the NSF (AST96-13717, AST93-13929). The JCMT is operated by the Joint Astronomy Centre on behalf of PPARC UK, NWO Netherlands, and NRC Canada. The W. M. Keck Observatory is operated as a scientific partnership between Caltech, University of California, and NASA. It was made possible by the generous financial support of the W. M. Keck Foundation.
