Abstract. Using data from the Voyager and Pioneer spacecraft, we examine the energy spectra of anomalous cosmic rays (ACRs) during 1992–1994, a period of rapidly increasing intensities of these particles in the outer heliosphere. The 1992 period appears to be in nonequilibrium, marked by a rapid decrease in the tilt of the current sheet from $\sim 63^\circ$ to $\sim 35^\circ$ and a complex, evolving magnetic topology that affects interplanetary drifts and drift acceleration along the solar wind termination shock. In addition, large propagating interplanetary disturbances in 1991 may have weakened the shock temporarily, reducing the intensity of accelerated ions. The 1993–1994 period appears to be in quasi-equilibrium, marked by a stable tilt of the current sheet and a steady, large-scale magnetic topology that provides stable conditions for propagation and acceleration. The ACR intensities of higher-rigidity particles rise slowly during this period, suggesting that the shock intensity has stabilized. At lower rigidities the ACR intensities are increasing rapidly, which we attribute to decreasing modulation. During 1994 days 157–209, we estimate that the shock was at 85 ± 5 AU. The shock strength s is estimated to be 2.63 ± 0.14 , significantly weaker than a strong shock ($s = 4$) and consistent with a termination shock modified by the pressure of galactic cosmic rays. By comparing these 1994 observations with those made in 1987, we estimate that the latitudinal gradient of ACR He with energies 31–57 MeV nucleon $^{-1}$ is $\sim 1.9\%/deg$ along the shock from the equator to the pole. We estimate that the ratio of the efficiency of injection of He $^+$ to H $^+$ pickup ions into the acceleration process is 7.0 ± 1.6 .

1. Introduction

Anomalous cosmic rays (ACRs) are thought to be interstellar neutrals [Fisk *et al.*, 1974] that have become ionized in the interplanetary medium and accelerated in the outer heliosphere, probably at the solar wind termination shock [Pesses *et al.*, 1981]. Seven elements have been identified in the ACR component: H, He, C, N, O, Ne, and Ar [McDonald *et al.*, 1974; Garcia-Munoz *et al.*, 1973; Hovestadt *et al.*, 1973; Cummings and Stone, 1988, 1990; Christian *et al.*, 1988, 1995; McDonald *et al.*, 1995]. Recently, observations have confirmed that the ACRs are singly ionized [Adams *et al.*, 1991; Singh *et al.*, 1991; Klecker *et al.*, 1995], and a study of their gradients has suggested that the solar wind termination shock was at 67 ± 5 AU in 1987 during the last period of minimum solar activity [Cummings *et al.*, 1994].

Other recent estimates of the location of the termination shock based on dynamic pressure balance [Belcher *et al.*, 1993; Whang and Burlaga, 1993; Lallement *et al.*, 1993], hydrogen Lyman α resonant scattering [Hall *et al.*, 1993], and kilohertz radio emissions [Grzedzielski and Lazarus, 1993; Zank *et al.*, 1994] range from 60 to 105 AU. However, Gurnett *et al.* [1993] ascribe the radio emissions to the heliopause region located at 116 to 177 AU.

Cummings *et al.* [1994] based their estimate of the location of the termination shock in 1987 on a model in which positive particles were drifting into the inner heliosphere along the Sun's neutral sheet. The radial gradient of the ACRs was observed to be correlated with the tilt of the neutral sheet for tilts less than $\sim 30^\circ$. The estimate of 67 AU for the shock location was derived by using the observed tilt of the sheet to infer the local gradient of the particles and then extrapolating the ACR intensity outward from the position of the Voyager 2 (V2) and Pioneer 10 (P10) spacecraft to a location where the extrapolated intensity was steady with time.

During the current segment of the solar cycle, after the solar magnetic field reversed in 1990, the ACR particles are expected to drift downward onto the heliographic equator from the polar regions [Jokipii *et al.*, 1977]. The cosmic ray intensity is expected to be less responsive to the changes in the tilt angle than in the $A < 0$ period [Le Roux and Potgieter, 1990], and hence we do not use the same technique of extrapolation to the shock that was employed for the 1987 data.

In the current study we have used another technique, similar to that used by Ip [1990] for estimating the location of the solar wind termination shock, that is valid for ~ 1993 onward during periods without large transient disturbances such as global merged interaction regions (GMIRs). To estimate the location of the solar wind termination shock, we employ a spherically symmetric model of solar modulation. Preliminary accounts of this work have been presented at the 24th International Cosmic Ray Conference [Stone *et al.*, 1995a, b].

Figure 1. Intensities of cosmic rays measured at Voyager 1. Solid circles represent helium with 9.3–22.3 MeV nucleon⁻¹ (0.53 to 0.82 GV); open squares are oxygen with 7.1–17.1 MeV nucleon⁻¹ (1.84 to 2.87 GV); and open circles are carbon with 40–106 MeV nucleon⁻¹ (0.55 to 0.91 GV).

2. Observations

In Figure 1 we show the time histories of the intensity of He, O, and C observed with the cosmic-ray experiment on Voyager 1 (V1) [Stone *et al.*, 1977]. The carbon intensity is for the energy range 40–106 MeV nucleon⁻¹ and is entirely due to galactic cosmic rays which are fully ionized. Prior to 1992 the He intensity is a mixture of solar, galactic, and anomalous cosmic rays. By 1992 the anomalous cosmic rays dominate this intensity. The O intensity is dominated by anomalous cosmic rays throughout the period shown in Figure 1.

The V1 He and O intensity profiles show the result of intense solar activity in early 1991. The ACR intensities rise rapidly after the effects of the transient decrease have passed. From the beginning of 1992 to the end of 1994, the ACR He intensity shows a ~ 40 -fold increase and the ACR O intensity increases by a factor of ~ 3 . Most of the O increase occurs during 1992, whereas the He intensity continues to increase steadily to the end of 1994. Following a small transient decrease in late 1991, the galactic cosmic ray C intensity rises by a factor of ~ 2.5 from the beginning of 1992 to the end of 1994. The energy interval of the O intensity measurements corresponds to a mean rigidity of ~ 2.4 GV, whereas the He intensity measurements correspond to a lower rigidity, ~ 0.7 GV. The equally rapid increases of the 0.7 GV and the 2.4 GV intensities in 1992 suggest a period of nonequilibrium recovery following the transient in late 1991. The much smaller increase in the 2.4 GV intensity during 1993 and 1994 suggests a period of quasi-equilibrium, during which the high-rigidity intensity is nearly the same as the unmodulated shock intensity and the lower-rigidity intensity continues to increase in response to decreasing modulation.

In Figure 2 we show the time dependence of several parameters of interest to this study. Figure 2c shows the radial gradient of the 10 to 22 MeV nucleon⁻¹ He intensities using the three-spacecraft method. In this method, we assume a constant radial and latitudinal gradient in each 52-day period and solve

for each from the two measured intensity ratios j_{P10}/j_{V2} and j_{V1}/j_{V2} , where j_{P10} , j_{V2} , and j_{V1} are the intensities at P10, V2, and V1, respectively (see Cummings *et al.* [1987] for more explanation). The radial gradient in Figure 2c shows no systematic trend but does exhibit nonstatistical variations.

In Figure 2e we show the tilt of the neutral sheet [Hoeksema, 1992] shifted to the midway position between V2 and P10. The tilt is in a rapid, steady decline until approximately the beginning of 1993, at which time it levels off at $\sim 35^\circ$. The rapidly changing tilt in 1992 implies that the magnetic field topology in the heliosphere is also evolving in a complex way, since the Sun's magnetic field is embedded in the solar wind and carried with it into the outer heliosphere. This changing magnetic field topology will affect the drift motion of the particles as well as the drift acceleration of the ACR particles at the solar wind termination shock. In addition, we might expect the GMIR [McDonald *et al.*, 1994] that evolved from the 1991 solar activity to cause other complex changes in the magnetic field topology and in the acceleration conditions at the shock [Zank *et al.*, 1994]. An interaction of this structure with the heliopause is thought to be responsible for the low-frequency radio emissions observed in 1992 and 1993 by the plasma wave experiment on the Voyager spacecraft [Gurnett *et al.*, 1993].

In Figure 3 we show the energy spectrum of He at V1 for seven 52-day periods beginning with days 105–157, 1992, and ending with 313–365, 1994. For the two 1992 spectra the entire energy spectrum is growing in intensity uniformly over the full energy range shown (~ 3 to 60 MeV nucleon⁻¹). This is consistent with a nonequilibrium period caused by effects on the drift of the particles from the changing magnetic field topology (Figure 2e) and effects of the 1991 GMIR on the strength of the termination shock. Beginning in 1993 the high-energy end of the spectrum changes intensity only slowly, whereas the lower-energy end continues to rise rapidly. This is consistent with the onset of a quasi-equilibrium period with a stable magnetic field topology (see Figure 2e) giving rise to stable

conditions for acceleration and propagation. The continued increase in intensities at low energies could result from an energy-dependent mean free path that is increasing with time or a decreasing distance between the shock and V1. The intensity increase is smaller at high energies where the modulation between the shock and the spacecraft is small. We note that the energy of the peak intensity of ACR He is ~ 6 MeV nucleon $^{-1}$ in late 1994, lower than previous observations and consistent with a lower level of ACR modulation than at any time in the past.

3. Distance to the Shock and Shock Spectrum

In order to estimate the distance to the termination shock, we have compared our observations at V1 and V2 during the quasi-equilibrium period in 1993 and 1994 with a spherically symmetric equilibrium model of the propagation of ACRs. In

Figure 2. (a) Intensity of helium (52-day averages) measured at P10 (crosses), V2 (solid circles), and V1 (open circles) versus time. The dashed line is the mean for the period indicated. (b) Intensity gradient between V1 and V2 for He with 9.3–22.3 MeV nucleon $^{-1}$. (c) Radial gradient of ACR He with ~ 10 –22 MeV nucleon $^{-1}$. (d) Latitudinal gradient of ACR He with ~ 10 –22 MeV nucleon $^{-1}$. (e) Estimated tilt of the neutral current sheet to the midpoint of V2 and P10. Each tilt observation (J. T. Hoeksema, private communication, 1994) covers a single solar rotation or ~ 26 days. We have performed a 3-solar-rotation moving average on the supplied tilt data set before plotting in order to approximate the average conditions between V2 and P10, which are ~ 17 AU apart.

Figure 3. Energy spectrum of helium measured at V1 for seven time periods.

1987 there were large latitudinal gradients of ACRs which would have made meaningful comparison with a spherically symmetric model difficult. Figure 2a shows 52-day average intensities of helium observed on V1, V2, and P10 with energies ~ 10 –22 MeV nucleon $^{-1}$ during 1992–1994. From the shape of the energy spectra we believe that the intensity in this energy interval is dominated by ACRs throughout the period shown, although the first two periods in 1992 have substantial contributions from galactic cosmic rays (GCRs). The intensities at all three spacecraft increase by a factor of ~ 40 from the beginning of 1992 to the end of 1994. The P10 and V1 intensities are in approximate agreement, although P10 leads V1 by a distance which varies from 6.2 to 4.2 AU during this period, and we would expect that the P10 intensity would be somewhat larger than the intensity at V1 if spherical symmetry prevails. The intensity at V2 is consistently lower than the intensity at P10 and V1.

In Figure 2d we show the latitudinal gradients, which show no systematic trend and the mean is 0.78% deg $^{-1}$ or equivalently $\sim 0.8\%$ AU $^{-1}$ in the latitudinal direction as compared with $\sim 4\%$ AU $^{-1}$ in the radial direction (see Figure 2c). Although the intensity gradient is mainly radial and therefore resembles that of a spherically symmetric model, the small positive latitudinal gradient means that the spectrum observed out of the heliographic equatorial plane at a given radius corresponds to that which would be observed at a somewhat larger “effective radius” in the equatorial plane. We use the following equation to estimate the effective location of a particular spacecraft:

$$\ln(r_{\text{eff}}/r_{\text{act}}) = (G_{\Theta} \cdot \Theta / G_0) \quad (1)$$

where G_{Θ} is the average latitudinal gradient and r_{eff} is the effective location, r_{act} is the actual location, and Θ is the latitude of the spacecraft, and where we have used a model in

Table 1. Spacecraft Locations

Period	Spacecraft	Latitude, deg	Actual Radius, AU	Effective Radius, AU
Days 157–209, 1994	V1	32.5	56.3	64.0
	V2	–12.0	43.3	45.4
Days 157–209, 1993	V1	32.2	52.6	59.8
	V2	–9.5	40.4	42.0

which the radial gradient in the intensity j is proportional to $1/r$, with $(1/j)(\partial j/\partial r) = G_0/r$. In this work we assume that the particle distributions are symmetrical about the heliographic equator [Jokipii, 1990], so we use the absolute value of the spacecraft latitude in all cases.

We thus need to know the average latitudinal gradient G_θ and the average radial gradient parameter G_0 . G_0 is related to the three-spacecraft radial gradient G_r by

$$G_0 = \frac{\Delta r \cdot G_r}{\ln(r_{10}/r_2)} \quad (2)$$

where r_{10} and r_2 are the radial positions of P10 and V2, respectively, and Δr is the radial separation distance between them.

It is important to pick time periods for study in which transient disturbances at V1 and V2 are absent. In Figure 2b we show the gradient of the intensities from V1 to V2:

$$G_{V1V2} = \ln(j_{V1}/j_{V2})/\Delta r \quad (3)$$

where Δr is the difference in the radial distances of V1 and V2. This gradient is clearly affected by transient disturbances but appears to show no systematic decrease or increase from 1992 through 1994. Although the latitudinal gradient ($0.8\% \text{ deg}^{-1}$, $\Delta\theta \sim 21^\circ$) contributes, this intensity gradient is dominated by the radial gradient ($\sim 4\%/AU$, $\Delta r \sim 12 \text{ AU}$). The near constancy of the intensity gradient implies that $C_f V/\kappa$, where C_f is the Compton-Getting factor (equal to $[2 - 2\gamma]/3$ for nonrelativistic particles, where γ is the average power law index of the differential energy spectrum), V is the solar wind velocity, and κ is the radial diffusion coefficient, is approximately unchanged while the intensities are increasing by a factor of ~ 40 . From Figure 2b we pick two recent 52-day periods, days 157–209, 1994, and 157–209, 1993, which have V1/V2 intensity gradients near the mean value.

For this study, we use the radial and latitudinal gradients from day 52, 1993, through 365, 1994, representing twelve 52-day periods in Figures 2c and 2d, in computing the parameters involved in calculating the effective radial locations for the V1 and V2 spacecraft. The average radial gradient, latitudinal gradient, and radial gradient parameter for the twelve periods are $G_r = 3.92 \pm 0.38\% \text{ AU}^{-1}$, $G_\theta = 0.78 \pm 0.18\% \text{ deg}^{-1}$, and $G_0 = 1.96 \pm 0.19$. In Table 1 we show the actual radius and latitude for V1 and V2 for the two selected time periods along with the calculated effective radial positions used in the model fits.

In the model calculations we fit both the ACR helium and oxygen spectra at V1 and V2. The ACR He shock spectrum is assumed to be a power law in energy per nucleon, $dJ/dT = j_0 [T/(1 \text{ MeV nucleon}^{-1})]^\gamma$. The ACR O shock spectrum is assumed to be a power law with the same index. For O this is an adequate approximation for energies up to $\sim 10 \text{ MeV nu-}$

cleon $^{-1}$. Above $\sim 10 \text{ MeV nucleon}^{-1}$ we will later show that the energy spectrum exhibits an approximately exponential roll-off. Similarly, for ACR He this approximation is valid up to $\sim 60 \text{ MeV nucleon}^{-1}$. We assume that the diffusion coefficient κ (in square centimeters per second) is given by

$$\kappa = \frac{\kappa_0 \beta (r/1 \text{ AU})(1 + \kappa_s^2)(R/1 \text{ GV})^2}{1 + (\kappa_s R)^2} \quad r \gg 1 \text{ AU} \quad (4)$$

where κ_0 is a scaling factor, β is particle speed, r is heliocentric radial distance, and R is rigidity. This form for the radial and rigidity dependence of κ can be derived from the quasi-linear formulation of Bieber *et al.* [1995], in which $\lambda_\perp = R_L \Omega \tau / (1 + \Omega^2 \tau^2)$, where R_L is the Larmor radius ($\sim R/B_0$), Ω is the gyrofrequency, τ is the scattering time, and $\Omega \tau = [(2R_L)/(3\lambda_c)](B_0^2/\delta B_x^2)$. Following Bieber *et al.*, we assume that the coherence length of the magnetic field scales as r ($\lambda_c \sim r$), that the root-mean-square field fluctuations are proportional to the mean field ($\delta B_x^2 \sim B_0^2$), and that $B_0 \sim r^{-1}$ for $r \gg 1 \text{ AU}$.

There are six free parameters in the model: the shock location R_s , the diffusion coefficient scaling factor κ_0 , the diffusion coefficient shape factor κ_s , the power law index γ of the energy spectrum at the shock, the intensity scaling factor j_0 of the ACR He shock spectrum, and the ratio of O to He at the shock, O/He. We assume that the solar wind velocity V is constant at 500 km s^{-1} , which is close to the average value at V2 of 490 km s^{-1} for day 1, 1993, through 365, 1994 (J. Richardson, private communication, 1995). The fits are sensitive to κ and V only in the ratio κ_0/V .

The data and best fit model curves for days 157–209, 1994, are shown in Figures 4a and 4b. The fits were made only in the energy regions shown by the solid lines. The χ^2 of the six-parameter best fit to the 39 data points in Figure 4 is 13.3. Figure 4c shows the best fit diffusion coefficient as a function of rigidity.

We investigated the confidence limits for each parameter in two ways. We first estimated the 68% confidence limits by iteratively changing and fixing the value of one parameter and refitting until we found the parameter value where the χ^2 had increased by 1 [see Press *et al.*, 1992]. We did this in turn for all six parameters. The best fit parameter values and the 68% confidence limits are shown in Table 2 for days 157–209, 1994.

In the second method we account for modeling uncertainties by estimating the uncertainty in the effective radial positions of V1 and V2 using (1) together with the uncertainties in the parameters G_0 and G_θ . We find that the uncertainties on the effective radial positions were 2 AU for V1 and 0.5 AU for V2. We performed two fits, one using the upper limits for the effective radial locations for V1 and V2 and another using the lower limits. The resulting parameters are shown as the model limits in Table 2.

The shock strength s [see, e.g., Potgieter and Moraal, 1988] is related to the spectral index by $s = (2\gamma - 2)/(2\gamma + 1)$. From the values of γ in Table 2, the inferred strength of the shock is 2.63 ± 0.14 . The shock is therefore not a strong shock ($s = 4$; $\gamma = -1$), and it may be modified by cosmic rays [see, e.g., Donohue and Zank, 1993]. We estimate that the shock location is $\sim 85 \pm 5 \text{ AU}$ during days 157–209, 1994 (see Table 2).

In Figure 5 we show the ACR He and O spectra at V1 and V2 for days 157–209, 1993, along with a four-parameter model fit ($\chi^2_\nu = 1.1$). We held the shock spectral index fixed at -1.42 and the shock O/He ratio fixed at 0.081, the values from the

1994 period. The fit indicates that the shock distance has not changed appreciably over the year despite the fact that the peak intensity at V1 has increased by a factor of ~ 3 . The best fit parameters and limits are shown in Table 3. This intensity increase is apparently due to a combination of two effects (see Tables 2 and 3): (1) the ratio of the diffusion coefficient at the peak energy of the He spectrum to solar wind velocity has increased by $\sim 50\%$, and (2) the best fit shock intensity scaling parameter has increased by $\sim 40\%$, much less than the factor of ~ 3 increase in the V1 peak intensity. The relatively constant shock intensity is consistent with quasi-equilibrium conditions for shock acceleration. During the 2-year period around the last solar minimum, *Cummings et al.* [1994] also found that a constant shock intensity was consistent with observed ACR He

Table 2. Fit Parameters for Figure 4: Days 157–209, 1994

Parameter ^a	Fit Value ^b	68% Lower Limit	68% Upper Limit	Model Lower Limit	Model Upper Limit
γ	$-1.42 (\pm 0.08)$	-1.49	-1.34	-1.42	-1.44
R_s , AU	$85.2 (\pm 5.3)$	81.7	88.2	81.2	89.5
$\kappa_0 (\times 10^{21})$	$3.76 (\pm 0.35)$	3.41	3.97	3.53	3.96
κ_s	$1.13 (\pm 0.15)$	0.98	1.28	1.16	1.12
j_0	$158 (\pm 44)$	116	203	153	167

Figure 4. (a) Energy spectra of ACR helium at the positions of V1 and V2 spacecraft for days 157–209, 1994. The curves represent the six-parameter best fit energy spectra at the solar wind termination shock, V1, and V2, as described in the text. (b) Same as Figure 4a except for ACR oxygen. (c) Best fit diffusion coefficient divided by particle velocity versus rigidity. The form of the diffusion coefficient is described in the text.

and O intensities that changed by factors of ~ 5 and ~ 8 , respectively.

4. Roll-Off Energy of Shock Spectrum

In Figures 4b and 5b the observed ACR oxygen spectra exhibit a roll-off in intensity above ~ 10 – 15 MeV nucleon $^{-1}$. This roll-off is present in other spectra as well as shown in Figure 6 where the V1 ACR O, N, and Ne spectra are displayed for days 157–365, 1994. Note that all three spectra show the roll-off in intensity above ~ 10 – 15 MeV nucleon $^{-1}$. This roll-off in the energy spectra is consistent with that expected in diffusive shock acceleration if the shock has a finite radius of curvature. Such a roll-off is predicted to occur when VR_s/κ is of the order of unity [see, e.g., *Potgieter and Moraal*, 1988], where V is the solar wind velocity, κ is the diffusion coefficient in the vicinity of the shock, and R_s is the shock radius.

Another interpretation of the roll-off in the energy spectrum is due to *Jokipii* [1990]. In his theory the ACR particles gain their energy by drifting along the shock from the equator to the pole during the $A > 0$ portion of the solar cycle (pole to equator during $A < 0$). The maximum energy gain is set by the electrostatic potential difference between the heliospheric equator and pole and is ~ 240 MeV. Since the ACR particles are singly ionized, the energy spectra of the different ACR ions would be expected to roll off above ~ 240 MeV.

In Figure 7 we plot the V1 differential energy spectra of ACR H, He, N, O, and Ne for days 157–365, 1994, as a function of energy instead of energy per nucleon. The intensities have been normalized before plotting by the factors shown in the figure. At low energies the effect of solar modulation causes the H and He spectra to peak at different energies. However, the agreement of the different spectra is good near the break which occurs at ~ 170 – 240 MeV, in rough agreement with the shock drift limit of *Jokipii* [1990]. We do not feel that we can distinguish experimentally between the two possible interpretations of the roll-off in the shock spectra.

5. Latitudinal Gradient Along Shock

The shock spectra of ACR He and O in Figures 4a and 4b are the spectra expected at the shock in the heliographic equator for days 157–209, 1994. Likewise, the shock spectra derived by *Cummings et al.* [1994] for days 105–313, 1987, are the spectra expected at the shock in the heliographic equator. For the 1987 period the intensity of ACR He at the shock in the energy range 31–57 MeV nucleon $^{-1}$ was determined to be 4.3

Figure 5. Same as Figure 4 except the period is days 157–209, 1993, the shock power law spectral index is fixed at -1.42 , and the O/He ratio is fixed at 0.081 .

$(\text{m}^2 \text{ s sr MeV/nucleon})^{-1}$. From Figure 4a the ACR He shock intensity during days 157–209, 1994, in this same energy range is $0.77 (\text{m}^2 \text{ s sr MeV/nucleon})^{-1}$. Thus the intensity at the shock at the heliographic equator in 1994 is a factor of ~ 5.5

Table 3. Fit Parameters for Figure 5: Days 157–209, 1993

Parameter ^a	Fit Value ^b	68% Lower Limit	68% Upper Limit	Model Lower Limit	Model Upper Limit
γ	1.42^c	0	0	0	0
R_s , AU	$82.3 (\pm 4.1)$	79.7	84.1	78.1	85.1
$\kappa_0 \times 10^{21}$	$3.35 (\pm 0.26)$	3.15	3.56	3.18	3.51
κ_s	$0.72 (\pm 0.10)$	0.62	0.81	0.73	0.69
j_0	$113 (\pm 9)$	104	122	111	111

^cHeld fixed.

Figure 6. Energy spectra of ACR O, N, and Ne for days 157–365, 1994. Small ($<10\%$) corrections for GCRs have been made before plotting.

smaller than it was in 1987. This difference can be understood in the context of shock drift acceleration [Jokipii, 1990] that causes the intensity to vary along the shock from the equator to the pole, the intensity being a maximum at the pole during the 1994 period ($A > 0$) and a maximum at the equator during 1987 ($A < 0$). Interpreted in this way, the factor of 5.5 difference observed in the 1994 shock intensity compared to the 1987 shock intensity could correspond to the latitudinal difference in the intensity at the equator and the pole in either of the years 1994 or 1987. This would imply a latitudinal gradient along the shock of $1.9^\circ \text{ deg}^{-1}$ from the equator to the pole during days 157–209, 1994, in qualitative agreement with shock drift acceleration. In Table 4 we show this value of the

Figure 7. Composite V1 energy spectrum of O for days 157–365, 1994, plotted as a function of total energy. The energy spectra of the different individual ions are normalized to O by the factors shown in the figure.

latitudinal gradient along with several other recent determinations for the latitudinal gradient of ACRs, most of which are based on comparisons of Ulysses measurements at high latitude with measurements near the ecliptic plane. In general, there is a correspondence of these measurements with the implied latitudinal gradient along the shock.

6. Energy Density of ACRs

The energy density of the ACR He shock spectrum in Figure 4a above an injection velocity of $2V_{SW}$ ($5.2 \text{ keV nucleon}^{-1}$ for $V_{SW} = 500 \text{ km s}^{-1}$) is $\sim 0.005 \text{ eV cm}^{-3}$. The corresponding value for ACR O in Figure 4b is $\sim 0.001 \text{ eV cm}^{-3}$. We can estimate the ACR H shock spectrum by scaling from the ACR He shock spectrum. Cummings *et al.* [1984] found that the ACR energy spectra of the different elements scale to each other with linear factors in energy and intensity if the diffusion coefficient is proportional to βR^α . The peak energies of the ACR H and He spectra are in the rigidity range ($\sim 0.3\text{--}0.4 \text{ GV}$) where α is ~ 2 (see Figures 4c and 5c). This implies an energy scaling factor of 6.3 [see Cummings *et al.*, 1984]. The intensity scaling factor is 0.40 ± 0.02 from Cummings and Stone [1995] for a period only slightly different from the one shown in Figure 4. Using these factors and the He spectrum from Figure 4a, we estimate that the power law portion of the ACR H shock spectrum for days 157–209, 1994, is given by $j_H = 868 E^{-1.42} (\text{m}^2 \text{ s sr MeV})^{-1}$. This implies an energy density of ACR H at the shock of 0.009 eV cm^{-3} , yielding a total ACR energy density of $0.015 \pm 0.002 \text{ eV cm}^{-3}$. The estimated uncertainty includes uncertainty in γ from Table 2 and the uncertainty in scaling the He shock spectrum to the H shock spectrum. For comparison, the energy density of the solar wind at low heliographic latitudes at 85 AU is $\sim 1.2 \text{ eV cm}^{-3}$, as scaled from $\sim 16 \text{ eV cm}^{-3}$ at 23 AU (derived from Figure 1 of Grzedzielski and Lazarus [1993]). Thus the ACR energy density is only $\sim 1\%$ that of the solar wind.

This ACR energy density is similar to that derived for the 1987 period by Cummings *et al.* [1994]. However, Cummings *et al.* [1994] assumed a strong shock with a power law index at low energies of -1 . The modulation effects were stronger in the 1987 spectrum at $\sim 23 \text{ AU}$ than they are in the 1994 spectrum at $\sim 56 \text{ AU}$, and the peak energy of the 1987 ACR He spectrum was $\sim 20\text{--}25 \text{ MeV nucleon}^{-1}$ compared to $\sim 6 \text{ MeV nucleon}^{-1}$ at V1 in 1994 (see Figure 4a). Consequently, in the

Figure 8. Same as Figure 5b from Cummings *et al.* [1994] showing the energy spectra of ACR O, He, and H for days 105–313, 1987. The open points are observations from V2. The solid points are the deduced intensities at the termination shock. Three power law lines have been added, normalized to the shock intensities, with power law index of -1.42 to indicate a possibly more realistic energy dependence of the shock spectra.

1987 observation there was very little information on the power law index of the shock spectrum. In Figure 8 we reproduce Figure 5b from Cummings *et al.* [1994] with the addition of lines indicating possible shock spectra with power law index of -1.42 in 1987. Assuming that this index was -1.42 in 1987 results in somewhat higher estimates of the energy density of ACRs at the shock than were derived by Cummings *et al.* [1994]. In Table 5 we show the estimated energy density for the 1994 period along with the old and new estimates for 1987. We also compare to the estimated energy density of the solar wind at the location of the shock. If we assume that the 1987 measurements with index -1.42 correspond to the maximum ACR intensity at the shock, then the energy density of ACRs is $\sim 5\%$ of the solar wind energy density in the region with maximum source intensity in 1994.

Table 4. Latitudinal Gradients of ACRs

	ACR	E , MeV nucleon $^{-1}$	r , AU	θ , deg	G_θ , % deg $^{-1}$
Polar/equatorial shock	He	31–57	67–85	90	1.9
ULY-IMP-V1-V2-P10 ^a	O	10	2.3	–77	2.1 ± 0.6
ULY-SAMPEX ^b	O	8–12	2.3	–80	2.12 ± 0.27
	O	12–16			1.75 ± 0.38
	He	11–20			0.10 ± 0.18
ULY-IMP 8 ^c	He ^c	30–70	~ 2	–80	0.57 ± 0.10^c
ULY-IMP-V1-V2-P10 ^d	O	10	4.2	–41	1.3 ± 0.3
V1-V2-P10 ^e	He	10–22	55	32	0.8 ± 0.1

7. Injection Efficiency of Pickup Ions at Shock

To estimate the efficiency r_i for the injection of pickup ions into the acceleration process, we follow the calculations of Lee [1983], from which it can be shown that the accelerated spectrum is given in units of $(\text{cm}^2 \text{ s sr MeV/nucleon})^{-1}$ by

Table 5. Estimated Energy Densities

Period	R_S , AU	γ	ϵ_{ACR} , ^a eV cm $^{-3}$	$\epsilon_{ACR}/\epsilon_{SW}$, %
1994	85	-1.42	0.015	1.3
1987	67	-1.00^b	0.028	1.5
1987	85	-1.42^c	0.058	4.8

^aAssumes spectral slope extends down to $5.2 \text{ keV nucleon}^{-1}$.

^bStrong shock assumed ($s = 4$).

^cShock $s = 2.63$ assumed.

$$j = p^2 f(p) = \frac{\nu r_i F_i}{4\pi} E_{0i}^{(v-4)/2} E^{(-v+2)/2} \quad (5)$$

where $\nu = 3/(1 - \rho_u/\rho_d) = 4.84$ for a downstream/upstream density ratio of 2.63, F_i (in square centimeters per second) is the pickup ion flux at the shock, and E_{0i} is the injection energy corresponding to $2V_{SW}$, taken here to be 5.2×10^{-3} MeV nucleon $^{-1}$. The pickup ion fluxes at the shock can be estimated from the observations of Gloeckler *et al.* [1993], who inferred the density of neutral H and He in the outer heliosphere as 0.077 ± 0.015 and 0.013 ± 0.003 cm $^{-3}$, respectively. Using these values, the model of Vasyliunas and Siscoe [1976] for the distribution of these neutrals throughout the heliosphere, and the long-term ionization rates at 1 AU of 8.0×10^{-7} s $^{-1}$ for H and 1.0×10^{-7} s $^{-1}$ for He [Gloeckler *et al.*, 1993], we estimate that the fluxes of H and He pickup ions at the nose of the heliosphere at 85 AU are 8500 ± 1700 cm $^{-2}$ s $^{-1}$ and 220 ± 50 cm $^{-2}$ s $^{-1}$, respectively.

Using these pickup ion fluxes, the calculated ACR He spectrum from Lee [1983] of $j_{He} = 9.28 \times 10^4 r_i F_i^{-1.42}$ (m 2 s sr MeV/nucleon) $^{-1}$ can be compared with the observed $j_{He} = 158 E^{-1.42}$ (m 2 s sr MeV/nucleon) $^{-1}$ to yield $r_i(\text{He}^+) = 0.0017 \pm 0.0008$. The estimated uncertainty includes the uncertainty in γ from Table 2 and the uncertainty in the pickup ion flux F_i . For H the calculated spectrum is $j_H = 3.59 \times 10^6 r_i F_i^{-1.42}$ (m 2 s sr MeV) $^{-1}$ and the "observed" spectrum is $j_H = 868 E^{-1.42}$ (m 2 s sr MeV) $^{-1}$. We thus find that the injection efficiency for H is $r_i(\text{H}^+) = 0.00024 \pm 0.00011$, where we include an additional uncertainty due to the scaling of the He shock spectrum to the H shock spectrum. The ratio of the injection efficiencies of He^+ and H^+ is relatively better determined than the absolute injection efficiencies of either because the spectral index uncertainty is removed in the ratio. We estimate that the ratio of the efficiency of injection of He^+ to H^+ pickup ions into the acceleration process is 7.0 ± 1.6 , where we have used the He to H scaling uncertainty in the shock spectra (16%) and the uncertainty on the ratio of the neutral densities of H to He in the outer heliosphere from Gloeckler *et al.* [1993] (17%) in estimating the uncertainty in the ratio. The observed preferential injection for He^+ compared to H^+ is qualitatively consistent with Monte Carlo studies of shock acceleration by Ellison *et al.* [1981].

8. Discussion

Our estimates of energy spectra and shock location correspond to the upwind termination shock in the heliographic equator, since both V1 and V2 are headed outward in that general direction. Even if the termination shock is elongated in the downwind direction [see, e.g., Seuss *et al.*, 1987], the nose region of the upwind shock should be reasonably approximated by a spherically symmetric diffusion model. In the downwind direction, azimuthal diffusion parallel to the magnetic field will become increasingly important with increasing shock elongation, tending to reduce upwind/downwind asymmetries in the ACR intensities.

We will continue to monitor the evolution of the energy spectra of ACRs at V1 and V2 and look for further clues to the strength of the shock and its location. The energy of the peak intensity should continue to decrease as the spacecraft approaches the shock. As the modulation lessens, the convergence of the V1 and V2 spectra should continue to lower energies, and we will obtain a better estimate of the shock

spectrum spectral index. As solar activity increases from the solar minimum conditions in 1998, the shock may move rapidly inward [see, e.g., Whang and Burlaga, 1993] from its position at ~ 85 AU and perhaps overrun the positions of the V1 and P10 spacecraft, which will both be at ~ 72 AU, some 5 AU beyond the estimated location of the shock 11 years earlier [Cummings *et al.*, 1994].

Acknowledgments. We are grateful to J. T. Hoeksema for providing the tilt observations prior to publication. We thank J. Richardson and J. Belcher for providing the Voyager 2 solar wind speed data. This work was supported by NASA under contract NAS7-918.

The Editor thanks D. T. Hall and two other referees for their assistance in evaluating this paper.
