I. STABILIZER FORMALISM

In this Section we state some facts concerning stabilizer groups and stabilizer states. Let \mathcal{P}_n be the n -qubit Pauli group. Any element of \mathcal{P}_n has the form $i^m P_1 \otimes \cdots \otimes P_n$, where each factor P_a is either the identity or a single-qubit Pauli operator X, Y, Z and $m \in \mathbb{Z}_4$. An abelian subgroup $\mathcal{G} \subseteq \mathcal{P}_n$ is called a stabilizer group if $-I \notin \mathcal{G}$. Each stabilizer group has the form $\mathcal{G} = \langle G_1, \dots, G_r \rangle$ for some generating set of pairwise commuting self-adjoint Pauli operators $G_1, \dots, G_r \in \mathcal{G}$ such that $|\mathcal{G}| = 2^r$. The integer r is called the dimension of \mathcal{G} and is denoted $r = \dim(\mathcal{G})$. A state $|\psi\rangle$ is said to be stabilized by \mathcal{G} if $P|\psi\rangle = |\psi\rangle$ for all $P \in \mathcal{G}$. States stabilized by \mathcal{G} span a ‘‘codespace’’ of dimension 2^{n-r} . A projector onto a codespace has the form

$$\Pi_{\mathcal{G}} = 2^{-r} \sum_{P \in \mathcal{G}} P. \quad (1)$$

A pure n -qubit state $|\psi\rangle$ is a stabilizer state iff $|\psi\rangle = U|0^{\otimes n}\rangle$ for some Clifford unitary U . Any stabilizer state $|\psi\rangle$ is uniquely defined (up to the overall phase) by a stabilizer group $\mathcal{G} \subseteq \mathcal{P}_n$ of dimension n such that $|\psi\rangle$ is the only state stabilized by \mathcal{G} . Let \mathcal{S}_n be the set of all n -qubit stabilizer states. This set is known to be a 2-design [1], that is,

$$|\mathcal{S}_n|^{-1} \sum_{\psi \in \mathcal{S}_n} |\psi\rangle\langle\psi|^{\otimes 2} = \int d\mu(\phi) |\phi\rangle\langle\phi|^{\otimes 2}, \quad (2)$$

where the integral is with respect to the Haar measure on the set of normalized n -qubit states $|\phi\rangle$.

Throughout the paper we assume that stabilizer states are represented in a certain standard form defined in Section IV B. In this representation, three basic tasks can be performed efficiently. First, one can compute the inner product between stabilizer states [2–4]. More precisely, consider stabilizer states $|\psi\rangle, |\phi\rangle \in \mathcal{S}_n$. Then $\langle\psi|\phi\rangle = b2^{-p/2}e^{i\pi m/4}$ for some $b = 0, 1$, integer $p \in [0, n]$ and $m \in \mathbb{Z}_8$ that can be computed in time $O(n^3)$, see Section IV C. Secondly, a projection of any stabilizer state onto the codespace of any stabilizer code is a stabilizer state which is easy to compute. More precisely, suppose $\mathcal{G} \subseteq \mathcal{P}_n$ is a stabilizer group and $|\varphi\rangle \in \mathcal{S}_n$. Then $\Pi_{\mathcal{G}}|\varphi\rangle = b2^{-p/2}|\phi\rangle$ for some $b = 0, 1$, some integer $p \geq 0$, and stabilizer state $|\phi\rangle \in \mathcal{S}_n$. One can compute $b, p, |\phi\rangle$ in time $O(rn^2)$ as explained in Section IV E. Recall that

$r = \dim(\mathcal{G})$. Finally, one can generate a random stabilizer state drawn from the uniform distribution on \mathcal{S}_n in time $O(n^2)$, see Section IV D.

II. CLASSICAL SIMULATION ALGORITHMS

In this Section we describe two classical simulation algorithms. The first algorithm is a classical Monte Carlo algorithm that approximates the probability $P_{out}(x)$ for a given string $x \in \{0, 1\}^w$ with a specified relative error ϵ and a failure probability p_f . The algorithm has runtime

$$\tau = O\left((w+t)(c+t) + (n+t)^3 + 2^{\beta t} t^3 \epsilon^{-2} p_f^{-1}\right), \quad (3)$$

where $\beta \leq 1/2$ is a constant that depends on the implementation details. The second algorithm is the classical simulation algorithm which allows one to sample the output string x from a distribution which is ϵ -close to P_{out} with respect to the L_1 -norm, with runtime given by Eq. (2) in the main text.

First consider the task of approximating the output probability $P_{out}(x)$. The algorithm described below consists of two stages with runtimes

$$\tau_1 = O\left((w+t)(c+t) + (n+t)^3\right)$$

and

$$\tau_2 = O(2^{\beta t} t^3 \epsilon^{-2} p_f^{-1}).$$

The first stage computes a stabilizer group $\mathcal{G} \subseteq \mathcal{P}_t$ and an integer u such that

$$P_{out}(x) = 2^{-u} \langle A^{\otimes t} | \Pi_{\mathcal{G}} | A^{\otimes t} \rangle. \quad (4)$$

We begin by replacing each T -gate in the original circuit U by the well-known gadget [5] shown in Fig. 2 in the main text. The gadget implements the T -gate by performing Clifford gates CNOT, S , and a 0,1-measurement. Each measurement outcome appears with the probability 1/2. The gate S is applied only if the outcome is ‘1’. The gadget also consumes one copy of the magic state $|A\rangle$ which is destroyed in the process.

Suppose we postselect the outcome ‘0’ in each gadget, i.e. replace each measurement by a projector $|0\rangle\langle 0|$. This removes the classically controlled S -gates such that each gadget adds a single CNOT to the original circuit U . Let V be the modified version of U . By definition, V acts on $n+t$ qubits and contains $c+t$ Clifford gates.

Let us agree that the t ancillary qubits initialized in the magic state are appended at the end of n computational qubits such that the circuit V acts on the initial state $|0^{\otimes n} \otimes A^{\otimes t}\rangle$. Combining the final measurement projector $\Pi(x) = |x\rangle\langle x|_{Q_{out}} \otimes I_{else}$ with the projectors $|0\rangle\langle 0|$ acting on the ancillary qubits gives a projector

$$\Pi = \Pi(x) \otimes |0\rangle\langle 0|^{\otimes t}$$

acting on $n + t$ qubits such that

$$P_{out}(x) = 2^t \langle 0^{\otimes n} \otimes A^{\otimes t} | V^\dagger \Pi V | 0^{\otimes n} \otimes A^{\otimes t} \rangle. \quad (5)$$

Here we noted that the postselection probability is 2^{-t} . Obviously, $\Pi = \Pi_{\mathcal{W}}$ for a stabilizer group $\mathcal{W} \subseteq \mathcal{P}_{n+t}$ of dimension $w + t$. Namely, let $q(j)$ be the j -th qubit of Q_{out} . Generators of \mathcal{W} are $R_j = (-1)^{x_j} Z_{q(j)}$ for $j = 1, \dots, w$ and $R_{w+j} = Z_{n+j}$ for $j = 1, \dots, t$. Since the conjugation by V maps Pauli operators to Pauli operators, we get $V^\dagger \Pi_{\mathcal{W}} V = \Pi_{\mathcal{V}}$, where \mathcal{V} is a stabilizer group of dimension $w + t$ generated by $R'_j = V^\dagger R_j V \in \mathcal{P}_{n+t}$ with $j = 1, \dots, w+t$. Assuming that the action of a single Clifford gate on a Pauli operator can be computed in time $O(1)$, one can compute each generator R'_j in time $O(c+t)$. Accordingly, \mathcal{V} can be computed in time $O((w+t)(c+t))$.

Let \mathcal{V}_0 be the subgroup of \mathcal{V} that includes all Pauli operators which act as I or Z on each of the first n qubits. Let $v = \dim(\mathcal{V}_0)$. A generating set $Q_1, \dots, Q_v \in \mathcal{V}_0$ can be computed in time $O(n(w+t) + (w+t)^3) = O((n+t)^3)$ using standard linear algebra. We get

$$\begin{aligned} \langle 0^{\otimes n} | V^\dagger \Pi V | 0^{\otimes n} \rangle &= \langle 0^{\otimes n} | \Pi_{\mathcal{V}} | 0^{\otimes n} \rangle \\ &= 2^{-w-t+v} \langle 0^{\otimes n} | \Pi_{\mathcal{V}_0} | 0^{\otimes n} \rangle. \end{aligned} \quad (6)$$

since $\langle 0^{\otimes n} | P | 0^{\otimes n} \rangle = 0 \quad \forall P \in \mathcal{V} \setminus \mathcal{V}_0$. Define t -qubit Pauli operators $G_i = \langle 0^{\otimes n} | Q_i | 0^{\otimes n} \rangle$, $i = 1, \dots, v$. These operators pairwise commute since \mathcal{V}_0 is abelian and Q_i commute with each other on the first n qubits. If $-I \in \langle G_1, \dots, G_v \rangle$ then there exists $Q \in \mathcal{V}_0$ with $-I = \langle 0^{\otimes n} | Q | 0^{\otimes n} \rangle$ and therefore

$$\Pi_{\mathcal{V}} | 0^{\otimes n} \rangle = \Pi_{\mathcal{V}} Q | 0^{\otimes n} \rangle = -\Pi_{\mathcal{V}} | 0^{\otimes n} \rangle = 0$$

in which case $P_{out}(x) = 0$ and we are done. Let us now consider the case $-I \notin \langle G_1, \dots, G_v \rangle$. In this case let $\mathcal{G} \subseteq \mathcal{P}_t$ be the stabilizer group generated by G_1, \dots, G_v and $r = \dim(\mathcal{G})$. One can check the condition $-I \notin \langle G_1, \dots, G_v \rangle$ and compute r in time $O(t^3)$. Without loss of generality, $\mathcal{G} = \langle G_1, \dots, G_r \rangle$. Noting that \mathcal{V}_0 must contain 2^{v-r} elements acting trivially on the last t qubits yields $\langle 0^{\otimes n} | \Pi_{\mathcal{V}_0} | 0^{\otimes n} \rangle = \Pi_{\mathcal{G}}$. This proves Eq. (4) with $u = w - v$ and the stabilizer group \mathcal{G} defined above. Combining all the steps needed to compute \mathcal{G} gives the promised runtime $\tau_1 = O((w+t)(c+t) + (n+t)^3)$.

The second stage of the algorithm computes the expectation value in Eq. (4) by decomposing $|A^{\otimes t}\rangle$ into a linear combination of stabilizer states. Suppose

$$|A^{\otimes t}\rangle = \sum_{a=1}^{\chi} y_a |\varphi_a\rangle \quad (7)$$

for some stabilizer states $|\varphi_a\rangle \in \mathcal{S}_t$ and some coefficients y_a . For each $a = 1, \dots, \chi$ compute $b_a \in \{0, 1\}$, an integer $p_a \geq 0$ and a stabilizer state $|\phi_a\rangle \in \mathcal{S}_t$ such that

$$\Pi_{\mathcal{G}} |\varphi_a\rangle = b_a 2^{-p_a/2} |\phi_a\rangle.$$

see Section IV E for details. As stated above, this computation takes time $O(\chi t^3)$. Introducing new coefficients $z_a = 2^{-(u+p_a)/2} y_a b_a$ and using Eqs. (4,7) one gets

$$P_{out}(x) = \|\psi\|^2, \quad |\psi\rangle = \sum_{a=1}^{\chi} z_a |\phi_a\rangle, \quad \phi_a \in \mathcal{S}_t. \quad (8)$$

Here $|\phi_a\rangle$ are t -qubit stabilizer states. Using the norm estimation subroutine described in the main text of the paper, $P_{out}(x) = \|\psi\|^2$ can be approximated in time $O(\chi t^3 \epsilon^{-2} p_f^{-1})$, as promised.

Since the runtime grows linearly with χ , we would like to choose a stabilizer decomposition in Eq. (7) with a small rank χ . Clearly, the optimal choice is $\chi = \chi_t$, where $\chi_t \equiv \chi_t(0)$ is the stabilizer rank defined in the introduction. Unfortunately, the exact value of χ_t is unknown. Using the identity

$$|A^{\otimes 2}\rangle = \frac{1}{2}(|00\rangle + i|11\rangle) + \frac{e^{i\pi/4}}{2}(|01\rangle + |10\rangle) \quad (9)$$

one can see that $|A^{\otimes 2}\rangle$ is a linear combination of two stabilizer states, that is, $\chi_2 = 2$. By dividing t qubits into $t/2$ pairs and applying the decomposition Eq. (9) to each pair one gets $\chi_t \leq 2^{t/2}$. The results of [4] give a slightly better bound $\chi_t \leq 2^{\beta t}$ with $\beta \approx 0.47$. This completes the analysis of the first algorithm.

Remark 1: One may attempt to derive a stronger bound on the failure probability p_f in the norm estimation algorithm. Namely, let ξ_H be a random variable defined in Eq. (7) in the main text where the states $|\theta_i\rangle$ are drawn from the Haar measure. Clearly, ξ and ξ_H have the same mean, $\bar{\xi}_H = \bar{\xi} = \|\psi\|^2$. Let $p'_f = \Pr[|\xi_H - \bar{\xi}_H| \geq \epsilon \bar{\xi}_H]$. Then $p'_f \leq 2 \exp(-CL\epsilon^2)$, where $C = O(1)$ is a constant, see Lemma II.3 of Ref. [6]. If a similar tail bound applies to the random variable ξ , one could achieve a failure probability p_f in the norm estimation algorithm using only $L = O(\epsilon^{-2} \log(p_f^{-1}))$ samples.

Remark 2: If \mathcal{G} has a small dimension, namely, $r < \beta$, it can be easier to compute $P_{out}(x)$ directly from Eqs. (1,4) which yield $P_{out}(x) \sim \sum_{P \in \mathcal{G}} \langle A^{\otimes t} | P | A^{\otimes t} \rangle$. Clearly, each term in the sum can be computed in time $O(t)$, so the overall runtime becomes $O(t|\mathcal{G}|) = O(t2^r)$.

Remark 3: An alternative strategy to estimate the expectation value in Eq. (4) is to compute the inner products

$$\langle \Pi_{\mathcal{G}} \theta_i | A^{\otimes t} \rangle = \sum_{a=1}^{\chi} y_a \langle \Pi_{\mathcal{G}} \theta_i | \varphi_a \rangle$$

for $i = 1, \dots, L$. Here $|\varphi_a\rangle$ are the stabilizer states defined in Eq. (7) and $|\theta_i\rangle$ are random stabilizer states. The

same arguments as above show that

$$\langle A^{\otimes t} | \Pi_{\mathcal{G}} | A^{\otimes t} \rangle = \|\Pi_{\mathcal{G}} | A^{\otimes t} \rangle\|^2 \approx \frac{d}{L} \sum_{i=1}^L |\langle \Pi_{\mathcal{G}} \theta_i | A^{\otimes t} \rangle|^2.$$

This may be beneficial in the regime $L \ll \chi$ since one has to compute the action of $\Pi_{\mathcal{G}}$ only L times rather than χ times.

Let us now describe the algorithm that allows one to sample x from the distribution P_{out} with statistical error ϵ . As before, we replace each T -gate in the original circuit U by the gadget shown on Fig. 2 in the main text, prepare all magic states $|A\rangle$ at the very first time step, and permute the qubits such that the initial state is $|0^{\otimes n} \otimes A^{\otimes t}\rangle$. Let $y_j \in \{0, 1\}$ be the outcome of the measurement performed in the j -th gadget and $y = (y_1, \dots, y_t)$. Let V_y be the Clifford circuit on $n + t$ qubits corresponding to measurement outcomes y . Each gadget with $y_j = 0$ contributes a CNOT gate to V_y , whereas each gadget with $y_j = 1$ contributes a CNOT and the S -gate to V_y . Thus V_y contains $c + t + |y|$ gates. A composition of all gadgets and Clifford gates of U implements a trace preserving completely positive (TPCP) map

$$\Phi(\rho) = \sum_y (I_n \otimes |y\rangle\langle y|) V_y \rho V_y^\dagger (I_n \otimes |y\rangle\langle y|).$$

Here I_n is the n -qubit identity operator and the sum runs over all t -bit strings y . Suppose first that Φ is applied to a state $\rho_{in} = |0\rangle\langle 0|^{\otimes n} \otimes |A\rangle\langle A|^{\otimes t}$. Then the final state of the n computational qubits is $U|0^{\otimes n}\rangle$ regardless of y and each y appears with probability 2^{-t} . Thus

$$\Phi(\rho_{in}) = U|0^{\otimes n}\rangle\langle 0^{\otimes n}|U^\dagger \otimes \frac{I}{2^t}. \quad (10)$$

Next suppose that Φ is applied to a state $\tilde{\rho}_{in} = |0\rangle\langle 0|^{\otimes n} \otimes |\psi\rangle\langle \psi|$, where $|\psi\rangle$ is a linear combination of χ stabilizer states $|\varphi_1\rangle, \dots, |\varphi_\chi\rangle \in \mathcal{S}_t$ that approximates $|A^{\otimes t}\rangle$ with a small error:

$$|\psi\rangle = \sum_{a=1}^{\chi} z_a |\varphi_a\rangle, \quad |\langle A^{\otimes t} | \psi \rangle|^2 \geq 1 - \epsilon^2/25. \quad (11)$$

Here z_a are some coefficients and we assume $|\psi\rangle$ has unit norm. The error $\epsilon^2/25$ is sufficient to ensure that the output distribution of the overall simulation algorithm is ϵ -close to P_{out} . From Eq. (11) one gets

$$\|\rho_{in} - \tilde{\rho}_{in}\|_1 = \||A\rangle\langle A|^{\otimes t} - |\psi\rangle\langle \psi|\|_1 \leq \frac{2}{5}\epsilon. \quad (12)$$

By definition of Φ ,

$$\Phi(\tilde{\rho}_{in}) = \sum_y p_y |\phi_y\rangle\langle \phi_y| \otimes |y\rangle\langle y|, \quad (13)$$

where

$$p_y = \langle 0^{\otimes n} \otimes \psi | V_y^\dagger (I_n \otimes |y\rangle\langle y|) V_y | 0^{\otimes n} \otimes \psi \rangle \quad (14)$$

and $|\phi_y\rangle$ are normalized t -qubit states defined by

$$|\phi_y\rangle = p_y^{-1/2} \langle y | V_y | 0^{\otimes n} \otimes \psi \rangle. \quad (15)$$

Clearly, p is a normalized probability distribution on the set of t -bit strings. The state $|\phi_y\rangle$ is defined only for $p_y > 0$. Combining Eqs. (10,12,13) and tracing out the last t qubits of $\Phi(\rho_{in})$ and $\Phi(\tilde{\rho}_{in})$ one infers that

$$\|U|0^{\otimes n}\rangle\langle 0^{\otimes n}|U^\dagger - \sum_y p_y |\phi_y\rangle\langle \phi_y|\|_1 \leq \frac{2}{5}\epsilon. \quad (16)$$

Here we noted that TPCP maps do not increase the trace distance. Combining Eqs. (10,12,13) and tracing out the first n qubits of $\Phi(\rho_{in})$ and $\Phi(\tilde{\rho}_{in})$ shows that the distribution p satisfies $\|p - u\|_1 \leq \frac{2}{5}\epsilon$, where u is the uniform distribution on the set of t -bit strings. Using this fact and Eq. (16) we arrive at

$$\|U|0^{\otimes n}\rangle\langle 0^{\otimes n}|U^\dagger - \frac{1}{2^t} \sum_y |\phi_y\rangle\langle \phi_y|\|_1 \leq \frac{4}{5}\epsilon. \quad (17)$$

For each t -bit string y define a probability distribution $P_{out}^y(x) = \langle \phi_y | \Pi(x) | \phi_y \rangle$. Below we give an algorithm which takes as input y and ϵ and produces a sample from a distribution \tilde{P}_{out}^y which satisfies

$$\|P_{out}^y(x) - \tilde{P}_{out}^y(x)\|_1 \leq \epsilon/5 \quad (18)$$

Our algorithm to approximately sample from P_{out} has two steps. We first generate a random uniformly distributed t -bit string y and then we sample x from \tilde{P}_{out}^y . From Eqs. (17,18) we see that the distribution over outputs $x \in \{0, 1\}^w$ produced by this algorithm approximates P_{out} within error ϵ in the trace norm.

We are now ready to describe how to sample from \tilde{P}_{out}^y satisfying Eq. (18). We first describe how to compute an approximation to $P_{out}^y(x)$ with relative error δ . Note that

$$P_{out}^y(x) = \frac{\langle 0^{\otimes n} \otimes \psi | V_y^\dagger (\Pi(x) \otimes |y\rangle\langle y|) V_y | 0^{\otimes n} \otimes \psi \rangle}{\langle 0^{\otimes n} \otimes \psi | V_y^\dagger (I_n \otimes |y\rangle\langle y|) V_y | 0^{\otimes n} \otimes \psi \rangle}. \quad (19)$$

Here we used Eqs. (14,15). Repeating the same arguments as in the derivation of Eq. (4) one gets

$$P_{out}^y(x) = \frac{2^{-u} \langle \psi | \Pi_{\mathcal{G}} | \psi \rangle}{2^{-v} \langle \psi | \Pi_{\mathcal{H}} | \psi \rangle} \quad (20)$$

for some stabilizer groups $\mathcal{G}, \mathcal{H} \subseteq \mathcal{P}_t$ and integers u, v that can be computed in time $\tau_1 = O((w+t)(c+t) + (n+t)^3)$. We already know a randomized algorithm which computes $\langle \psi | \Pi_{\mathcal{G}} | \psi \rangle$ and $\langle \psi | \Pi_{\mathcal{H}} | \psi \rangle$ with a relative error δ in time $\tau_2 = O(\chi^3 \delta^{-2} p_f^{-1})$. Recall that p_f is the probability that the algorithm does not achieve the desired approximation. Thus we can compute $P_{out}^y(x)$ with a relative error 2δ in time $\tau_1 + \tau_2$.

Now consider the task of sampling from P_{out}^y . Assume for simplicity that $Q_{out} = \{1, 2, \dots, w\}$. For each $j = 1, \dots, w-1$ define conditional probabilities

$$P_{out}^y(z | x_1, \dots, x_{j-1}) = \frac{P_{out}^y(x_1, \dots, x_{j-1}, z)}{P_{out}^y(x_1, \dots, x_{j-1})}, \quad (21)$$

where $z \in \{0, 1\}$. Suppose the bits x_1, \dots, x_{j-1} have already been sampled (initially $j = 1$). Then the next bit x_j can be sampled by tossing a coin with bias $P_{out}^y(0|x_1, \dots, x_{j-1})$. Things are complicated by the fact that we cannot exactly compute this conditional probability. We use the same simulation strategy except that at each step the conditional probability $P_{out}^y(0|x_1, \dots, x_{j-1})$ is replaced by an approximation q_j . Here we require that with probability at least $1 - p_f$, both q_j and $1 - q_j$ approximate the conditional probabilities $P_{out}^y(0|x_1, \dots, x_{j-1})$ and $P_{out}^y(1|x_1, \dots, x_{j-1})$ respectively with relative error $O(\delta)$. Such an approximation q_j can be computed in time $O(\tau_1 + \tau_2)$ using the procedure described above for approximating the probabilities on the right-hand side of Eq. (21). Indeed, first compute a, b which, with probability at least $1 - p_f$, approximate $P_{out}^y(0|x_1, \dots, x_{j-1})$ and $P_{out}^y(1|x_1, \dots, x_{j-1})$ respectively with relative error δ . If $a \leq b$ then we set $q_j = a$ while if $b < a$ then we set $q_j = 1 - b$.

We now analyze the resulting simulation algorithm and show that we can ensure Eq. (18) by choosing approximation error $\delta = O(\epsilon w^{-1})$ and failure probability $p_f = O(\epsilon w^{-1})$. Let us first suppose that all probabilities q_j computed by the algorithm achieve the desired approximation δ (i.e., no failures occur). Conditioned on this event we see that the output distribution produced by the algorithm approximates $P_{out}^y(x)$ with relative error $O(\delta w)$. This conditional probability distribution can therefore be made $\epsilon/10$ -close (say) to P_{out}^y by choosing $\delta = O(\epsilon w^{-1})$. It remains to show that by choosing $p_f = O(\epsilon w^{-1})$ we can ensure that the output distribution \tilde{P}_{out}^y of the simulation algorithm is $\epsilon/10$ -close to the distribution conditioned on no failures. This follows because the algorithm computes $O(w)$ probabilities $\{q_j\}$ in total and choosing $p_f = O(\epsilon w^{-1})$ we can ensure that all of them are computed to within the desired approximation error δ , with probability at least $1 - \epsilon/20$. With this choice we have $\tilde{P}_{out}^y = (1 - \epsilon/20)P_A + \epsilon/20P_B$ where P_A is the distribution conditioned on no failures, and thus $\|\tilde{P}_{out}^y - P_A\|_1 \leq \epsilon/10$ as claimed.

The overall running time of this algorithm is $\tau'_1 + \tau'_2$, where $\tau'_1 = O(w\tau_1) = O(w(w+t)(c+t) + w(n+t)^3)$ and $\tau'_2 = O(w\tau_2) = O(\chi w^4 t^3 \epsilon^{-3})$.

Remark: This algorithm can be modified slightly to handle certain Clifford+ T circuits which use measurement and classical control. To see how, recall that in the T -gate gadget from Fig. 2 in the main text, a single qubit is measured in the computational basis (yielding both outcomes with equal probability) and a Clifford operation is classically controlled on the measurement outcome. In our simulation algorithm the measurement is replaced by a uniformly chosen postselection bit y_j . Exactly the same strategy can be used for other simple gadgets which involve measurement and classical control. For example, the Toffoli gate can be implemented as a Clifford+ T circuit with only four T -gates if we allow two ancillas, measurement, and classical control [7] (otherwise it requires seven T -gates [8, 9]). Fortunately it is possible

to use the less costly circuit with four T -gates in the above simulation algorithm by including one additional postselection bit per Toffoli gate.

III. APPROXIMATING MAGIC STATES

In this section we show how to compute a decomposition Eq. (11) with $\chi = O(2^{\gamma t} \epsilon^{-2})$, where γ satisfies Eq. (3) in the main text. Define a state

$$|H\rangle = \cos(\pi/8)|0\rangle + \sin(\pi/8)|1\rangle.$$

We note that the magic state $|A\rangle$ is equivalent to $|H\rangle$ modulo Clifford gates and a global phase, $|A\rangle = e^{i\pi/8} H S^\dagger |H\rangle$. Thus it suffices to construct a state

$$|\psi\rangle = \sum_{a=1}^{\chi} z_a |\varphi_a\rangle, \quad \varphi_1, \dots, \varphi_\chi \in \mathcal{S}_t \quad (22)$$

such that $\|\psi\| = 1$,

$$|\langle H^{\otimes t} |\psi\rangle|^2 \geq 1 - \delta \quad \text{and} \quad \chi = O(2^{\gamma t} \delta^{-1}) \quad (23)$$

for all sufficiently small $\delta > 0$.

Our starting point is the identity

$$|H^{\otimes t}\rangle = \frac{1}{(2\nu)^t} \sum_{x \in \mathbb{F}_2^t} |\tilde{x}_1 \otimes \tilde{x}_2 \otimes \dots \otimes \tilde{x}_t\rangle \quad (24)$$

where $|\tilde{0}\rangle \equiv |0\rangle$, $|\tilde{1}\rangle \equiv H|0\rangle = 2^{-1/2}(|0\rangle + |1\rangle)$, and

$$\nu \equiv \cos(\pi/8).$$

The right-hand side of Eq. (24) is a uniform superposition of 2^t non-orthogonal stabilizer states labeled by elements of the vector space \mathbb{F}_2^t . We shall construct an approximation $|\psi\rangle$ which is a uniform superposition of states $|\tilde{x}_1 \otimes \tilde{x}_2 \otimes \dots \otimes \tilde{x}_t\rangle$ over a linear subspace of \mathbb{F}_2^t .

Let $L(t, k)$ be the set of all k -dimensional linear subspaces $\mathcal{L} \subseteq \mathbb{F}_2^t$. We will fix k below. For each $\mathcal{L} \in L(t, k)$ define a state

$$|\mathcal{L}\rangle = \frac{1}{\sqrt{2^k Z(\mathcal{L})}} \sum_{x \in \mathcal{L}} |\tilde{x}_1 \otimes \tilde{x}_2 \otimes \dots \otimes \tilde{x}_t\rangle \quad (25)$$

where

$$Z(\mathcal{L}) \equiv \sum_{x \in \mathcal{L}} 2^{-|x|/2}. \quad (26)$$

Using the identity $\langle \tilde{a} | \tilde{b} \rangle = 2^{-|a \oplus b|/2}$, where $a, b \in \{0, 1\}$, and the fact that \mathcal{L} is a linear subspace one can easily check that $|\mathcal{L}\rangle$ is a normalized state, $\langle \mathcal{L} | \mathcal{L} \rangle = 1$. We take our approximation $|\psi\rangle$ from Eq. (22) to be Eq. (25) for a suitably chosen subspace $\mathcal{L}^* \in L(t, k)$, which gives an approximate decomposition of $|H^{\otimes t}\rangle$ using $\chi = 2^k$ stabilizer states. How small can we hope to make k ? Using the fact that $\langle H | \tilde{0} \rangle = \langle H | \tilde{1} \rangle = \nu$ we see that

$$|\langle H^{\otimes t} | \mathcal{L} \rangle|^2 = \frac{2^k \nu^{2t}}{Z(\mathcal{L})} \quad (27)$$

From this we immediately get a lower bound on k . Indeed, since $Z(\mathcal{L}) \geq 1$ we will need $2^k \geq \nu^{-2t}(1 - \delta)$ to achieve the desired approximation. Below we describe a randomized algorithm which outputs a subspace \mathcal{L}^* with $2^k = O(\delta^{-1}\nu^{-2t})$. Thus for constant δ we achieve the best possible scaling of k with t . We will use the following fact about random subspaces of \mathbb{F}_2^t .

Lemma 1. *Let $\mathcal{L} \in L(t, k)$ be chosen uniformly at random. Then*

$$\mathbb{E}(Z(\mathcal{L})) \leq 1 + 2^k \nu^{2t}. \quad (28)$$

Proof. By linearity, we have

$$\mathbb{E}(Z(\mathcal{L})) = 1 + \sum_{x \in \mathbb{F}_2^t \setminus 0} 2^{-|x|/2} \cdot \mathbb{E}(\chi_{\mathcal{L}}(x)), \quad (29)$$

where $\chi_{\mathcal{L}}(x)$ is the indicator function of \mathcal{L} . The expectation value $\mathbb{E}(\chi_{\mathcal{L}}(x))$ with respect to \mathcal{L} for a fixed x is $(2^k - 1)/(2^t - 1)$. Thus we arrive at

$$\begin{aligned} \mathbb{E}(Z(\mathcal{L})) &= 1 + \frac{(2^k - 1)}{(2^t - 1)} \sum_{x \in \mathbb{F}_2^t \setminus 0} 2^{-|x|/2} \\ &= 1 + \frac{(2^k - 1)}{(2^t - 1)} (2^t \nu^{2t} - 1) \\ &\leq 1 + 2^k \nu^{2t}. \end{aligned}$$

□

As a corollary, there exists at least one $\mathcal{L} \in L(t, k)$ such that $Z(\mathcal{L}) \leq 1 + 2^k \nu^{2t}$. We now fix k to be the unique positive integer satisfying

$$4 \geq 2^k \nu^{2t} \delta \geq 2. \quad (30)$$

Consider a subspace $\mathcal{L} \in L(t, k)$ chosen uniformly at random. Using Markov's inequality and Lemma 1 we get

$$\begin{aligned} \Pr \left[\frac{Z(\mathcal{L})}{(1 + 2^k \nu^{2t})(1 + \delta/2)} \geq 1 \right] &\leq \frac{\mathbb{E}(Z(\mathcal{L}))}{(1 + 2^k \nu^{2t})(1 + \delta/2)} \\ &\leq 1 - \frac{\delta}{2 + \delta}. \end{aligned}$$

For a given $\mathcal{L} \in L(t, k)$ we may compute $Z(\mathcal{L})$ in time $O(t2^k)$. By randomly choosing $O(1/\delta)$ subspaces \mathcal{L} we obtain one \mathcal{L}^* satisfying

$$Z(\mathcal{L}^*) \leq (1 + 2^k \nu^{2t})(1 + \delta/2) \quad (31)$$

with constant probability. Plugging Eq. (31) into Eq. (27) we see that

$$\begin{aligned} |\langle H^{\otimes t} | \mathcal{L}^* \rangle|^2 &\geq \frac{1}{(1 + 2^{-k} \nu^{-2t})(1 + \delta/2)} \\ &\geq \frac{1}{(1 + \delta/2)^2} \\ &\geq 1 - \delta, \end{aligned}$$

where in the second line we used Eq. (30). The state $|\psi\rangle = |\mathcal{L}^*\rangle$ obtained in this way therefore satisfies Eq. (23) with

$$\chi = 2^k \leq 4\nu^{-2t} \delta^{-1} = O(\nu^{-2t} \delta^{-1}) = O(2^{\gamma t} \delta^{-1}). \quad (32)$$

This algorithm has running time $O(t\nu^{-2t} \delta^{-2})$, since we must check the condition Eq. (31) for each of the $O(\delta^{-1})$ randomly sampled elements of $L(t, k)$ (note that the time required to sample each element is $O(\text{poly}(t))$).

Remark: One may ask whether a stronger bound on χ can be obtained by truncating the expansion of $|H^{\otimes t}\rangle$ in some other basis of stabilizer states. For example, consider the standard 0, 1-basis of t qubits. The expansion of $|H^{\otimes t}\rangle$ in this basis is concentrated on basis vectors $x \in \mathbb{F}_2^t$ with Hamming weight $|x| = (1 - \nu^2)t \pm O(t^{1/2})$. The number of such basis vectors scales as $\chi \sim 2^{tH_2(\nu^2)} \approx 2^{0.6t}$, where $H_2(p)$ is the binary Shannon entropy function. Thus replacing the $\tilde{0}, \tilde{1}$ -basis by the 0, 1-basis gives a significantly worse bound on χ .

As noted above, taking δ to be a constant our construction has the best possible scaling $\chi = O(\nu^{-2t})$ of any decomposition of the form Eq. (25). In fact, we prove the following lower bound on the stabilizer rank of $|H^{\otimes t}\rangle$.

Lemma 2. *Consider a state $|\psi\rangle = \sum_{a=1}^{\chi} z_a |\phi_a\rangle$, where $|\phi_a\rangle \in \mathcal{S}_t$. Suppose $\| |\psi\rangle \| = 1$ and $|\langle \psi | H^{\otimes t} \rangle| \geq f$. Then $\chi \geq \nu^{-2t} f^2 \|z\|^{-2}$, where $z = (z_1, \dots, z_{\chi}) \in \mathbb{C}^{\chi}$.*

Proof. First, let us show that

$$F_t \equiv \max_{\phi \in \mathcal{S}_t} |\langle \phi | H^{\otimes t} \rangle| = \nu^t. \quad (33)$$

The lower bound $F_t \geq \nu^t$ is obvious since $\langle 0^{\otimes t} | H^{\otimes t} \rangle = \nu^t$. We shall use induction in t to show that $F_t \leq \nu F_{t-1}$. Consider some fixed t and let $F_t = |\langle \phi | H^{\otimes t} \rangle|$ for some $|\phi\rangle \in \mathcal{S}_t$. Suppose we measure the first qubit of $|\phi\rangle$ in the 0, 1 basis. Let P_a be the probability of getting the outcome $a = 0, 1$. It is well-known that $P_a \in \{0, 1, 1/2\}$ for any stabilizer state $|\phi\rangle$. Consider three cases.

Case 1: $P_0 = 1$. Then $|\phi\rangle = |0\rangle \otimes |\psi\rangle$ for some $|\psi\rangle \in \mathcal{S}_{t-1}$ and $F_t = \nu |\langle \psi | H^{\otimes(t-1)} \rangle| \leq \nu F_{t-1}$.

Case 2: $P_0 = 0$. Then $|\phi\rangle = |1\rangle \otimes |\psi\rangle$ for some $|\psi\rangle \in \mathcal{S}_{t-1}$ and $F_t = \sqrt{1 - \nu^2} |\langle \psi | H^{\otimes(t-1)} \rangle| < \nu F_{t-1}$.

Case 3: $P_0 = 1/2$. Then

$$|\phi\rangle = 2^{-1/2} (|0\rangle \otimes |\psi_0\rangle + |1\rangle \otimes |\psi_1\rangle)$$

for some $|\psi_0\rangle, |\psi_1\rangle \in \mathcal{S}_{t-1}$. By triangle inequality,

$$F_t \leq 2^{-1/2} (\nu + \sqrt{1 - \nu^2}) F_{t-1} = \nu F_{t-1}.$$

The base of induction $F_1 = \nu$ is trivial. This proves Eq. (33). From Eq. (33) one gets

$$f \leq |\langle \psi | H^{\otimes t} \rangle| \leq \nu^t \sum_{a=1}^{\chi} |z_a| \leq \nu^t \chi^{1/2} \|z\|.$$

This is equivalent to the statement of the lemma. □

We conjecture that any approximate stabilizer decomposition of $|H^{\otimes t}\rangle$ that achieves a constant approximation error must use at least $\Omega(\nu^{-2t})$ stabilizer states.

IV. IMPLEMENTATION OF THE ALGORITHMS

A. Quadratic forms

The remaining sections provide more details on implementation of our algorithms. Section IV A presents some basic facts about quadratic forms over finite fields and describes a subroutine for computing certain exponential sums. The standard form of stabilizer states used in all our algorithms is defined in Section IV B Then we present algorithms for computing the inner product between stabilizer states (IV C), generating a random uniformly distributed stabilizer state (IV D), and computing the action of Pauli measurements on stabilizer states (IV E). The three algorithms have running time $O(n^3)$, $O(n^2)$, and $O(n^2)$ respectively, where n is the number of qubits. We provide pseudocode for all algorithms and report timing analysis for a MATLAB implementation. Section IV F describes simulation of the hidden shift algorithm.

Below we consider functions that map binary vectors to integers modulo eight. We define a special class of such functions that are analogous to quadratic forms over the real field. The definition of \mathbb{Z}_8 -valued quadratic forms given below was proposed to us by Kitaev [10]. Analogous definitions and computations using \mathbb{Z}_4 -valued quadratic forms can be found in [11]. For a general theory of quadratic forms over a finite field see Ref. [12]. Throughout the rest of the paper arithmetic operations \pm are performed modulo eight (unless stated otherwise), whereas addition of binary vectors modulo two is denoted \oplus . Elements of \mathbb{F}_2^n are considered as binary row vectors. A binary inner product between vectors $x, y \in \mathbb{F}_2^n$ will be denoted $(x, y) \equiv \sum_{i=1}^n x_i y_i \pmod{2}$. A set of binary matrices of size $a \times b$ is denoted $\mathbb{F}_2^{a \times b}$. A transpose of a matrix M is denoted M^T .

Recall that a subset $\mathcal{K} \subseteq \mathbb{F}_2^n$ is called an affine space of dimension k iff $\mathcal{K} = \mathcal{L}(\mathcal{K}) \oplus h$ for some k -dimensional linear subspace $\mathcal{L}(\mathcal{K}) \subseteq \mathbb{F}_2^n$ and a shift vector $h \in \mathbb{F}_2^n$. Note that \mathcal{K} uniquely determines $\mathcal{L}(\mathcal{K})$, namely, $\mathcal{L}(\mathcal{K}) = \{x \oplus y : x, y \in \mathcal{K}\}$. The shift vector h however is not uniquely defined. Obviously, $|\mathcal{K}| = |\mathcal{L}(\mathcal{K})| = 2^k$.

Definition 1. Consider an affine space $\mathcal{K} \subseteq \mathbb{F}_2^n$. A function $q : \mathcal{K} \rightarrow \mathbb{Z}_8$ is called a quadratic form iff there exists a function $J : \mathcal{L}(\mathcal{K}) \times \mathcal{L}(\mathcal{K}) \rightarrow \mathbb{Z}_8$ such that

$$q(x \oplus y \oplus z) + q(z) - q(x \oplus z) - q(y \oplus z) = J(x, y) \quad (34)$$

for all $z \in \mathcal{K}$ and for all $x, y \in \mathcal{L}(\mathcal{K})$.

Informally, Eq. (34) demands that a discrete analogue of the second derivative $\frac{\partial^2 q}{\partial x \partial y}$ evaluated at some point $z \in \mathcal{K}$ does not depend on z , as it is the case for quadratic forms over the real field. The next lemma states properties of the function $J(x, y)$ that follow from Eq. (34).

Lemma 3. The function $J(x, y)$ defined by Eq. (34) is a symmetric bilinear form that takes values $0, 4 \pmod{8}$.

Namely, $J(x, y) = J(y, x)$, $J(0, y) = 0$, $J(x' \oplus x'', y) = J(x', y) + J(x'', y)$, and $J(x, y) = 0, 4 \pmod{8}$ for all $x, x', x'', y \in \mathcal{L}(\mathcal{K})$.

Proof. Let $x = x' \oplus x''$. Substituting $x \leftarrow x'$ in Eq. (34) gives

$$J(x', y) = q(x' \oplus y \oplus z) + q(z) - q(x' \oplus z) - q(y \oplus z).$$

Substituting $x \leftarrow x''$ and $z \leftarrow z \oplus x'$ in Eq. (34) gives

$$J(x'', y) = q(x \oplus y \oplus z) + q(x' \oplus z) - q(x \oplus z) - q(x' \oplus y \oplus z).$$

This shows that $J(x, y) = J(x', y) + J(x'', y)$. The identities $J(0, y) = 0$ and $J(x, y) = J(y, x)$ follow trivially from Eq. (34). Replacing z by $z \oplus x$ in Eq. (34) yields

$$J(x, y) = q(y \oplus z) + q(x \oplus z) - q(z) - q(x \oplus y \oplus z).$$

Combining this and Eq. (34) one gets $2J(x, y) = 0$, that is, $J(x, y) = 0 \pmod{4}$. \square

As a corollary, one gets $q(x \oplus z) - q(z) \in \{0, 2, 4, 6\}$ for all $z \in \mathcal{K}$ and for all $x \in \mathcal{L}(\mathcal{K})$. This can be checked by choosing $x = y$ in Eq. (34) and using the fact that $J(x, x) \in \{0, 4\}$.

Suppose $g^1, \dots, g^k \in \mathcal{L}(\mathcal{K})$ is some fixed basis of $\mathcal{L}(\mathcal{K})$, $h \in \mathcal{K}$ is some fixed shift vector, and $x \in \mathcal{K}$. Then

$$x = h \oplus x_1 g^1 \oplus \dots \oplus x_k g^k, \quad x_i \in \{0, 1\}.$$

We shall write $\vec{x} \equiv (x_1, \dots, x_k)$ to avoid confusion between a point $x \in \mathcal{K}$ and its coordinates. Applying Eq. (34) and Lemma 3 one can describe q in a basis-dependent way as

$$q(\vec{x}) = Q + \sum_{a=1}^k D_a x_a + \sum_{1 \leq a < b \leq k} J_{a,b} x_a x_b, \quad (35)$$

where $Q \equiv q(h) \in \mathbb{Z}_8$,

$$D_a = q(g^a \oplus h) - q(h) \in \{0, 2, 4, 6\}, \quad (36)$$

$$J_{a,b} = J_{b,a} = J(g^a, g^b) \in \{0, 4\}. \quad (37)$$

We shall consider J as a symmetric $k \times k$ matrix. Although Eq. (35) depends only on off-diagonal matrix elements of J , it will be convenient to retain the diagonal of J . Combining Eqs. (34,35) one gets

$$J_{a,a} = 2D_a, \quad 1 \leq a \leq k. \quad (38)$$

A connection between quadratic forms and stabilizer states is established by the following lemma.

Lemma 4. Any n -qubit stabilizer state can be uniquely written as

$$|\mathcal{K}, q\rangle \equiv 2^{-k/2} \sum_{x \in \mathcal{K}} e^{\frac{i\pi}{4} q(x)} |x\rangle, \quad (39)$$

where $\mathcal{K} \subseteq \mathbb{F}_2^n$ is an affine space of dimension $0 \leq k \leq n$ and $q : \mathcal{K} \rightarrow \mathbb{Z}_8$ is a quadratic form.

Proof. The claim that any stabilizer state can be written in the form Eq. (39) follows from the explicit characterization of quadratic forms Eqs. (35,36,37) and the canonical form of stabilizer states derived in Refs. [13–15]. The uniqueness of the decomposition Eq. (39) is obvious. \square

Next let us describe how the representation of q transforms under various basis changes. Suppose $R \in \mathbb{F}_2^{k \times k}$ is an invertible matrix. Consider a basis change

$$g^a \leftarrow \sum_{b=1}^k R_{a,b} g^b \pmod{2}, \quad (40)$$

where $1 \leq a \leq k$. The shift vector h remains unchanged. Applying Eq. (35) where \vec{x} is chosen as the a -th row of R , one can easily check that the coefficients (Q, D, J) transform according to $Q \leftarrow Q$,

$$D_a \leftarrow \sum_{b=1}^k R_{a,b} D_b + \sum_{1 \leq b < c \leq k} J_{b,c} R_{a,b} R_{a,c}, \quad (41)$$

and

$$J \leftarrow R J R^T. \quad (42)$$

The matrix multiplications are performed in the ring \mathbb{Z}_8 . Next consider a basis change that alters the shift vector,

$$h \leftarrow h \oplus y, \quad \text{where } y = \sum_{a=1}^k y_a g^a \pmod{2}. \quad (43)$$

Using Eq. (36) one can easily check that the coefficients (Q, D, J) transform according to

$$Q \leftarrow Q + \sum_{a=1}^k D_a y_a + \sum_{1 \leq a < b \leq k} J_{a,b} y_a y_b, \quad (44)$$

$$D_a \leftarrow D_a + \sum_{b=1}^k J_{a,b} y_b, \quad (45)$$

and $J \leftarrow J$.

The above rules determine the representation (Q, D, J) of q in any basis of \mathcal{K} . What is the cost of computing this representation? Clearly, all updates can be expressed as a constant number of matrix-matrix (matrix-vector) multiplications with \mathbb{Z}_8 -valued matrices of size k . Thus the updates have cost $O(k^3)$ in the worst case. We shall often consider basis changes Eq. (40) such that the matrix R is sparse. Let $|R|$ be the total number of non-zeros in R . Using sparse matrix-matrix multiplication one can perform all updates in Eqs. (41,42) in time $O(|R|^2)$. Indeed, let w_a be the number of non-zeros in the a -th row of R . One can update D_a and $J_{a,b}$ for any fixed a, b in time w_a^2 and $w_a w_b$ respectively. Thus D and J can be updated in time $O((\sum_{a=1}^k w_a)^2) = O(|R|^2)$. Since the updates Eq. (45,44) require time $O(k^2)$ and $|R| \geq k$, the

overall time is $O(|R|^2)$. We conclude that computing the representation (Q, D, J) of q in the new basis takes time

$$\tau_{\text{update}} = O(\min(k^3, |R|^2)). \quad (46)$$

In the rest of this section we show how to compute certain exponential sums associated with quadratic forms, namely,

$$W(q) \equiv \sum_{x \in \mathbb{F}_2^k} e^{i \frac{\pi}{4} q(\vec{x})}, \quad (47)$$

where $q(\vec{x})$ is defined by Eq. (35). Of course, the addition in Eq. (47) is over the complex field. Our algorithm takes as input the data k, Q, D, J describing $q(\vec{x})$ and outputs $W(q)$. The algorithm has running time $O(k^3)$. It will be used as a subroutine for computing the inner product between two stabilizer states, see Section IV C.

It will be convenient to consider a more general sum

$$W(\mathcal{K}, q) = \sum_{x \in \mathcal{K}} e^{i \frac{\pi}{4} q(x)}, \quad (48)$$

where $\mathcal{K} = \mathcal{L}(\mathcal{K}) \oplus h$ is an affine space and $q : \mathcal{K} \rightarrow \mathbb{Z}_8$ is a quadratic form on \mathcal{K} . Clearly, Eq. (47) is a special case of Eq. (48). Let us say that $g^1, \dots, g^k \in \mathcal{L}(\mathcal{K})$ is a *canonical basis* of $\mathcal{L}(\mathcal{K})$ iff the set of basis vectors can be partitioned into disjoint subsets

$$[k] = \mathcal{D}_1 \cup \dots \cup \mathcal{D}_r \cup M \cup S, \quad (49)$$

such that

$$|\mathcal{D}_1| = \dots = |\mathcal{D}_r| = 2, \quad |S| \leq 1, \quad (50)$$

$$J_{a,a} = \begin{cases} 0 & \text{if } a \notin S, \\ 4 & \text{if } a \in S. \end{cases} \quad (51)$$

$$a \in M \Rightarrow J_{a,b} = 0 \quad \forall b \in [k] \setminus S, \quad (52)$$

and $\mathcal{D}_i = \{a, b\}$ implies

$$J_{a,b} = 4 \quad \text{and} \quad J_{a,c} = J_{b,c} = 0 \quad \forall c \notin S \cup \{a, b\}. \quad (53)$$

Some of the subsets in Eq. (49) can be empty. Let us write

$$\mathcal{D}_j = \{a(j), b(j)\}, \quad j = 1, \dots, r.$$

Assume that $\mathcal{L}(\mathcal{K})$ is already equipped with a canonical basis g^1, \dots, g^k and show how to compute the sum $W(\mathcal{K}, q)$. Suppose first $S = \emptyset$. By repeatedly applying Eq. (35) and using Eqs. (50,52,53) one can check that

$$q(\vec{x}) = Q + \sum_{j=1}^r q_j(x_{a(j)}, x_{b(j)}) + \sum_{c \in M} D_c x_c. \quad (54)$$

where $q_j : \mathbb{F}_2^2 \rightarrow \mathbb{Z}_8$ is defined by

$$q_j(y, z) = 4yz + D_{a(j)}y + D_{b(j)}z. \quad (55)$$

Examination of Eqs. (48,54,55) reveals that the sum $W(\mathcal{K}, q)$ factorizes into a product of $O(k)$ terms such that each term can be computed in time $O(1)$. Specifically,

$$W(\mathcal{K}, q) = e^{i\frac{\pi}{4}Q} \cdot \prod_{c \in M} (1 + e^{i\frac{\pi}{4}D_c}) \cdot \prod_{j=1}^r \Gamma_j, \quad (56)$$

where

$$\Gamma_j = 1 + e^{i\frac{\pi}{4}D_{a(j)}} + e^{i\frac{\pi}{4}D_{b(j)}} - e^{i\frac{\pi}{4}(D_{a(j)} + D_{b(j)})} \quad (57)$$

Combining Eqs. (56,57) one can compute $W(\mathcal{K}, q)$ in time $O(k)$.

Consider now the remaining case $S \neq \emptyset$. Since $|S| \leq 1$, we have $S = \{s\}$ for some $s \in [k]$. By repeatedly applying Eq. (35) and using Eqs. (50,52,53) one can check that

$$q(\vec{x}) = Q + D_s x_s + \sum_{j=1}^r q_j(x_{a(j)}, x_{b(j)}, x_s) + \sum_{c \in M} (D_c x_c + J_{c,s} x_c x_s), \quad (58)$$

where $q_j : \mathbb{F}_2^3 \rightarrow \mathbb{Z}_8$ is defined by

$$q_j(y, z, \sigma) = 4yz + J_{a(j),s} y\sigma + J_{b(j),s} z\sigma + D_{a(j)} y + D_{b(j)} z. \quad (59)$$

We have $W(\mathcal{K}, q) = W_0 + W_1$, where

$$W_\sigma \equiv \sum_{x \in \mathcal{K} : x_s = \sigma} e^{i\frac{\pi}{4}q(\vec{x})}, \quad \sigma = 0, 1. \quad (60)$$

Examination of Eqs. (58,59) reveals that W_σ factorizes into a product of $O(k)$ terms such that each term can be computed in time $O(1)$. Specifically,

$$W_\sigma = e^{i\frac{\pi}{4}(Q + \sigma D_s)} \prod_{c \in M} (1 + e^{i\frac{\pi}{4}(D_c + \sigma J_{c,s})}) \cdot \prod_{j=1}^r \Gamma_j(\sigma), \quad (61)$$

where

$$\begin{aligned} \Gamma_j(\sigma) &= 1 + \exp \left[i\frac{\pi}{4} (J_{a(j),s} \sigma + D_{a(j)}) \right] \\ &+ \exp \left[i\frac{\pi}{4} (J_{b(j),s} \sigma + D_{b(j)}) \right] \\ &- \exp \left[i\frac{\pi}{4} (J_{a(j),s} \sigma + J_{b(j),s} \sigma + D_{a(j)} + D_{b(j)}) \right]. \end{aligned} \quad (62)$$

Combining Eqs. (61,62) one can compute $W_0 + W_1$ in time $O(k)$.

To transform an arbitrary basis g^1, \dots, g^k of $\mathcal{L}(\mathcal{K})$ into the canonical form we shall use a version of the Gram-Schmidt orthogonalization. It involves at most k basis changes Eq. (40) with sparse matrices R such that $|R| = O(k)$. Computing the coefficients (D, J) in the canonical basis thus takes time $O(k|R|^2) = O(k^3)$, see Eq. (46).

Recall that $D_a \in \{0, 2, 4, 6\}$. Define a subset

$$S = \{a \in [k] : D_a \in \{2, 6\}\}.$$

If S is non-empty, pick an arbitrary element $s \in S$. Perform a basis change $g^a \leftarrow g^a \oplus g^s$ for each $a \in S \setminus s$. From Eq. (41) one gets $D_a \leftarrow D_a + D_s + J_{a,s} \in \{0, 4\}$ for all $a \in S \setminus s$ and $D_a \leftarrow D_a$ for all $a \notin S$. Set $S = \{s\}$. Now we can assume that $D_a \in \{0, 4\}$ for all $a \notin S$ for some subset S such that $|S| \leq 1$. From Eq. (38) we infer

$$J_{a,a} = 0 \quad \text{for all } a \notin S. \quad (63)$$

Let us say that a pair of basis vectors (g^a, g^b) with $a, b \notin S$ is a dimer if it obeys Eq. (53), that is, $J_{a,b} = 4$ and $J_{a,c} = J_{b,c} = 0$ for all $c \notin S \cup \{a, b\}$. Note that a basis vector can belong to at most one dimer. Let us say that a basis vector g^a with $a \notin S$ is a monomer if it obeys Eq. (52), that is, $J_{a,b} = 0$ for all $b \in [k] \setminus S$. Partition the set of basis vectors into four disjoint sets,

$$[k] = \mathcal{D} \cup M \cup S \cup E, \quad (64)$$

such that \mathcal{D} is the union of all dimers, M is the union of all monomers, and E is the complement of \mathcal{DMS} . By definition, a basis has a canonical form iff E is empty. Initially \mathcal{D}, M are empty, and E is the complement of S . Suppose E is non-empty. Pick any $a \in E$. If $J_{a,b} = 0$ for all $b \in E$, move a from E to M . Otherwise $J_{a,b} = 4$ for some $b \in E$. Let us define a binary matrix \mathbf{J} corresponding to J such that $\mathbf{J}_{a,b} = 1$ if $J_{a,b} = 4$ and $\mathbf{J}_{a,b} = 0$ otherwise. Perform a basis change

$$g^c \leftarrow g^c \oplus \mathbf{J}_{a,c} g^b \oplus \mathbf{J}_{b,c} g^a \quad \text{for all } c \in E \setminus \{a, b\}. \quad (65)$$

Using Eq. (63) one can check that the new basis vectors obey $J(g^c, g^a) = J(g^c, g^b) = 0$ for all $c \in \mathcal{DME} \setminus \{a, b\}$. Thus we can move a, b from E to \mathcal{D} by creating a new dimer $\mathcal{D}_i = \{a, b\}$ in Eq. (49). By repeating the above steps at most k times one makes $E = \emptyset$. Furthermore, the R matrices corresponding to the basis change Eq. (65) are sparse since any row of R contains at most three non-zero elements. Thus the original basis is transformed into the canonical form by $O(k)$ basis changes Eq. (40) with sparse matrices R such that $|R| = O(k)$. This has cost $O(k|R|^2) = O(k^3)$. We summarize the algorithm below.

```

function EXPONENTIALSUM( $Q, D, J$ )
   $S \leftarrow \{a \in [k] : D_a \in \{2, 6\}\}$ 
  if  $S \neq \emptyset$  then
    Pick any  $a \in S$ 
    for  $b \in S \setminus \{a\}$  do
       $g^b \leftarrow g^b \oplus g^a$ 
    end for
    Update  $(D, J)$  using Eqs. (41,42)
     $S \leftarrow \{a\}$ 
  end if
   $\triangleright$  Now  $J_{a,a} = 0$  for all  $a \notin S$

  else
    Compute  $W_{0,1}$  from Eq. (61)
    Set  $W(\mathcal{K}, q) = W_0 + W_1$ 
  end if
end function

```

Comments: The basis vectors g^a only serve a notational purpose to describe the basis change matrix R that must be used in the update formulas Eqs. (41,42). There are no actual data representing g^a or operations performed with them. For example, the first **for** loop corresponds to a matrix $R = I \oplus \sum_{b \in S \setminus \{a\}} (e^b)^T e^a$, where e^a is the binary vector with a single ‘1’ at the a -th position. As was shown in Ref. [4], the sum $W(\mathcal{K}, q)$ can be represented by a triple of integers $p \geq 0, m \in \mathbb{Z}_8$, and $\epsilon \in \{0, 1\}$ such that $W(\mathcal{K}, q) = \epsilon \cdot 2^{p/2} \cdot e^{i\pi m/4}$. Our implementation of the algorithm uses such representation for all intermediate sums to avoid roundoff errors. Timing analysis for a MATLAB implementation is reported in Table 1.

B. Standard form of stabilizer states

Suppose $|\mathcal{K}, q\rangle \in \mathcal{S}_n$ is a stabilizer state of n qubits defined in Eq. (39). An affine space $\mathcal{K} = \mathcal{L}(\mathcal{K}) \oplus h \subseteq \mathbb{F}_2^n$ of dimension k will be represented by a tuple

$$(n, k, h \in \mathbb{F}_2^n, G, \bar{G} \in \mathbb{F}_2^{n \times n}),$$

such that $\mathcal{L}(\mathcal{K})$ is spanned by the first k rows of the matrix G and $\bar{G} \equiv (G^{-1})^T$, that is,

$$G\bar{G}^T = I \pmod{2}. \quad (66)$$

We shall write g^a and \bar{g}^a for the a -th row of G and \bar{G} respectively. Thus $\mathcal{L}(\mathcal{K}) = \text{span}(g^1, \dots, g^k)$ and $(g^a, \bar{g}^b) = \delta_{a,b}$ for $1 \leq a, b \leq n$. We shall refer to g^a and \bar{g}^a as the primal and the dual basis vectors.

A quadratic form $q : \mathcal{K} \rightarrow \mathbb{Z}_8$ will be specified by a list of coefficients (Q, D, J) that describe $q(\vec{x})$ in the basis g^1, \dots, g^k of $\mathcal{L}(\mathcal{K})$, see Eqs. (35,36,37), with the shift vector h . Thus, a stabilizer state $|\mathcal{K}, q\rangle$ of n qubits is described by the following data:

$$(n, k, h, G, \bar{G}, Q, D, J),$$

where $Q \in \mathbb{Z}_8, D_1, \dots, D_k \in \{0, 2, 4, 6\}$, and J is a symmetric $k \times k$ such that $J_{a,b} \in \{0, 4\}$ for all a, b . A valid data must satisfy conditions Eq. (66) and Eq. (38).

We shall often use a subroutine that alters a stabilizer state $|\mathcal{K}, q\rangle$ by shrinking the affine space \mathcal{K} reducing its dimension by one. Namely, consider a vector $\xi \in \mathbb{F}_2^n$ and $\alpha \in \mathbb{F}_2$. Define

$$\mathcal{M} = \mathcal{K} \cap \{x \in \mathbb{F}_2^n : (\xi, x) = \alpha\}. \quad (67)$$

Clearly, \mathcal{M} is an affine space which is either empty, or $\mathcal{M} = \mathcal{K}$, or \mathcal{M} has dimension $k - 1$. Below we describe an algorithm that takes as input a stabilizer state $|\mathcal{K}, q\rangle$ and computes the standard form of the state $|\mathcal{M}, q\rangle$ (or reports that \mathcal{M} is empty). Here it is understood that the form q is restricted onto \mathcal{M} . The algorithm has runtime $O(kn)$. First we note that

$$\mathcal{M} = h \oplus \{y \in \mathcal{L}(\mathcal{K}) : (\xi, y) = \beta\},$$

where $\beta = \alpha \oplus (\xi, h)$. Let

$$S = \{a \in [k] : (\xi, g^a) = 1\}.$$

One can compute S in time $O(kn)$. If $S = \emptyset$ and $\beta = 1$ then \mathcal{M} is empty. If $S = \emptyset$ and $\beta = 0$ then $\mathcal{M} = \mathcal{K}$. Otherwise pick any element $i \in S$ and remove i from S . Change the basis of $\mathcal{L}(\mathcal{K})$ according to

$$g^a \leftarrow g^a \oplus g^i \quad \text{for } a \in S.$$

Change the dual basis according to

$$\bar{g}^i \leftarrow \bar{g}^i \oplus \sum_{a \in S} \bar{g}^a.$$

Now $(g^a, \bar{g}^b) = \delta_{a,b}$ for all a, b . The basis change requires time $O(kn)$. Let us also swap the i -th and the k -th basis vectors. Updating the coefficients (D, J) using Eqs. (41,42) takes time $O(k^2) = O(kn)$. Now basis vectors g^1, \dots, g^{k-1} are orthogonal to ξ and $(\xi, g^k) = 1$. Thus

$$\mathcal{M} = h' \oplus \text{span}(g^1, \dots, g^{k-1}) \equiv h' \oplus \mathcal{L}(\mathcal{M}),$$

where $h' = h \oplus \beta g^k$ is the new shift vector. Update the coefficients (Q, D) using Eqs. (44,45), where $y = \beta g^k$. This takes time $O(k)$. Now restricting the form q onto \mathcal{M} is equivalent to removing the k -th row/column from the matrix J and removing the k -th element from D . We obtained the standard form of the state $|\mathcal{M}, q\rangle$. The entire algorithm is summarized below.

```

function SHRINK( $|\mathcal{K}, q\rangle, \xi, \alpha$ )
   $S \leftarrow \{a \in [k] : (\xi, g^a) = 1\}$ 
   $\beta \leftarrow \alpha \oplus (\xi, h)$ 
  if  $S = \emptyset$  and  $\beta = 1$  then
    return EMPTY
  end if
  if  $S = \emptyset$  and  $\beta = 0$  then
    return SAME
  end if
  Pick any  $i \in S$ 
   $S \leftarrow S \setminus \{i\}$ 
  for  $a \in S$  do
     $g^a \leftarrow g^a \oplus g^i$ 
    Update  $(D, J)$  using Eqs. (41,42)
  end for
   $\bar{g}^i \leftarrow \bar{g}^i \oplus \sum_{a \in S} \bar{g}^a$ 
  Swap  $g^i$  and  $g^k$ . Swap  $\bar{g}^i$  and  $\bar{g}^k$ .
  Update  $(D, J)$  using Eqs. (41,42)
   $h \leftarrow h \oplus \beta g^k$ 
  Update  $(Q, D)$  using Eqs. (44,45)
  Remove the  $k$ -th row/column from  $J$ 
  Remove the  $k$ -th element from  $D$ 
   $k \leftarrow k - 1$ 
  return SUCCESS
end function

```

To simplify notations, here we assume that the function SHRINK modifies the data describing the input state. The function reports whether the new affine space \mathcal{K} is empty or the same as the initial space. It reports SUCCESS whenever the dimension of the affine space has been reduced by one. The function has runtime $O(kn)$. Sometimes we shall use a “lazy” version of the function that does not update the coefficients of q . We shall use the notation SHRINK* for such lazy version.

C. The inner product

Consider a pair of n -qubit stabilizer states

$$|\phi_\alpha\rangle = |\mathcal{K}_\alpha, q_\alpha\rangle, \quad \alpha = 1, 2$$

with the standard forms $(n, k_\alpha, h_\alpha, G_\alpha, \bar{G}_\alpha, Q_\alpha, D_\alpha, J_\alpha)$. Below we describe an algorithm that computes the inner product

$$\langle \phi_2 | \phi_1 \rangle = 2^{-(k_1+k_2)/2} \sum_{x \in \mathcal{K}_1 \cap \mathcal{K}_2} e^{i\frac{\pi}{4}(q_1(x) - q_2(x))}. \quad (68)$$

in time $O(n^3)$. First we note that $x \in \mathcal{K}_2$ iff

$$x \oplus h_2 \in \mathcal{L}(\mathcal{K}_2) = \text{span}(g_2^1, \dots, g_2^{k_2}).$$

Thus $x \in \mathcal{K}_2$ iff $x \oplus h_2$ is orthogonal to all dual basis vectors \bar{g}_2^b with $k_2 < a \leq n$. Here and below g_α^b and \bar{g}_α^b denote the b -th row of G_α and \bar{G}_α respectively. Thus

$$\mathcal{K} \equiv \mathcal{K}_1 \cap \mathcal{K}_2 = \bigcap_{b=k_2+1}^n \{x \in \mathcal{K}_1 : (\bar{g}_2^b, x) = (h_2, \bar{g}_2^b)\}.$$

One can compute the standard form of $|\mathcal{K}, q_1\rangle$ by $n - k_2$ calls to the function SHRINK defined in Section IV B with $\xi = \bar{g}_2^b$ and $\alpha = (h_2, \bar{g}_2^b)$ for $b = k_2 + 1, \dots, n$. This takes time

$$\tau_1 = O((n - k_2)k_1 n)$$

since we have to call SHRINK $n - k_2$ times.

Let $\mathcal{K} = (n, k, h, G, \bar{G})$ be the standard form of \mathcal{K} and (Q_1, D_1, J_1) be the coefficients of q_1 restricted onto \mathcal{K} in the basis g^1, \dots, g^k (as usual, g^a is the a -th row of G).

The next step so the compute coefficients (Q_2, D_2, J_2) of the form q_2 restricted to \mathcal{K} in the basis g^1, \dots, g^k with the shift vector h . We note that

$$h = h_2 \oplus \sum_{a=1}^{k_2} y_a g_2^a, \quad \text{where } y_a = (h \oplus h_2, \bar{g}_2^a).$$

One can compute y_1, \dots, y_{k_2} in time $O(k_2 n)$ and then compute the updated coefficients (Q_2, D_2) from Eqs. (44,45). This takes time $O(k_2^2)$. A simple algebra shows that $\mathcal{L}(\mathcal{K}) = \mathcal{L}(\mathcal{K}_1) \cap \mathcal{L}(\mathcal{K}_2)$, that is, $g^a \in \mathcal{L}(\mathcal{K}_2)$ for all $a = 1, \dots, k$. Define a matrix R of size $k \times k_2$ such that

$$g^a = \sum_{b=1}^{k_2} R_{a,b} \bar{g}_2^b \pmod{2}, \quad 1 \leq a \leq k.$$

Using the dual basis of \mathcal{K}_2 one gets $R_{a,b} = (g^a, \bar{g}_2^b)$. One can compute the entire matrix R in time $O(kk_2 n)$. Then the coefficients (D_2, J_2) in the basis g^1, \dots, g^k can be computed from Eqs. (41,42) which takes time $O(kk_2^2)$, see Eq. (46). (Here we used a slightly stronger version of Eq. (46) taking into account that R is a rectangular matrix.) The runtime up to this point is

$$\tau_2 = \tau_1 + O(kk_2 n).$$

Now the restrictions of both forms q_1, q_2 onto \mathcal{K} are defined in the same basis g^1, \dots, g^k and the same shift vector h . Thus $q \equiv q_1 - q_2$ has coefficients (Q, D, J) , where $Q = Q_1 - Q_2$, $D = D_1 - D_2$, and $J = J_1 - J_2$. We get

$$\langle \phi_2 | \phi_1 \rangle = 2^{-(k_1+k_2)/2} \cdot W(Q, D, J),$$

where $W(Q, D, J)$ is the exponential sum Eq. (47) that can be computed in time $O(k^3)$, see Section IV A. The overall running time is thus

$$\tau = \tau_2 + O(k^3) = O((n - k_2)k_1n + kk_2n + k^3) = O(n^3).$$

We summarize the entire inner product algorithm below.

```

function INNERPRODUCT( $(|\mathcal{K}_1, q_1\rangle, |\mathcal{K}_2, q_2\rangle)$ )
   $\mathcal{K} \leftarrow \mathcal{K}_1$ 
  for  $b = k_2 + 1$  to  $n$  do
     $\alpha \leftarrow (h_2, \bar{g}_2^b)$ 
     $\epsilon \leftarrow \text{SHRINK}(|\mathcal{K}, q_1\rangle, \bar{g}_2^b, \alpha)$ 
    if  $\epsilon = \text{EMPTY}$  then
      return 0
    end if
  end for
   $\triangleright$  Now  $\mathcal{K} = \mathcal{K}_1 \cap \mathcal{K}_2 = (n, k, h, G, \bar{G})$ 
  for  $a = 1$  to  $k_2$  do
     $y_a \leftarrow (h \oplus h_2, \bar{g}_2^a)$ 
    for  $b = 1$  to  $k$  do
       $R_{b,a} \leftarrow (g^b, \bar{g}_2^a)$ 
    end for
  end for
   $h_2 \leftarrow h_2 \oplus \sum_{a=1}^{k_2} y_a g_2^a = h$ 
  Update  $(Q_2, D_2)$  using Eqs. (44,45) with  $y$ 
  Update  $(D_2, J_2)$  using Eqs. (41,42) with  $R$ 
   $\triangleright$  Now  $q_1, q_2$  are defined in the same basis
   $Q \leftarrow Q_1 - Q_2$ 
   $D \leftarrow D_1 - D_2$ 
   $J \leftarrow J_1 - J_2$ 
  return  $2^{-(k_1+k_2)/2} \cdot \text{ExponentialSum}(Q, D, J)$ 
end function

```

Comments: As before, we assume that the output is converted to a triple of integers (ϵ, p, m) such that $\langle \phi_2 | \phi_1 \rangle = \epsilon \cdot 2^{p/2} \cdot e^{i\pi m/4}$. If both k_1 and k_2 are small, one can compute the intersection $\mathcal{K}_1 \cap \mathcal{K}_2$ directly by solving a linear system

$$\sum_{a=1}^{k_1} x_a g_1^a \oplus \sum_{b=1}^{k_2} y_b g_2^b = h_1 \oplus h_2$$

with $k_1 + k_2$ variables and n equations. This provides a shift vector and a basis for \mathcal{K} in time $O(n(k_1 + k_2)^2)$. Then one can compute the updated coefficients of q_1 and q_2 in the new basis in time $O(k(k_1^2 + k_2^2))$. Thus the overall running time is

$$\tau = O(k_1^2 n + k_2^2 n + k^3) \quad (69)$$

which is linear in n provided that both $k_1, k_2 = O(1)$. We note however that the vast majority of stabilizer states have $k_\alpha \approx n$, see Section IV D, so the above method provides no speedup in the generic case.

The timing analysis of the function InnerProduct reported in Table 1 was performed for inner products $\langle \tilde{x} | \phi \rangle$, where $\phi \in \mathcal{S}_n$ is drawn from the uniform distribution (as described in Section IV D), $x \in \mathbb{F}_2^n$ is a random uniformly

distributed string, and $|\tilde{x}\rangle \equiv |\tilde{x}_1 \otimes \tilde{x}_2 \otimes \cdots \otimes \tilde{x}_n\rangle$, where $|\bar{0}\rangle = |0\rangle$ and $|\bar{1}\rangle = H|0\rangle$. This choice is justified since our simulation algorithm only requires inner products of the above form.

D. Random stabilizer states

Let us now describe an algorithm that generates a random uniformly distributed stabilizer state $|\mathcal{K}, q\rangle \in \mathcal{S}_n$. The algorithm has average-case runtime $O(n^2)$ and the worst-case runtime $O(n^3)$.

For each $0 \leq k \leq n$ define a subset of stabilizer states

$$\mathcal{S}_n^k = \{|\mathcal{K}, q\rangle \in \mathcal{S}_n : \dim(\mathcal{K}) = k\}.$$

For example, \mathcal{S}_n^0 includes all basis vectors, whereas \mathcal{S}_n^n includes stabilizer states supported on all basis vectors. Our algorithm first picks a random integer $d = 0, 1, \dots, n$ drawn from a distribution

$$P(d) = \frac{|\mathcal{S}_n^{n-d}|}{\sum_{m=0}^n |\mathcal{S}_n^m|} \quad (70)$$

and generates a random subspace $\mathcal{K} \subseteq \mathbb{F}_2^n$ of dimension $k = n - d$. To compute $P(d)$ we need the following fact.

Lemma 5.

$$|\mathcal{S}_n^{n-d}| = 8 \cdot 2^{n+\frac{1}{2}[n(n+1)-d(d+1)]} \cdot \prod_{a=1}^d \frac{1 - 2^{d-n-a}}{1 - 2^{-a}}. \quad (71)$$

for any $d = 1, \dots, n$ and $|\mathcal{S}_n^n| = 8 \cdot 2^{n+\frac{1}{2}n(n+1)}$.

Proof. Let $k \equiv n - d$. The number of k -dimensional linear subspaces $\mathcal{L} \subseteq \mathbb{F}_2^n$ is known to be

$$\Gamma_n^k = \Gamma_n^d = \prod_{m=0}^{d-1} \frac{2^n - 2^m}{2^d - 2^m}$$

For a given \mathcal{L} there are 2^{n-k} affine spaces \mathcal{K} such that $\mathcal{K} = \mathcal{L} \oplus h$ for some shift vector h . Finally, for a given affine space \mathcal{K} there are

$$\Lambda_n^k = 8 \cdot 2^{2k} \cdot 2^{k(k-1)/2}$$

quadratic forms $q : \mathcal{K} \rightarrow \mathbb{Z}_8$. Here the three factors represent the number of choices for the coefficients (Q, D, J) in Eqs. (35,36,37) respectively (recall that the diagonal of J is determined by D , see Eq. (38)). It follows that $|\mathcal{S}_n^k| = 2^{n-k} \cdot \Gamma_n^k \cdot \Lambda_n^k$, which gives Eq. (71). \square

One can rewrite Eq. (70) as

$$P(d) = \frac{\eta(d)}{\sum_{m=0}^n \eta(m)}, \quad (72)$$

where $\eta(0) = 1$ and

$$\eta(d) = 2^{-d(d+1)/2} \cdot \prod_{a=1}^d \frac{1 - 2^{d-n-a}}{1 - 2^{-a}}$$

for $d = 1, \dots, n$. One can compute a lookup table for the function $\eta(d)$ offline since it depends only on n . Clearly, $d = O(1)$ with high probability. Thus, the average-case online complexity of sampling d from the distribution $P(d)$ is $O(1)$.

We start by choosing the zero shift vector such that \mathcal{K} is a random linear space of dimension k . We shall generate \mathcal{K} by repeatedly picking a random matrix $X \in \mathbb{F}_2^{d \times n}$ until X has rank d and then choosing $\mathcal{K} = \ker(X)$. It is well-known that X has rank d with probability

$$p_{n,d} = \prod_{a=0}^{d-1} (1 - 2^{-n+a}) \geq \max\{1/4, 1 - 2^{-n+d}\}.$$

Note that $p_{n,d}$ is exponentially close to 1 whenever $d = O(1)$. Thus X has full rank after $O(1)$ attempts with high probability. Furthermore, one can compute the rank of X in time $O(nd^2)$ using the Gaussian elimination by bringing X into the row echelon form. It is also well-known that conditioned on X having full rank, the subspace $\ker(X)$ is distributed uniformly on the set of all subspaces of \mathbb{F}_2^n of dimension $n - d$. Thus we can choose $\mathcal{K} = \ker(X)$.

The next step is computing $n \times n$ matrices G and \bar{G} such that \mathcal{K} is spanned by the first k rows of G and $G\bar{G}^T = I$. Let us first set $\mathcal{K} = \mathbb{F}_2^n$ and $G = \bar{G} = I$. Choose a zero quadratic form $q(x) = 0$ for all $x \in \mathcal{K}$. Let ξ^a be the a -th row of the matrix X . One can make \mathcal{K} orthogonal to ξ^1, \dots, ξ^d by making d calls to the function $\text{SHRINK}^*(|\mathcal{K}, q), \xi^a, 0)$ defined in Section IV B. (Recall that SHRINK^* does not update the coefficients of q .) Finally we shift \mathcal{K} by a random uniformly distributed vector $h \in \mathbb{F}_2^n$. At this point \mathcal{K} is a random affine space represented in the standard form. It remains to choose random coefficients of the quadratic form $q : \mathcal{K} \rightarrow \mathbb{Z}_8$ in the basis g^1, \dots, g^k . Since q must be distributed uniformly on the set of all quadratic forms $q : \mathcal{K} \rightarrow \mathbb{Z}_8$, we must choose $Q \in \mathbb{Z}_8$, $D_a \in \{0, 2, 4, 6\}$, and $J_{a,b} \in \{0, 4\}$ for $a < b$ as random uniform elements of the respective sets. Then the entire matrix J is determined by $J_{b,a} = J_{a,b}$ and $J_{a,a} = 2D_{a,a}$, see Eq. (38). The entire algorithm is summarized below.

```

function RANDOMSTABILIZERSTATE( $n$ )
  Compute  $P(0), \dots, P(n)$  from Eq. (72)
  Sample  $d \in \{0, 1, \dots, n\}$  from  $P(d)$ 
   $k \leftarrow n - d$ 
  repeat
    Pick random  $X \in \mathbb{F}_2^{d \times n}$ 
  until  $\text{rank}(X) = d$ 
   $G \leftarrow I, \bar{G} \leftarrow I, h \leftarrow 0^k$ 
   $\mathcal{K} \leftarrow (n, k, h, G, \bar{G})$ 
   $\triangleright$  Now  $\mathcal{K} = \mathbb{F}_2^n$  is full binary space
   $q \leftarrow$  all-zeros function on  $\mathcal{K}$ 
  for  $a = 1$  to  $d$  do
     $\xi \leftarrow a$ -th row of  $X$ 
     $\text{SHRINK}^*(|\mathcal{K}, q), \xi, 0)$ 
  end for
   $\triangleright$  Now  $\mathcal{K} = \ker(X)$ 
   $\triangleright \mathcal{K}$  has the standard form
  Pick random  $h \in \mathbb{F}_2^n$ 
  Pick random  $Q \in \mathbb{Z}_8$ 
  Pick random  $D_a \in \{0, 2, 4, 6\}$ 
  Pick random  $J_{a,b} = J_{b,a} \in \{0, 4\}$  for  $a \neq b$ 
  Set  $J_{a,a} = 2D_a \pmod{8}$ 
  return  $(n, k, h, G, \bar{G}, Q, D, J)$ 
end function

```

Each call to SHRINK takes time $O(n^2)$, see Section IV B, whereas each computation of $\text{rank}(X)$ takes time $O(dn^2)$. Thus the entire algorithm takes time $O(dn^2)$. Since $d = O(1)$ with high probability, see above, the average runtime is $O(n^2)$, whereas the worst-case runtime is $O(n^3)$. Timing analysis for a MATLAB implementation is reported in Table 1.

E. Pauli measurements

Suppose $|\mathcal{K}, q) \in \mathcal{S}_n$ is a stabilizer state of n qubits represented in the standard form and $P \in \mathcal{P}_n$ is a Pauli operator. Define an operator

$$P_+ \equiv \frac{1}{2}(I + P).$$

It is well-known that P_+ maps stabilizer states to (unnormalized) stabilizer states. Note that P_+ is a projector if P is self-adjoint and $\sqrt{2}P_+$ is a unitary Clifford operator if $P^\dagger = -P$. Below we describe an algorithm that computes the normalization and the standard form of the state $P_+|\mathcal{K}, q)$. The algorithm has runtime $O(n^2)$. We shall be mostly interested in the case when P_+ is a projector (although our algorithm applies to the general case). Note that a projector onto the codespace of any stabilizer code with a stabilizer group $\mathcal{G} \subseteq \mathcal{P}_n$ can be written as a product of at most n projectors P_+ associated with some set of generators of \mathcal{G} . Thus a projected state $\Pi_{\mathcal{G}}|\mathcal{K}, q)$ can be computed in time $O(n^3)$ using the above algorithm.

Let $\mathcal{K} = (n, k, h, G, \bar{G})$ be the standard form of \mathcal{K} and

$$P = i^m Z(\zeta)X(\xi), \quad m \in \mathbb{Z}_4, \quad \xi, \zeta \in \mathbb{F}_2^n. \quad (73)$$

We shall consider two cases depending on whether or not $\xi \in \mathcal{L}(\mathcal{K})$. This inclusion can be checked in time $O(kn)$ by computing inner products $\xi_a = (\xi, \bar{g}^a)$ with $a = 1, \dots, k$. Namely, $\xi \in \mathcal{L}(\mathcal{K})$ iff $\xi = \sum_{a=1}^k \xi_a g^a \pmod{2}$.
Case 1: $\xi \in \mathcal{L}(\mathcal{K})$. Define a function

$$\chi(x) = q(x \oplus \xi) - q(x). \quad (74)$$

By definition of a quadratic form one has

$$\chi(h \oplus y) = \chi(h) + J(\xi, y) \quad \text{for all } y \in \mathcal{L}(\mathcal{K}). \quad (75)$$

The state $P_+|\mathcal{K}, q\rangle$ can be written as

$$2^{-k/2-1} \sum_{x \in \mathcal{K}} e^{i\frac{\pi}{4}q(x)} \left(1 + i^m (-1)^{(\zeta, x)} e^{i\frac{\pi}{4}\chi(x)}\right) |x\rangle. \quad (76)$$

Perform a change of variable $x = h \oplus y$ with $y \in \mathcal{L}(\mathcal{K})$. Using Eq. (75) one can rewrite the above state as

$$2^{-k/2-1} \sum_{y \in \mathcal{L}(\mathcal{K})} e^{i\frac{\pi}{4}q(h \oplus y)} \left(1 + e^{i\frac{\pi}{4}(\omega + \lambda(y))}\right) |h \oplus y\rangle, \quad (77)$$

with

$$\omega = 2m + 4(\zeta, h) + q(h \oplus \xi) - q(h) \in \{0, 2, 4, 6\} \quad (78)$$

and

$$\lambda(y) = 4(\zeta, y) + J(\xi, y) \in \{0, 4\}. \quad (79)$$

Let us first compute ω . We have

$$\xi = \sum_{a=1}^k \xi_a g^a \pmod{2}, \quad \xi_a = (\bar{g}^a, \xi). \quad (80)$$

The decomposition Eq. (80) can be computed in time $O(kn)$. Once the coefficients ξ_a are known, one can compute ω from

$$\omega = 2m + 4(\zeta, h) + \sum_{a=1}^k D_a \xi_a + \sum_{1 \leq a < b \leq k} J_{a,b} \xi_a \xi_b. \quad (81)$$

This takes time $O(kn)$.

Suppose first that $\omega \in \{0, 4\}$. Then $e^{i\frac{\pi}{4}\omega} = \pm 1$ and thus

$$1 + e^{i\frac{\pi}{4}(\omega + \lambda(y))} = \begin{cases} 2 & \text{if } \lambda(y) + \omega = 0 \pmod{8} \\ 0 & \text{if } \lambda(y) + \omega = 4 \pmod{8}. \end{cases}$$

We get

$$P_+|\mathcal{K}, q\rangle = 2^{-k/2} \sum_{x \in \mathcal{M}} e^{i\frac{\pi}{4}q(x)} |x\rangle. \quad (82)$$

where

$$\mathcal{M} = \mathcal{K} \cap \{x \in \mathbb{F}_2^n : \lambda(h \oplus x) = \omega\}. \quad (83)$$

Let us choose a vector $\gamma \in \mathbb{F}_2^n$ such that $\lambda(y) = 4(\gamma, y)$ for all $y \in \mathcal{L}(\mathcal{K})$. We shall look for

$$\gamma = \sum_{b=1}^k \eta_b \bar{g}^b \pmod{2}, \quad \eta_b \in \{0, 1\}. \quad (84)$$

Choosing $y = g^a$ and using $(g^a, \bar{g}^b) = \delta_{a,b}$ one gets

$$4\eta_a = \lambda(g^a) = 4(\zeta, g^a) + J(\xi, g^a), \quad 1 \leq a \leq k. \quad (85)$$

To compute (ζ, g^a) and $J(\xi, g^a)$ consider expansions Eq. (80) and

$$\zeta = \sum_{a=1}^n \zeta_a \bar{g}^a \pmod{2}, \quad \zeta_a = (g^a, \zeta). \quad (86)$$

One can compute all the coefficients ζ_1, \dots, ζ_k in time $O(kn)$. The fact that $J(x, y)$ is a bilinear form implies

$$4\eta_a = 4\zeta_a + \sum_{b=1}^k J_{a,b} \xi_b, \quad 1 \leq a \leq k. \quad (87)$$

Thus η_1, \dots, η_k can be computed in time $O(kn)$. Let $\omega = 4\omega'$ with $\omega' \in \{0, 1\}$. We arrived at

$$\mathcal{M} = \mathcal{K} \cap \{x \in \mathbb{F}_2^n : (\gamma, x) = \alpha\}, \quad \alpha \equiv \omega' \oplus (\gamma, h).$$

The standard form of the state defined in Eq. (82) can be computed by calling the function SHRINK($|\mathcal{K}, q\rangle, \gamma, \alpha$), see Section IV B, which takes time $O(kn)$.

Next suppose that $\omega \in \{2, 6\}$. Then $e^{i\frac{\pi}{4}\omega} = \pm i$ and thus

$$1 + e^{i\frac{\pi}{4}(\omega + \lambda(y))} = \begin{cases} \sqrt{2}e^{i\frac{\pi}{4}} & \text{if } \lambda(y) + \omega = 2 \pmod{8} \\ \sqrt{2}e^{-i\frac{\pi}{4}} & \text{if } \lambda(y) + \omega = 6 \pmod{8} \end{cases}$$

We shall choose a quadratic form $\lambda' : \mathcal{K} \rightarrow \mathbb{Z}_8$ such that

$$\lambda'(h \oplus y) = \begin{cases} 0 & \text{if } \lambda(y) = 0, \\ 2 & \text{if } \lambda(y) = 4. \end{cases} \quad (88)$$

Define

$$\sigma = \begin{cases} 1 & \text{if } \omega = 2, \\ -1 & \text{if } \omega = 6. \end{cases} \quad (89)$$

Then the state in Eq. (77) can be written as

$$P_+|\mathcal{K}, q\rangle = 2^{-(k+1)/2} \sum_{x \in \mathcal{K}} e^{i\frac{\pi}{4}q'(x)} |x\rangle = 2^{-1/2} |\mathcal{K}, q'\rangle \quad (90)$$

with a quadratic form

$$q'(x) = \sigma + q(x) - \sigma \lambda'(x). \quad (91)$$

To get the standard form of $|\mathcal{K}, q'\rangle$ we need to choose $\lambda'(x)$ satisfying Eq. (88) and compute the coefficients of

$\lambda'(x)$ in the basis g^1, \dots, g^k of $\mathcal{L}(\mathcal{K})$. First, let us compute the basis-dependent representation of $\lambda(y)$. Suppose $y = \sum_{a=1}^k y_a g^a \pmod{2}$ and let $\vec{y} = (y_1, \dots, y_k)$. Substituting Eqs. (80,86) into Eq. (79) one gets

$$\lambda(\vec{y}) = 4 \sum_{a=1}^k \eta_a y_a,$$

where $\eta_a \in \{0, 1\}$ are defined by Eq. (87). For any $z_1, \dots, z_k \in \{0, 1\}$ one has the following identity:

$$2(z_1 \oplus \dots \oplus z_k) = 2 \sum_{a=1}^k z_a - 4 \sum_{1 \leq a < b \leq k} z_a z_b \pmod{8}.$$

Choose $z_a = \eta_a y_a$ such that $\lambda(\vec{y}) = 4(z_1 \oplus \dots \oplus z_k)$. Then a function $\lambda'(y)$ satisfying Eq. (88) has a basis-dependent representation $\lambda'(\vec{y}) = 2(z_1 \oplus \dots \oplus z_k)$, that is,

$$\lambda'(h \oplus y) = 2 \sum_{a=1}^k \eta_a y_a - 4 \sum_{1 \leq a < b \leq k} \eta_a \eta_b y_b y_b. \quad (92)$$

To summarize, the coefficients of the form q' in the basis g^1, \dots, g^k are (Q', D', J') , where

$$Q' = Q + \sigma, \quad D'_a = D_a - 2\sigma\eta_a, \quad (93)$$

and

$$J'_{a,b} = J_{a,b} + 4\eta_a \eta_b \quad \text{for } a \neq b. \quad (94)$$

This determines the standard form of $|\mathcal{K}, q'\rangle$.

Case 2: $\xi \notin \mathcal{L}(\mathcal{K})$. Then $\xi \oplus x \notin \mathcal{K}$ for any $x \in \mathcal{K}$ and thus the states $|\mathcal{K}, q\rangle$ and $P|\mathcal{K}, q\rangle$ are supported on disjoint subsets of basis vectors. Define an affine space $\mathcal{M} = \mathcal{L}(\mathcal{M}) \oplus h$ of dimension $k+1$, where $\mathcal{L}(\mathcal{M})$ is spanned by $\mathcal{L}(\mathcal{K})$ and ξ . We equip $\mathcal{L}(\mathcal{M})$ with a basis g^1, \dots, g^{k+1} , where $g^{k+1} \equiv \xi$. Then any vector $x \in \mathcal{M}$ can be written in a basis-dependent way as

$$x = h \oplus \sum_{a=1}^{k+1} x_a g^a \pmod{2}.$$

Let $\vec{x} = (x_1, \dots, x_{k+1})$. A simple algebra shows that

$$P_+ |\mathcal{K}, q\rangle = 2^{-1-k/2} \sum_{x \in \mathcal{M}} e^{i\frac{\pi}{4} q'(x)} |x\rangle = 2^{-1/2} |\mathcal{M}, q'\rangle, \quad (95)$$

where $q' : \mathcal{M} \rightarrow \mathbb{Z}_8$ is a quadratic form defined by

$$q'(\vec{x}) = q(\vec{x}) + [2m + 4(\zeta, h \oplus \xi)] x_{k+1} + 4 \sum_{a=1}^k \zeta_a x_a x_{k+1}. \quad (96)$$

Here it is understood that $q(\vec{x})$ depends only on the first k coordinates of x . Thus the coefficients of q' in the chosen basis of $\mathcal{L}(\mathcal{M})$ are $Q' = Q$, $D' = [D, 2m + 4(\zeta, h \oplus \xi)]$, and

$$J' = \begin{bmatrix} J & 4\zeta^T \\ 4\zeta & 4m \end{bmatrix}. \quad (97)$$

Here $\zeta \equiv (\zeta_1, \dots, \zeta_k)$ is a row vector.

It remains to compute the standard form of \mathcal{M} . Below we define a function $\text{EXTEND}(\mathcal{K}, \xi)$ that takes as input an affine space $\mathcal{K} = (n, k, h, G, \bar{G})$ and a vector $\xi \in \mathbb{F}_2^n$. If $\xi \in \mathcal{L}(\mathcal{K})$, the function does nothing. Otherwise, the function outputs an affine space $\mathcal{M} = (n, k+1, h, H, \bar{H})$ such that the first k rows of G and H are the same and the $(k+1)$ -th row of H equals ξ . Since the function EXTEND is very similar to the function SHRINK defined in Section IV B, we just state the algorithm skipping the analysis.

```

function  $\mathcal{M} = \text{EXTEND}(\mathcal{K}, \xi)$ 
   $S \leftarrow \{a \in [n] : (\xi, \bar{g}^a) = 1\}$ 
   $T \leftarrow S \cap \{k+1, \dots, n-1, n\}$ 
  if  $T = \emptyset$  then
     $\triangleright \xi \in \mathcal{L}(\mathcal{K})$ 
    return  $\mathcal{K}$ 
  end if
  Pick any  $i \in T$ 
   $S \leftarrow S \setminus \{i\}$ 
  for  $a \in S$  do
     $\bar{g}^a \leftarrow \bar{g}^a \oplus \bar{g}^i$ 
  end for
   $g^i \leftarrow g^i \oplus \sum_{a \in S} g^a$ 
   $\triangleright$  Now  $g^i = \xi$ 
  Swap  $g^i$  and  $g^{k+1}$ . Swap  $\bar{g}^i$  and  $\bar{g}^{k+1}$ .
  return  $(n, k+1, h, G, \bar{G})$ 
end function

```

It has runtime $O(n^2)$. We do not have to update the coefficients of q' since Eq. (96) defines q' in the basis g^1, \dots, g^k, ξ which coincides with the new basis of \mathcal{M} . We conclude that the projected state $2^{-1/2} |\mathcal{M}, q'\rangle$ can be computed in time $O(n^2)$.

Below we summarize the entire algorithm as a function MeasurePauli that takes as input a stabilizer state $|\mathcal{K}, q\rangle \in \mathcal{S}_n$ and a Pauli operator $P \in \mathcal{P}_n$. The function returns the norm of the projected state $\Gamma = \|P_+ |\mathcal{K}, q\rangle\|$. If $\Gamma \neq 0$, the function computes the standard form of the projected state $P_+ |\mathcal{K}, q\rangle$. As before, we assume that the function can modify the data describing the input state.

```

function  $\Gamma = \text{MEASUREPAULI}(|\mathcal{K}, q\rangle, P)$ 
     $\triangleright P = i^m Z(\zeta) X(\xi)$ 
     $\triangleright \mathcal{K} = (n, k, h, G, \bar{G})$ 
     $\triangleright q = (Q, D, J)$ 

    for  $a = 1$  to  $k$  do
         $\xi_a \leftarrow (\bar{g}^a, \xi)$ ,  $\zeta_a \leftarrow (g^a, \zeta)$ 
    end for
     $\xi' \leftarrow \sum_{a=1}^k \xi_a g^a \pmod{2}$ 
    Compute  $\omega \in \{0, 2, 4, 6\}$  using Eq. (81)
    if  $\xi' = \xi$  and  $\omega \in \{0, 4\}$  then
        Compute  $\eta_1, \dots, \eta_k$  using Eq. (87)
         $\gamma \leftarrow \sum_{a=1}^k \eta_a g^a \pmod{2}$ 
         $\omega' \leftarrow \omega/4$ 
         $\alpha \leftarrow \omega' \oplus (\eta, h)$ 
         $\epsilon \leftarrow \text{SHRINK}(|\mathcal{K}, q\rangle, \gamma, \alpha)$ 
        if  $\epsilon = \text{EMPTY}$  then
             $\Gamma \leftarrow 0$ 
            return
        end if
        if  $\epsilon = \text{SAME}$  then
             $\Gamma \leftarrow 1$ 
            return
        end if
        if  $\epsilon = \text{SUCCESS}$  then
             $\Gamma \leftarrow 2^{-1/2}$ 
            return
        end if
    end if
    if  $\xi' = \xi$  and  $\omega \in \{2, 6\}$  then
         $\sigma \leftarrow 2 - (\omega/2)$ 
        Compute  $(Q', D', J')$  using Eqs. (93,94)
         $(Q, D, J) \leftarrow (Q', D', J')$ 
         $\Gamma \leftarrow 2^{-1/2}$ 
        return
    end if
    if  $\xi' \neq \xi$  then
         $\mathcal{K} \leftarrow \text{EXTEND}(\mathcal{K}, \xi)$ 
         $D \leftarrow [D, 2m + 4(\zeta, h \oplus \xi)]$ 
         $J \leftarrow J'$ , where  $J'$  is defined in Eq. (97)
         $\Gamma \leftarrow 2^{-1/2}$ 
        return
    end if
end function

TABLE I. Average runtime in milliseconds for a MATLAB implementation of our algorithms. Simulations were performed on a laptop with 2.6GHz Intel i5 Dual Core CPU.

F. Simulation of the hidden shift algorithm

Here we provide further details of the simulations reported in Fig. 1 of the main text. Recall that we simulate a circuit

$$U = H^{\otimes n} O_f H^{\otimes n} O_f H^{\otimes n}, \quad (98)$$

where $O_f|x\rangle = f(x)|x\rangle$ and $O_{f'}|x\rangle = f'(x)|x\rangle$ are oracle circuits for some bent functions $f, f' : \mathbb{F}_2^n \rightarrow \{+1, -1\}$ such that

$$f'(x \oplus s) = 2^{-n/2} \sum_{y \in \mathbb{F}_2^n} (-1)^{x \cdot y} f(y) \quad \text{for all } x \in \mathbb{F}_2^n. \quad (99)$$

Here $s \in \mathbb{F}_2^n$ is the hidden shift that can be found from $|s\rangle = U|0^{\otimes n}\rangle$. In our simulations the hidden shift s was chosen at random from the uniform distribution. The function f was chosen from (a subclass of) the Maiorana McFarland family of bent functions. In general, a Maiorana McFarland bent function is defined as follows. Suppose n is even. Let

$$g : \mathbb{F}_2^{n/2} \rightarrow \mathbb{F}_2 \quad \text{and} \quad \pi : \mathbb{F}_2^{n/2} \rightarrow \mathbb{F}_2^{n/2}$$

be any Boolean function and any permutation respectively. For any such pair g, π we may define a bent function $f : \mathbb{F}_2^n \rightarrow \{+1, -1\}$ according to

$$f(x, y) = (-1)^{g(x) + y \cdot \pi(x)} \quad x, y \in \mathbb{F}_2^{n/2}. \quad (100)$$

The Hadamard transform of f is given by

$$2^{-n/2} \sum_{u, v} (-1)^{u \cdot x + v \cdot y} f(u, v) = (-1)^{x \cdot \pi^{-1}(y) + g(\pi^{-1}(y))}. \quad (101)$$

In our simulations we only used bent functions of the form Eq. (100) with $\pi = I$ (the identity permutation). The Boolean function g was chosen at random, as explained below. Letting O_g be the $n/2$ -qubit diagonal unitary

$$O_g|x\rangle = (-1)^{g(x)}|x\rangle \quad x \in \mathbb{F}_2^{n/2}$$

we see that a quantum circuit which implements the n -qubit unitary oracle $O_f|x, y\rangle = f(x, y)|x, y\rangle$ can be decomposed as

$$O_f = \left(\prod_{i=1}^{n/2} CZ_{i, i+n/2} \right) O_g \otimes I$$

where $CZ = \text{diag}(1, 1, 1, -1)$ is the two-qubit controlled- Z gate. Here the tensor product separates the first $n/2$ qubits from the last $n/2$. Likewise, from Eqs. (99,101) one infers that

$$O_{f'} = X(s) \left[\left(\prod_{i=1}^{n/2} CZ_{i, i+n/2} \right) I \otimes O_g \right] X(s)$$

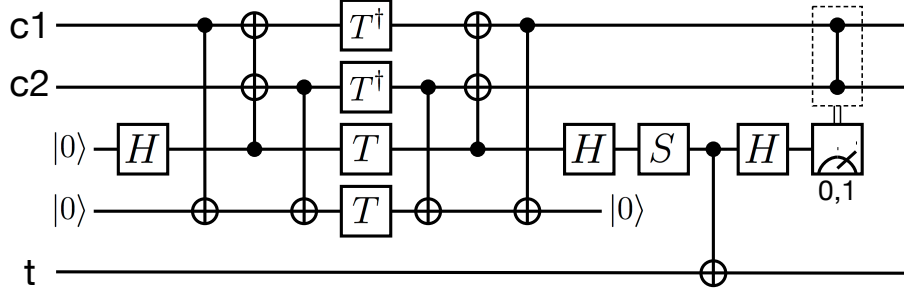

FIG. 1. Gadget from Ref. [7] implementing the Toffoli gate. The two control qubits and the target qubit are denoted c_1, c_2 and t respectively. Both measurement outcomes appear with probability $1/2$. The final controlled- Z gate on qubits c_1, c_2 is applied only if the measurement outcome is ‘1’.

Note that the total T -count of the circuit U is twice the T -count of O_g . To construct a circuit implementing O_g we chose a sequence of gates from the set $\{Z, CZ, CCZ\}$, where CCZ is the controlled-controlled- Z gate. We first fixed the number of CCZ gates (five and six for the simulations reported in the left/right plots of Fig. 1 in the main text respectively), and then produced a circuit O_g alternating the CCZ gates (on a randomly chosen triple of qubits) with random sequences of 200 Clifford gates from the set $\{Z, CZ\}$. Note that the CCZ gate can be replaced by the Toffoli gate using the identity

$$CCZ = (I \otimes I \otimes H)\text{Toff}(I \otimes I \otimes H). \quad (102)$$

To decompose Toffoli gates into Clifford and T -gates we used a gadget proposed by Jones [7], see Fig. 1. The gadget uses four T -gates, two ancillary qubits initialized in the state $|0\rangle$, several Clifford gates, and the 0, 1-measurement. The final Clifford gate is classically controlled by the measurement outcome. To simulate the gadget we use the trick described in the remark between Eqs. (21, 22). Namely, in our simulation the measurement of the ancillary qubit is replaced by postselection on a random output bit y in exactly the same way as was done for the T -gate gadget. The second ancilla in the gadget is never measured and is returned to the state $|0\rangle$ at the output; this ancilla is reused by all Toffolis in the circuit.

To produce each data point in Fig. 1 we first fixed the output qubit $q \in \{1, 2, \dots, 40\}$. We then estimated the ratio (cf. Eq. (19))

$$P_{out}^y(1) = \frac{\langle 0^{\otimes N} \otimes \psi | V_y^\dagger (|1\rangle\langle 1|_q \otimes |y\rangle\langle y|) V_y | 0^{\otimes N} \otimes \psi \rangle}{\langle 0^{\otimes N} \otimes \psi | V_y^\dagger (I_{n+1} \otimes |y\rangle\langle y|) V_y | 0^{\otimes N} \otimes \psi \rangle}. \quad (103)$$

for a randomly chosen postselection bit-string y . For us $N = n + n_{anc}$ where $n = 40$ is the number of qubits in the original circuit to be simulated while n_{anc} is the number of ancillae initialized in the state $|0\rangle$ which are used for

the Toffoli gadgets. Since each Toffoli gadget requires two ancilla, one of which is shared by all of them, we have $n_{anc} = 1 + \text{TF}$ where TF is the number of Toffoli gadgets used. In Eq. (103) the number of postselection bits is $|y| = t + \text{TF}$ where t is the number of T -gates in the circuit (including the four T -gates within each Toffoli gadget). The unitary V_y is a $(n + 1 + \text{TF} + t)$ -qubit Clifford unitary which is obtained by replacing all Toffoli gadgets and T gate gadgets by the appropriate Clifford circuits obtained by postselecting on the measurement outcomes defined by the bit string y . Finally, the state $|\psi\rangle$ in Eq. (103) is a t -qubit state which approximates t copies of the magic state $|A\rangle^{\otimes t}$. In particular, $|\psi\rangle$ was derived from a k -dimensional subspace \mathcal{L} of \mathbb{F}_2^k in the manner described in the main text of the paper. In our simulations we used $k = 11$ (left plot in Fig. 1) and $k = 12$ (right plot in Fig. 1). The fidelities were $|\langle A^{\otimes t} | \psi \rangle| \approx 0.81$ and $|\langle A^{\otimes t} | \psi \rangle| \approx 0.69$ respectively.

To estimate $P_{out}^y(1)$ we computed integers u, v and stabilizer groups \mathcal{F}, \mathcal{G} such that

$$\langle 0^{\otimes N} \otimes \psi | V_y^\dagger (|1\rangle\langle 1|_q \otimes |y\rangle\langle y|) V_y | 0^{\otimes N} \otimes \psi \rangle = 2^{-u} \langle \psi | \Pi_{\mathcal{F}} | \psi \rangle \quad (104)$$

and

$$\langle 0^{\otimes N} \otimes \psi | V_y^\dagger (|0\rangle\langle 0|_q \otimes |y\rangle\langle y|) V_y | 0^{\otimes N} \otimes \psi \rangle = 2^{-v} \langle \psi | \Pi_{\mathcal{G}} | \psi \rangle \quad (105)$$

and then, if $\Pi_{\mathcal{F}} \neq 0$ and $\Pi_{\mathcal{G}} \neq 0$, we computed approximations α, β to the quantities Eqs. (105,104) using the norm estimation procedure described in the main text. The number of random stabilizer states sampled by the norm estimation procedure was chosen to be 100 (left plot in Fig. 1) or 50 (right plot in Fig. 1). Our estimate of $P_{out}^y(1)$ was then $\alpha/(\alpha + \beta)$ (cf. Eq. (103)). Note that if either $\Pi_{\mathcal{F}} = 0$ or $\Pi_{\mathcal{G}} = 0$ then α, β , and $P_{out}^y(1)$ can be computed without ever calling the norm estimation subroutine. This special case occurred for all qubits $1, 2, \dots, 20$ in both our simulations (as well as for some of the other data points).
