

# A Multirate DSP Model for Estimation of Discrete Probability Density Functions

Byung-Jun Yoon, *Student Member, IEEE*, and P. P. Vaidyanathan, *Fellow, IEEE*

**Abstract**—The problem of estimating a probability density function (PDF) from measurements has been widely studied by many researchers. Even though much work has been done in the area of PDF estimation, most of it was focused on the continuous case. In this paper, we propose a new model-based approach for modeling and estimating discrete probability density functions or probability mass functions. This approach is based on multirate signal processing theory, and it has several advantages over the conventional histogram method. We illustrate the PDF estimation procedure and analyze the statistical properties of the PDF estimates. Based on this model, a novel scheme is introduced that can be used for estimating the PDF in the presence of noise. Furthermore, the proposed ideas are extended to the more general case of estimating multivariate PDFs. Finally, we also consider practical issues such as optimizing the coefficients of a digital filter, which is an integral part of the model. This allows us to apply the proposed model to solve real-world problems. Simulation results are given where appropriate in order to demonstrate the ideas.

**Index Terms**—Discrete probability density functions, multirate signal processing, multivariate PDF estimation, PDF estimation, probability mass functions.

## I. INTRODUCTION

THE problem of estimating a probability density function has been widely studied by many researchers in the mathematics as well as signal processing communities for many decades [1]–[6], [10], [11], [14]–[16], [20]. The goal is to obtain a good estimate of a probability density function (PDF)  $f(v)$  of a random variable  $v$  from the observations. The most common way to estimate density functions is the histogram method, and many other methods have been suggested, each with its own advantages and disadvantages. Even though histograms may give reasonable estimates of the true PDF when there are enough observations, it is discontinuous in nature, making it less preferable for estimating continuous random variables. It has been shown that a model-based approach has several advantages compared to the histogram method, especially when the number of observations is limited [3], [4]. For example, the kernel-based method assumes that the PDF  $f(v)$  can be represented as

$$f(v) = \sum_k c_k \phi(v - s_k, \sigma_k) \quad (1)$$

where  $\phi(v)$  is called the kernel function. It disperses the mass  $c_k$  around the center point  $s_k$ , where  $\sigma_k$  decides the extent to which it will disperse the mass. The kernel function  $\phi(v)$  can be any appropriate positive function, such as a Gaussian [5], a spline [6], etc. The preceding model tries to represent the unknown PDF with a linear combination of shifted copies of the fixed function  $\phi(v)$ . With the shifts  $s_k$  and the dispersion factors  $\sigma_k$  typically fixed,<sup>1</sup> the weighting factors  $c_k$  are adjusted based on the measurements of the random variable  $v$  so that the resulting PDF estimate  $\hat{f}(v)$  approximates the original PDF  $f(v)$  satisfactorily. One advantage of this method is the fact that the resulting PDF estimate  $\hat{f}(v)$  retains most of the properties of the kernel function. For example, if we choose a  $\phi(v)$  with certain smoothness, the estimate  $\hat{f}(v)$  will also enjoy the same property. Let us consider the histogram in Fig. 1(a). This can be considered to be a special case of (1) where  $\phi(v)$  is chosen to be a rectangular pulse,  $\sigma_k$  are fixed so that the width of the pulse is  $\Delta$ , and the shifts are uniform satisfying  $s_k = k\Delta$ . In this case, the mass  $c_k$  will be taken to be proportional to the number of observations that fall in the domain of the  $k$ th pulse  $\phi(v - k\Delta)$ . Generally,  $\phi(v)$  will be chosen such that it is smooth so that we can obtain a smooth PDF estimate. Fig. 1(b) shows an example of such a  $f(v)$  with uniform shifts and fixed  $\sigma_k$ . Further discussions on model-based methods can be found in many references, e.g., [3]–[6].

Even though much work has been done in the area of PDF estimation, most of it was focused on the continuous case. In this paper, we propose a PDF model for discrete random variables, which are restricted to have uniformly spaced values (assumed to be integers without loss of generality). Thus, if we denote the PDF as  $x(n)$ , it will be a function of an integer argument  $n$ . The proposed model is based on multirate signal processing concepts, and it will be shown that it has several advantages over the traditional histogram based method.

## A. Outline

In Section II, we introduce the basic multirate filter model for modeling a discrete PDF. Analogy to the kernel method and the relation to the wavelet method will be pointed out. We illustrate how we can get a PDF estimate based on the observations. It will be seen that the concept of biorthogonal partners [8] plays an important role in the estimation procedure. In Section III, we illustrate the estimation procedure in more detail, considering practical issues such as how to obtain a positive PDF estimate. Simulation results will be given that clearly show the advantage

<sup>1</sup>The shifts  $s_k$  and the dispersion factors  $c_k$  may also be adjusted based on the measurements. For example, [7] addresses this in the context of the estimation of Gaussian mixture models.

Fig. 1. (a) Histogram as a special case of kernel based representation when  $\phi(v)$  is rectangular. (b) PDF representation as a linear combination of shifted versions of the kernel  $\phi(v)$ .

of the proposed model. In Section IV, we propose an efficient and stable scheme for estimating a PDF in the presence of noise. The statistical properties of the estimates such as bias and variance are analyzed in Section V and compared to the bias and variance of the histogram estimate. The model-based approach can also be used for modeling and estimating a joint PDF of several random variables, which will be illustrated in Section VI. Finally, in Section VII, we consider optimizing the coefficients of a digital filter that is an integral part of the model, which opens up the way for this model to be used in practical applications.

### B. Notations

All notations are as in [9]. Thus,  $\downarrow M$  and  $\uparrow M$  represent the  $M$ -fold decimator and expander, respectively. Therefore,  $[X(z)]_{\downarrow M}$  denotes the  $z$ -transform of the decimated version  $x(Mn)$ , and similarly,  $[X(z)]_{\uparrow M} = X(z^M)$  denotes the  $z$ -transform of the expanded version.

## II. MULTIRATE FILTER MODEL FOR DISCRETE PDFS

### A. Basic Model

Let us consider a discrete probability density function  $x(n)$  of an integer random variable  $n$ . We assume that this  $x(n)$  can be represented as the output of an interpolation filter  $f(n)$  preceded by an  $M$ -fold expander, as shown in Fig. 2, where  $F(z)$  is the  $z$ -transform of  $f(n)$ .

The input signal  $c(k)$  is the free parameter that is to be adjusted based on the measurements, while  $M$  and  $f(n)$  are fixed. If we let the subspace  $\mathcal{V}_0 = \text{span of } \{f(n - Mk)\}$ , where  $k$  is any integer, then  $x(n) \in \mathcal{V}_0$  and can be written as

$$x(n) = \sum_k c(k)f(n - Mk) \quad (2)$$

which is a linear combination of  $f(n)$ ,  $f(n \pm M)$ ,  $f(n \pm 2M)$ , and so on. Notice the analogy to the continuous case in (1). If both the driving signal  $c(k)$  and the impulse response  $f(n)$  of the interpolation filter are in  $\ell_2$ , the resulting PDF  $x(n)$  also belongs to  $\ell_2$ ; hence,  $\mathcal{V}_0$  is a subset of the  $\ell_2$  space.<sup>2</sup> Since this can

<sup>2</sup>Strictly speaking,  $F(e^{j\omega})$  should be bounded for this.

Fig. 2. Basic PDF model.

Fig. 3. Example of a two channel PDF model.

be viewed as one channel of a  $M$ -channel synthesis filterbank,  $\mathcal{V}_0$  is in fact a proper subspace of  $\ell_2$ . If we choose  $f(n)$  to be a lowpass filter, the resulting  $\mathcal{V}_0$  will be a low-frequency subspace.

We can add one or more channels to the model, thereby adding more fine scale components to the PDF. Fig. 3 shows one possible example of such a multi-channel PDF model. In this model,  $F_0(z)$  and  $F_1(z)$  occupy different bands in the frequency domain. Suppose we have a multichannel model with  $M$  channels with an  $m_k$ -fold expander in the  $k$ th channel, where  $m_k$  satisfies

$$\sum_{k=0}^{M-1} \frac{1}{m_k} = 1. \quad (3)$$

In this case, if the corresponding filters  $F_k(z)$  are from a perfect reconstruction filterbank, the subspace  $\mathcal{V}_0$  can be the whole  $\ell_2$  space. This, in principle, can be related to the density estimation method based on wavelet thresholding, which was proposed by Donoho *et al.* [10]. Since  $x(n)$  can be any function in  $\ell_2$ , the model may look degenerate in this case, but the value of the wavelet based method lies in the fact that nonlinear operations (such as thresholding) can be done in the subbands to improve the quality of the estimate. In fact, it has been observed that this method suppresses the estimation error without compromising the sharpness of the underlying density function [10].

### B. Estimating the PDF

Let us consider again the single channel model in Fig. 2. For a PDF  $x(n) \in \mathcal{V}_0$ , how can we get the best estimate based on the measurements? In order to answer this question, let us consider a filter  $G(z)$  that satisfies

$$[G(z)F(z)]_{\downarrow M} = 1. \quad (4)$$

This  $G(z)$  is called a biorthogonal partner of  $F(z)$  with respect to  $M$  [8]. One obvious example of such a filter is  $G(z) = 1/F(z)$ . In fact, any  $G(z)$  that can be expressed in the form

$$G(z) = \frac{A(z)}{([A(z)F(z)]_{\downarrow M})_{\uparrow M}} \quad (5)$$

for some  $A(z)$  is a biorthogonal partner of  $F(z)$ ; hence, the partner is not unique. It is also possible to have an FIR biorthogonal partner  $G(z)$  under mild conditions on  $F(z)$  [8]. A detailed study of biorthogonal partners can be found in [8].

Fig. 4. Reconstruction of the driving signal  $c(k)$ .

The importance of biorthogonal partners in estimating the PDF arises as follows. Let us consider  $x(n)$  in Fig. 2. Its  $z$ -transform  $X(z)$  can be written as

$$X(z) = C(z^M)F(z). \quad (6)$$

From this  $x(n)$ , we can recover the underlying driving signal  $c(k)$  by using a biorthogonal partner  $G(z)$  as in Fig. 4. To show this, observe that the output of Fig. 4 has the  $z$ -transform

$$\begin{aligned} [G(z)X(z)]_{\downarrow M} &= [G(z)C(z^M)F(z)]_{\downarrow M} \\ &= C(z)[G(z)F(z)]_{\downarrow M} \\ &= C(z) \quad [\text{from (4)}] \end{aligned} \quad (7)$$

and hence,  $c(k)$  is recovered. Fig. 4 shows that  $c(k)$  can be written as

$$c(k) = \sum_n x(n)g(Mk - n). \quad (8)$$

Notice that the signal  $x(n)$  is a PDF of an integer random variable  $n$ . Therefore, the variable  $n$  in the equation above should be interpreted as a random variable that is distributed according to  $x(n)$  (instead of as the traditional “time index”). From this point of view,  $g(Mk - n)$  is also a random variable because  $n$  is random, and the right-hand side of (8) can be viewed as the expectation of the random variable  $g(Mk - n)$  with respect to  $n$ . Therefore, (8) can be rewritten as

$$c(k) = E_n[g(Mk - n)]. \quad (9)$$

This kind of interpretation of a signal as the expectation of a random variable naturally appears in almost any nonparametric density estimation scheme [4], [10]–[13], the earliest being perhaps the work of Čencov [11] in 1962. In fact, this plays an important role in the PDF estimation method being proposed in this paper since this allows us to relate the measurements to the PDF estimate. Assume that we have  $N$  measurements of the random variable  $n$ , and denote them as  $n_i$ ,  $0 \leq i \leq N - 1$ . Given these measurements, the expectation in (9) can be approximated by its sample mean as follows:

$$\hat{c}(k) = \frac{1}{N} \sum_{i=0}^{N-1} g(Mk - n_i). \quad (10)$$

If we define the signal  $h(n)$  as the relative occurrence of the integer value  $n$  in the measurements  $\{n_i\}$ , we can write  $\hat{c}(k)$  as

$$\hat{c}(k) = \sum_n h(n)g(Mk - n). \quad (11)$$

Since  $h(n)$  is nothing but the histogram obtained from the measurements  $\{n_i\}$ , this means that we can get an estimate of the

driving signal  $c(k)$  by feeding the histogram  $h(n)$  to the decimation filter  $g(n)$  and decimating the output by  $M$ . This is shown in Fig. 5. Now that we have the estimate  $\hat{c}(k)$ , this can be used in the original model shown in Fig. 2 to obtain the estimate  $\hat{x}(n)$  of the original PDF. The entire picture is shown in Fig. 5. The following summarizes the procedure of PDF estimation.

- 1) We make measurements  $\{n_i\}$  of the random variable  $n$ .
- 2) We construct the histogram  $h(n)$  from the measurements. Notice that  $h(n)$  is a coarse representation of the original PDF  $x(n)$ , and it need not belong to the subspace  $\mathcal{V}_0$ .
- 3) The histogram obtained from above is passed through the system that is shown in Fig. 5 to obtain the PDF estimate  $\hat{x}(n)$ . This PDF estimate belongs to  $\mathcal{V}_0$  as the original PDF.

Note that if the input to the system in Fig. 5 is  $x(n) \in \mathcal{V}_0$ , since  $G(z)$  and  $F(z)$  are biorthogonal partners, the output is also  $x(n)$ . So, if we denote the input–output mapping of Fig. 5 by a linear operator  $\mathcal{P}$ , then  $\mathcal{P}x(n) = x(n)$ . Now, consider an arbitrary input signal  $x'(n) \in \ell_2$ , and let us denote the corresponding output by  $y(n) = \mathcal{P}x'(n)$ . Since  $y(n) \in \mathcal{V}_0$ , we have  $\mathcal{P}^2x'(n) = \mathcal{P}\{\mathcal{P}x'(n)\} = \mathcal{P}y(n) = y(n) = \mathcal{P}x'(n)$ . This shows that  $\mathcal{P}^2 = \mathcal{P}$ , which means that the operator  $\mathcal{P}$  is a projection operator. From this, we can see that the above estimation procedure is just a projection of the histogram  $h(n)$  onto the subspace  $\mathcal{V}_0$ , where the original PDF  $x(n)$  belongs.

### C. Choice of $G(z)$

Let us assume that  $F(z)$  and  $M$  are fixed. Since the biorthogonal partner of a filter  $F(z)$  is not unique, the quality of the estimate  $\hat{x}(n)$  may vary depending on the choice of the partner  $G(z)$ . So, the natural question that may arise is how to choose  $G(z)$  in order to obtain the best PDF estimate  $\hat{x}(n)$ , based on the limited number of measurements. To answer this question, let us consider the following. Given  $h(n)$ , suppose we wish to find the signal  $\hat{x}(n) \in \mathcal{V}_0$  that is closest to  $h(n)$  in least square sense, i.e., we want to minimize

$$\|h(n) - \hat{x}(n)\|^2 \triangleq \sum_n |h(n) - \hat{x}(n)|^2. \quad (12)$$

The resulting  $\hat{x}(n)$  is in fact the orthogonal projection of  $h(n)$  onto  $\mathcal{V}_0$ . It can be shown [8] that if the filter  $G(z)$  in Fig. 4 is chosen as

$$G(z) = \frac{\tilde{F}(z)}{([\tilde{F}(z)F(z)]_{\downarrow M})_{\uparrow M}} \quad (13)$$

where  $\tilde{F}(z) \triangleq F^*(1/z^*)$ , then  $\hat{x}(n)$  is indeed the orthogonal projection of  $h(n)$  onto  $\mathcal{V}_0$ . Since this  $G(z)$  is also a biorthogonal partner of  $F(z)$  [8], it is called the least squares biorthogonal partner (LSBP). If we choose any other biorthogonal partner  $G(z)$ , the projection  $\mathcal{P}$  will be “oblique” rather than orthogonal. The advantage of the orthogonal projection is that the projected signal  $\hat{x}(n)$  is guaranteed to be closer to the original PDF  $x(n)$  than the histogram  $h(n)$  is. In other words, we always have

$$\|h(n) - x(n)\| \geq \|\hat{x}(n) - x(n)\|. \quad (14)$$

Fig. 5. Estimation of the driving signal  $c(k)$  from the histogram  $h(n)$  and subsequent estimation of the PDF  $x(n)$ .

In order to see this, note that since the  $\hat{x}(n)$  is the orthogonal projection of  $h(n)$  onto  $\mathcal{V}_0$ , we can write  $h(n) = \hat{x}(n) + e(n)$ , where  $e(n) \in \mathcal{V}_0^\circ$ . Therefore, we have  $h(n) - x(n) = \hat{x}(n) - x(n) + e(n)$ . As  $\hat{x}(n) - x(n) \in \mathcal{V}_0$  and  $e(n) \in \mathcal{V}_0^\circ$  (the orthogonal complement of  $\mathcal{V}_0$ ), it follows that

$$\begin{aligned} \|h(n) - x(n)\|^2 &= \|\hat{x}(n) - x(n)\|^2 + \|e(n)\|^2 \\ &\geq \|\hat{x}(n) - x(n)\|^2 \end{aligned} \quad (15)$$

hence proving (14). Now, suppose that we are going to choose the decimation filter  $G(z)$  to be the LSBP of  $F(z)$  with respect to  $M$  as in (13). If we look at the denominator  $B(z) = ([\tilde{F}(z)F(z)]_{\downarrow M})_{\uparrow M}$  of  $G(z)$ , we can see that it satisfies

$$B(z) = \tilde{B}(z) = B^* \left( \frac{1}{z^*} \right). \quad (16)$$

Therefore, if  $B(z)$  has a zero at  $z_0$ , then there exists another zero at  $1/z_0^*$ . This can be a problem, since it means that  $G(z)$  cannot have all the poles inside the unit circle, and therefore, it cannot be a causal stable filter. One way to get around this problem is to choose  $F(z)$  such that its magnitude square is Nyquist ( $M$ ), i.e.,

$$[\tilde{F}(z)F(z)]_{\downarrow M} = 1. \quad (17)$$

In this case, the least squares partner becomes  $G(z) = \tilde{F}(z)$ , which can be written as  $g(n) = f^*(-n)$  in the time-domain. We can observe that (17) is equivalent to imposing the orthonormality constraint on the basis functions  $\{f(n - kM)\}$  that span the subspace  $\mathcal{V}_0$ . An interpolation filter  $F(z)$  that satisfies (17) can be designed using one of many known techniques [9].

#### D. Square-Root Model

However, the use of an  $F(z)$  that satisfies (17) suffers from one disadvantage, namely, the fact that the positivity of the outcome  $x(n)$  cannot be guaranteed. This is an important point when using the estimation process shown in Fig. 5, since the resulting estimate  $\hat{x}(n)$  may not be positive. If we design the filter  $F(z)$  as in (17), then  $f(n)$  will necessarily have negative coefficients unless it has order  $< M$ . Since the projection  $\hat{x}(n)$  consists of a linear combination of shifted copies of  $f(n)$ , it is highly probable that  $\hat{x}(n)$  will have some negative coefficients as well.

A simple way to overcome this problem is to use the output of the model in Fig. 2 to model the square-root of the PDF instead of the PDF itself. This is similar to the idea proposed by Good and Gaskins many years ago for estimating continuous PDFs [14]. In this model, we assume that  $x_s(n)$ , which is the square-

root of the PDF, can be represented as the output of the filter  $F(z)$  preceded by an  $M$ -fold expander. Therefore, we have

$$x_s(n) = \sum_k c_s(k) f(n - kM) \quad (18)$$

where the PDF  $x(n)$  is

$$x(n) = \{x_s(n)\}^2. \quad (19)$$

We can still use the model similar to Fig. 5 with slight modifications in the estimation procedure. The square-root PDF model is elaborated in [15], and it has the advantage that the resulting PDF estimate is guaranteed to be positive.

Despite this advantage, the square-root model has also several shortcomings. For example, in order to get a satisfactory estimate from the measurements, we have to adjust the sign of the square-root of the histogram, before it is used in the estimation procedure [15], [16]. The searching process for the optimal signature sequence can be computationally very expensive. Another disadvantage of this model is the fact that the estimation results are not easy to analyze analytically due to the nonlinearity of the model. In Section III, we consider a method that is free from all these problems.

### III. FIR TRUNCATION OF THE LSBP

In this section, we consider a linear model for representing PDFs, which ensures that the resulting estimate is positive and uses only stable and realizable filters in the estimation procedure. Let us consider again the model in Fig. 2. In order to ensure that the PDF estimate is non-negative, all the coefficients of the filter  $f(n)$  should be non-negative as well as the driving signal  $c(k)$ . Now take  $G(z)$  to be the least squares partner of  $F(z)$  as in (13). We know from Section II-D that unless  $F(z)$  has a filter order  $< M$ ,  $G(z)$  has poles both inside and outside the unit-circle, which means that  $G(z)$  cannot be a causal stable filter. However, it is possible to approximate such a filter by an FIR filter by choosing the region of convergence properly, as long as there are no poles on the unit circle [17]. In order to illustrate the idea, let us consider an all-pole filter  $Q(z)$  defined as

$$Q(z) = \prod_i \frac{1}{(1 - p_i z^{-1})}. \quad (20)$$

Its pole-zero plot may be as in Fig. 6. We assume that there are no poles lying on the unit circle. Let  $p_{\text{in}}$  be the pole with the largest modulus among all poles inside the unit circle. Similarly, let  $p_{\text{out}}$  be the pole with the smallest modulus among all poles outside the unit circle. We choose the region of convergence to be the annular region in the  $z$ -plane that satisfies  $|p_{\text{in}}| < |z| <$

Fig. 6. Pole-zero plot of  $Q(z)$ .

$|p_{\text{out}}|$ . Then,  $Q(z)$  can be expressed as follows using the partial fraction expansion

$$Q(z) = \sum_{|p_i| < 1} \frac{c_i}{1 - p_i z^{-1}} + \sum_{|p_i| > 1} \frac{c_i}{1 - p_i z^{-1}}. \quad (21)$$

The first term in the right-hand side of (21) corresponds to a right-sided sequence, whereas the second term corresponds to a left-sided sequence. Using inverse  $z$ -transform, (21) will be

$$q(n) = \sum_{|p_i| < 1} c_i p_i^n u(n) - \sum_{|p_i| > 1} c_i p_i^n u(-n - 1) \quad (22)$$

in the time domain. Now, we may truncate  $q(n)$  to get an FIR filter  $q_L(n)$  as follows:

$$q_L(n) = \begin{cases} q(n), & \text{if } |n| \leq L \\ 0, & \text{otherwise.} \end{cases} \quad (23)$$

This corresponds to multiplying  $q(n)$  with a rectangular window. Note that  $L$  should be large enough such that most of the energy of  $q(n)$  is confined in  $|n| \leq L$ . Unless there are poles very close to the unit circle, it is possible to approximate  $q(n)$  with a reasonable length  $L$ . For example, it is shown in [17] that the cubic B-spline filter can be well approximated by a truncated FIR filter of length only five or seven.

Returning to our original interest, let us consider again  $G(z)$ : the least squares partner of  $F(z)$ . Let  $B(z)$  be the denominator of  $G(z)$ . If we choose  $f(n)$  such that  $f(n) \geq 0$  and  $B(z) = ([\tilde{F}(z)F(z)]_{\downarrow M} \uparrow_M)$  has zeros sufficiently away from the unit circle, it is possible to approximate  $G(z)$  by an FIR filter  $G_L(z)$ , by truncating it using a window function. Using this FIR filter  $G_L(z)$  in place of  $G(z)$  in Fig. 5, we can use a similar estimation procedure as elaborated in Section II-B. However, one more remark remains to be made regarding the positivity of the PDF estimate. Since the interpolation filter  $f(n)$  is non-negative, it is possible to make the output signal also non-negative by taking a non-negative driving signal  $c(k)$ . So, when modeling the original PDF  $x(n) = \sum_k c(k)f(n - Mk)$ , we can make it a valid PDF by choosing  $c(k) \geq 0$  and normalizing  $x(n)$  so that it adds up to 1, but when feeding the histogram  $h(n)$  into the system shown in Fig. 5, there is no guarantee that the estimate  $\hat{c}(k)$  will be non-negative for  $\forall k$ . Correspondingly, the orthogonal projection  $\hat{x}(n)$  may not satisfy the nonnegativity condition. In order to guarantee that the PDF estimate is non-negative,

we simply drop the negative values of  $\hat{x}(n)$  to obtain a positive estimate as follows:

$$\hat{x}_p(n) = \begin{cases} \hat{x}(n), & \text{if } \hat{x}(n) \geq 0 \\ 0, & \text{otherwise.} \end{cases} \quad (24)$$

Note that this  $\hat{x}_p(n)$  may not necessarily belong to  $\mathcal{V}_0$ . However, this is not a problem since by taking  $\hat{x}_p(n)$  instead of  $\hat{x}(n)$ , the PDF estimate gets even closer to the original PDF  $x(n)$ . To see this, notice that

$$\begin{aligned} \|\hat{x}(n) - x(n)\|^2 &= \sum_n |\hat{x}(n) - x(n)|^2 \\ &= \sum_{\hat{x}(n) \geq 0} |\hat{x}(n) - x(n)|^2 \\ &\quad + \sum_{\hat{x}(n) < 0} |\hat{x}(n) - x(n)|^2 \\ &\geq \sum_{\hat{x}(n) \geq 0} |\hat{x}(n) - x(n)|^2 + \sum_{\hat{x}(n) < 0} |x(n)|^2 \\ &= \|\hat{x}_p(n) - x(n)\|^2. \end{aligned}$$

Combining this result with the inequality in (14), we get the following inequality:

$$\|h(n) - x(n)\| \geq \|\hat{x}_p(n) - x(n)\| \quad (25)$$

which guarantees that the PDF estimate  $\hat{x}_p(n)$  is always closer to the true PDF  $x(n)$  than is the histogram.

In order to demonstrate the ideas, let us consider the following example. We assume  $M = 2$  and use  $F(z) = (1 + z^{-1})^6 / 2^6$ . Notice that this filter leads to the fifth-order spline function [18].  $G(z)$  is chosen to be the least squares partner of  $F(z)$ , truncated by a rectangular window of length 39. Since all the poles of  $G(z)$  are located far away from the unit circle, the energy—or the square of the  $\ell_2$  norm—of the truncated filter  $\|g_L(n)\|^2$  was almost identical to  $\|g(n)\|^2$  in this case.<sup>3</sup> By choosing an appropriate driving signal  $c(k)$  for the sake of generating an example, we obtained a sample PDF  $x(n)$  of length 37. We made 500 measurements of the random variable  $n$  according to  $x(n)$ , and the histogram  $h(n)$  was obtained from the observations. Then, the histogram was passed through the system in Fig. 5 to get the orthogonal projection of the histogram. Finally, negative values in the output of Fig. 5 were dropped, and the result was normalized to get the PDF estimate  $\hat{x}(n)$ . Fig. 7 shows the simulation results. The histogram shown in the top of Fig. 7 is quite different from the original PDF, whereas the model-based estimate is considerably close to the PDF, as can be seen in the bottom Fig. 7. The estimation error was

$$\sum_n |h(n) - x(n)|^2 = 0.00151128 \quad (26)$$

for the histogram and

$$\sum_n |\hat{x}(n) - x(n)|^2 = 0.00017605 \quad (27)$$

<sup>3</sup>In order to preserve a “near-biorthogonality,”  $L$  has to be chosen such that  $\|g_L(n)\|^2$  is almost identical to  $\|g(n)\|^2$ .

Fig. 7. PDF estimation using FIR truncation of the LSBP. (Top) Original PDF and the histogram. (Bottom) Original PDF and the model-based PDF estimate.

for the model-based estimate, which is only about 12% of the error of the histogram. This clearly shows that the proposed approach is superior to the conventional histogram method.

#### IV. ESTIMATING THE PDF IN THE PRESENCE OF NOISE

Another advantage of the PDF model in Fig. 2 is the fact that it gives rise to a simple and efficient way of removing noise present in the measurements as we shall show next. Suppose that the original samples are corrupted by additive noise. Our measurements  $\{m_i\}$  can be expressed as

$$m_i = n_i + e_i (i = 0, 1, \dots, N-1) \quad (28)$$

where  $\{n_i\}$  are the original samples, and  $\{e_i\}$  are i.i.d. noise that are independent of  $\{n_i\}$ . Let the PDF of  $n_i$  be  $x(n)$ , and let  $e(n)$  be the PDF of the noise random variable  $e_i$ . Then, the density  $y(n)$  of the measurement  $m_i$  is

$$y(n) = (x * e)(n). \quad (29)$$

Since the PDF  $x(n)$  comes from the model in Fig. 2,  $y(n)$  can be represented as the output of the model shown in Fig. 8. Therefore, if we let  $D(z) = F(z)E(z)$ , we can write  $Y(z) = C(z^M)D(z)$ . Now, let us define  $S(z)$  as the least squares partner of the filter  $D(z)$  so that

$$S(z) = \frac{\tilde{D}(z)}{([\tilde{D}(z)D(z)]_{\downarrow M})_{\uparrow M}}. \quad (30)$$

We can recover the driving signal  $c(k)$  by passing  $y(n)$  through  $S(z)$  and decimating it by  $M$ , as shown in Fig. 9. This can be proved in a similar manner as (7). Knowing the driving signal  $c(k)$ , if we pass it through the system in Fig. 2, we can get the original PDF  $x(n)$  back. As  $S(z)$  has poles both inside and outside the unit circle (unless  $D(z)$  has order  $< M$ ), it cannot be directly used, but we can use the FIR truncation  $S_L(z)$  instead, as in Section III. The whole estimation procedure is illustrated in Fig. 10. The system in Fig. 10 takes  $h(n)$  as the input, which is a coarse representation of the PDF  $y(n)$  of the noisy observations. It eliminates the effect of the noise and yields an estimate

Fig. 8. Original PDF convolved with the noise PDF.

Fig. 9. Reconstruction of the driving signal from the PDF in the presence of noise.

$\hat{x}(n)$  of the original PDF  $x(n)$ , as expected. In order to ensure that  $\hat{x}(n)$  is a valid PDF, we should drop the negative coefficients and then normalize the PDF estimate as described in Section III.

Experiment shows that this approach has a considerable advantage over the inverse filtering method. Knowing the noise PDF  $e(n)$ , we may use the inverse filter  $1/E(z)$  to filter out the noise as shown in Fig. 11. Generally, the noise PDF  $e(n)$  will be symmetric around  $n = 0$ , resulting in a zero-mean random noise. Due to the symmetry,  $E(z)$  will have zeros both inside and outside the unit circle. Therefore, the corresponding inverse filter  $1/E(z)$  will have poles both inside and outside the unit circle resulting in an unstable filter. In such cases, we may again use the FIR truncation method, as in Section III, but the experiment shows that this tends to amplify the estimation error that is present in the histogram, which makes the PDF estimate very unreliable. The reason why this did not happen when we were using the least squares partner  $S(z)$  in the previous discussion was because the whole system worked as an orthogonal projection operator, which tends to suppress the error instead of amplifying it.

To demonstrate, consider the following example. We assume  $M = 2$  and use the same filter as in Section III. In addition to this, a sample noise PDF  $e(n)$  of length 5 is chosen.<sup>4</sup> From this, we compute the filter  $D(z) = F(z)E(z)$ , and let  $S(z)$  be the least squares partner of  $D(z)$ . We made 500 measurements  $n_i \sim x(n)$  and generated the same number of observations of the random noise  $e_i \sim e(n)$ . Adding these measurements, respectively, we obtained 500 noisy observations  $m_i = n_i + e_i$ . The histogram was constructed from these observations, as can be seen in the top of Fig. 12. The figure clearly shows that there is a huge difference between the original PDF and the histogram due to the noise. In addition to this, there exists also a considerable estimation error between the histogram and the PDF with noise, resulting in an error of

$$\sum_n |h(n) - y(n)|^2 = 0.0068871 \quad (31)$$

where  $y(n) = (x * e)(n)$  is the PDF of the noisy samples. Now, consider the model-based PDF estimate. The histogram is put into the model in Fig. 10, and the output is normalized after removing the negative coefficients, to get the final estimate  $\hat{x}(n)$ . The result is shown in the bottom plot of Fig. 12. It can be noticed that the noise is effectively removed, resulting in an

<sup>4</sup>The noise PDF  $e(n)$  had the following coefficients:  $[e(0) \dots e(4)] = [0.0332 \ 0.2339 \ 0.3780 \ 0.2660 \ 0.0689]$ .

Fig. 10. Estimation of the PDF in the presence of noise.

Fig. 11. Traditional way to estimate the PDF in the presence of noise using the inverse filter  $1/E(z)$ .

excellent estimate of the original PDF. The final estimation error between the estimate  $\hat{x}(n)$  and the original PDF  $x(n)$  was

$$\sum_n |\hat{x}(n) - x(n)|^2 = 0.0004767. \quad (32)$$

Note that this error is much smaller than the initial estimation error between the histogram  $h(n)$  and the PDF with noise  $y(n)$ . Conventional inverse filtering of the histogram yielded a very oscillatory output, a considerable portion of which was negative, and therefore, we have not shown the result here.

## V. BIAS AND VARIANCE OF THE ESTIMATES

Since the PDF estimates are based on random observations, the estimates themselves are random as well. Therefore, it is important to understand their statistical properties such as the bias and the variance. Let  $\theta$  be the true value (or function) that is to be estimated, and let  $\hat{\theta}_N$  be an estimate based on  $N$  observations. An estimate is unbiased if  $\mathcal{E}\{\hat{\theta}_N\} = \theta$  [19]. It is desirable to have an estimate that is unbiased and has a small variance at the same time. In Sections VI and VII, we focus on the model in Fig. 2, analyze its bias and variance, and finally compare them with those of the histogram method. It will be demonstrated that both methods yield unbiased estimates. However the model-based method results in a smaller variance, giving us a more reliable estimate than the histogram method.

### A. Histogram Method

Let us first consider the histogram method. Assume that we have  $N$  observations of a random variable  $n$ , where the underlying PDF is  $x(n)$ . The probability that the  $i$ th observation will be  $n_i = n$  is

$$P\{n_i = n\} = x(n) \quad (33)$$

for all  $i = 0, 1, 2, \dots, N-1$ . Therefore, if we let  $t(n)$  be the number of observations in  $\{n_i\}$  that have the value  $n$ , the probability  $P\{t(n) = k\}$  is simply

$$P\{t(n) = k\} = \binom{N}{k} x^k(n) (1-x(n))^{N-k} \quad (34)$$

and therefore,  $t(n)$  is a binomial random variable that follows  $B(N, x(n))$ . From this, we have  $\mathcal{E}[t(n)] = Nx(n)$  and

Fig. 12. PDF estimation when noise is present. (Top) Original PDF, the PDF with noise, and the histogram. (Bottom) Original PDF, the PDF with noise, and the model-based PDF estimate.

$\text{Var}[t(n)] = Nx(n)(1-x(n))$ . Notice that the histogram can be represented as  $h(n) = t(n)/N$ . Therefore, the expectation of  $h(n)$  is

$$\mathcal{E}[h(n)] = \frac{1}{N} \mathcal{E}[t(n)] = x(n) \quad (35)$$

which shows that the histogram estimate is unbiased. In addition, from  $h(n) = t(n)/N$ , we get the following variance for  $h(n)$ :

$$\text{Var}[h(n)] = \frac{1}{N^2} \text{Var}[t(n)] = \frac{1}{N} x(n)(1-x(n)). \quad (36)$$

The variance of the histogram estimate, which is defined as  $\sum_n \text{Var}[h(n)]$ , is therefore

$$\mathcal{E}[\|h(n) - x(n)\|^2] = \sum_n \text{Var}[h(n)] = \frac{1}{N} \left(1 - \sum_n x^2(n)\right). \quad (37)$$

From (37), we can see that the variance of the estimate decreases as the number of observations  $N$  increases, as expected.

### B. Model-Based Method

Let us consider the model in Fig. 5 again. We can write the output as

$$\hat{x}(n) = \sum_l \sum_k h(k) g(Ml-k) f(n-Ml). \quad (38)$$

Therefore, the expectation  $\mathcal{E}[\hat{x}(n)]$  can be written as

$$\begin{aligned}\mathcal{E}[\hat{x}(n)] &= \sum_l \sum_k \mathcal{E}[h(k)]g(Ml - k)f(n - Ml) \\ &= \sum_l \sum_k x(k)g(Ml - k)f(n - Ml).\end{aligned}\quad (39)$$

We can see that the last expression in (39) is the output of Fig. 5 when the input signal is  $x(n)$ . Since  $x(n) \in \mathcal{V}_0$  and as passing an input signal through Fig. 5 is just a projection onto  $\mathcal{V}_0$ , the right-hand side of (39) reduces to  $x(n)$ . This proves that the model-based method results in an unbiased PDF estimate.

In order to compute the variance of  $\hat{x}(n)$ , let us first consider the following expectation:

$$\begin{aligned}\mathcal{E}[\hat{x}^2(n)] &= \sum_{k_1, k_2} \sum_{l_1, l_2} (\mathcal{E}[h(k_1)h(k_2)]g(Ml_1 - k_1) \\ &\quad \times g(Ml_2 - k_2)f(n - Ml_1)f(n - Ml_2)).\end{aligned}\quad (40)$$

It can be shown that  $\mathcal{E}[h(k_1)h(k_2)]$  is

$$\mathcal{E}[h(k_1)h(k_2)] = \begin{cases} \frac{N-1}{N}x(k_1)x(k_2), & \text{if } k_1 \neq k_2 \\ \frac{1}{N}x(k_1)(1 + (N-1)x(k_1)), & \text{if } k_1 = k_2. \end{cases}\quad (41)$$

Detailed derivation of (41) can be found in Appendix. From this, we get

$$\begin{aligned}\mathcal{E}[\hat{x}^2(n)] &= \frac{1}{N} \sum_k \sum_{l_1, l_2} \left( x(k)g(Ml_1 - k)g(Ml_2 - k) \right. \\ &\quad \left. \times f(n - Ml_1)f(n - Ml_2) + \frac{N-1}{N}x^2(n) \right).\end{aligned}\quad (42)$$

Since  $\mathcal{E}[\hat{x}(n)] = x(n)$ , we get the following variance for  $\hat{x}(n)$ :

$$\begin{aligned}\text{Var}[\hat{x}(n)] &= \mathcal{E}[\hat{x}^2(n)] - (\mathcal{E}[\hat{x}(n)])^2 \\ &= \frac{1}{N} \sum_k \sum_{l_1, l_2} (x(k)g(Ml_1 - k)g(Ml_2 - k) \\ &\quad \times f(n - Ml_1)f(n - Ml_2)) \\ &\quad - \frac{1}{N}x^2(n).\end{aligned}\quad (43)$$

Using this, it can be shown that the variance of the PDF estimate is

$$\begin{aligned}\mathcal{E}[\|\hat{x}(n) - x(n)\|^2] &= \sum_n \text{Var}[\hat{x}(n)] \\ &= \frac{1}{N} \left( \sum_k \sum_l x(k + Ml)g(-k)f(k) \right. \\ &\quad \left. - \sum_n x^2(n) \right).\end{aligned}\quad (44)$$

Now, let us compare the variance of the two estimates. It can be shown that the variance of the model-based estimate is always

smaller than that of the histogram. In fact, this is an immediate result of (15). If we subtract the variance of the model-based estimate from that of the histogram, we get

$$\begin{aligned}\mathcal{E}[\|h(n) - x(n)\|^2] - \mathcal{E}[\|\hat{x}(n) - x(n)\|^2] \\ &= \mathcal{E}[\|h(n) - x(n)\|^2 - \|\hat{x}(n) - x(n)\|^2] \\ &= \mathcal{E}[\|e(n)\|^2] \geq 0.\end{aligned}\quad (45)$$

This shows that the model-based PDF estimate in Fig. 5 has a smaller variance than the histogram-based estimate. The reduced variance is due to the fact that the PDF estimate  $\hat{x}(n)$  is restricted to  $\mathcal{V}_0$ , which is a proper subspace of  $\ell_2$ .

Consider again the example given in Section III. We now compute the bias and the variance of the histogram and the model-based estimate. We made 500 measurements of the random variable  $n$  and constructed the histogram and the model-based estimate. This experiment was repeated 100 times. The mean value of the 100 estimates was almost identical to the original PDF  $x(n)$  for both methods, which verifies that both the histogram estimate and the model-based estimate are unbiased. Fig. 13 shows the variance  $\text{Var}[h(n)]$  and  $\text{Var}[\hat{x}(n)]$  at each  $n$ . The figure shows that the variance of the histogram is larger than that of the model-based PDF estimate at nearly all points. The variance or, equivalently, the mean squared error (MSE) of the histogram estimate was

$$\sum_n \text{Var}[h(n)] = 0.00191544 \quad (46)$$

and the variance of the model-based estimate was

$$\sum_n \text{Var}[\hat{x}(n)] = 0.00091091 \quad (47)$$

which is less than half of the variance of the histogram estimate. These values are indeed very close to the theoretical values computed from (37) and (44). The variances predicted by (37) and (44) are

$$\mathcal{E}[\|h(n) - x(n)\|^2] = 0.00191044 \quad (48)$$

$$\mathcal{E}[\|\hat{x}(n) - x(n)\|^2] = 0.00091044 \quad (49)$$

which are very close to the values in (46) and (47) obtained from the simulation.

## VI. MULTIVARIATE PDF ESTIMATION

Up to this point, we have considered only PDFs of a single random variable  $n$ . However, it is not hard to extend the basic ideas in the univariate PDF estimation to the multivariate case. Suppose we have  $K$  random variables  $(n_0, \dots, n_{K-1})$ , where the joint PDF is  $x(n_0, \dots, n_{K-1})$ . We may model such a  $K$ -dimensional density function, using a  $K$ -dimensional interpolation filter  $F(z_0, \dots, z_{K-1})$  and a  $K \times K$  sampling matrix  $\mathbf{M}$ . This is shown in Fig. 14. Suppose we are going to use a separable filter

$$F(z_0, \dots, z_{K-1}) = F_0(z_0)F_1(z_1) \dots F_{K-1}(z_{K-1}) \quad (50)$$

Fig. 13. Variance of the histogram and the model-based estimate.

Fig. 14. Multivariate PDF model.

and a diagonal sampling matrix

$$\mathbf{M} = \begin{bmatrix} M_0 & 0 & \dots & 0 \\ 0 & M_1 & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \dots & 0 & M_{K-1} \end{bmatrix} \quad (51)$$

for modeling the PDF. In this case, the estimation procedure becomes very similar to that in Section II-B. First of all, we compute the least squares partner of  $F_i(z)$  as in (13) for all  $i = 0, \dots, K-1$ . Therefore, we have

$$G_i(z) = \frac{\tilde{F}_i(z)}{([\tilde{F}_i(z)F_i(z)]_{\downarrow M_i})_{\uparrow M_i}} \quad (i = 0, 1, \dots, K-1). \quad (52)$$

As we have seen in Section III, we may approximate this least squares partner by a truncated FIR filter, if necessary. Now, these filters can be used to construct the following filter:

$$G(z_0, \dots, z_{K-1}) = G_0(z_0)G_1(z_1)\dots G_{K-1}(z_{K-1}). \quad (53)$$

It can be seen that  $G(\mathbf{z})$  is a biorthogonal partner of  $F(\mathbf{z})$  with respect to the sampling matrix  $\mathbf{M}$ , where  $\mathbf{z} = [z_0 \dots z_{K-1}]$ . This is shown in the following.

$$\begin{aligned} [G(\mathbf{z})F(\mathbf{z})]_{\downarrow \mathbf{M}} &= [G_0(z_0)\dots G_{K-1}(z_{K-1})F_0(z_0)\dots \\ &\quad F_{K-1}(z_{K-1})]_{\downarrow \mathbf{M}} \\ &= [G_0(z_0)F_0(z_0)]_{\downarrow M_0} \dots \\ &\quad [G_{K-1}(z_{K-1})F_{K-1}(z_{K-1})]_{\downarrow M_{K-1}} \\ &= 1. \end{aligned} \quad (54)$$

Note that we can reconstruct  $C(\mathbf{z})$  if we pass  $x(\mathbf{n})$  through  $G(\mathbf{z})$  and decimate it by the sampling matrix  $\mathbf{M}$ . To prove this, notice that when using the filter in (50) and the sampling matrix in (51), the output  $X(\mathbf{z})$  of Fig. 14 can be written as

$$X(\mathbf{z}) = C(z_0^{M_0} \dots z_{K-1}^{M_{K-1}}) F(\mathbf{z}). \quad (55)$$

If we pass it through the filter  $G(\mathbf{z})$  and decimate by  $\mathbf{M}$ , we get

$$\begin{aligned} [X(\mathbf{z})G(\mathbf{z})]_{\downarrow \mathbf{M}} &= [C(z_0^{M_0} \dots z_{K-1}^{M_{K-1}}) F(\mathbf{z})G(\mathbf{z})]_{\downarrow \mathbf{M}} \\ &= C(\mathbf{z})[F(\mathbf{z})G(\mathbf{z})]_{\downarrow \mathbf{M}} \\ &= C(\mathbf{z}). \end{aligned}$$

Now, the estimation procedure is as follows. First, we construct the histogram based on the observations. Next, we pass it through the  $K$ -dimensional filter  $G(\mathbf{z})$  and decimate the output by  $\mathbf{M}$ . This yields the estimate  $\hat{C}(\mathbf{z})$  of the original driving signal  $C(\mathbf{z})$ . Then, we feed this estimate to the PDF model in Fig. 14, to get the PDF estimate  $\hat{x}(n_0, \dots, n_{K-1})$ . The entire estimation procedure can be found in Fig. 15. It has to be noted that although the filter  $F(z_0, \dots, z_{K-1})$  is separable and the matrix  $\mathbf{M}$  is diagonal, the resulting PDF may not be a separable PDF. For example, let us choose  $C(z_0, z_1)$ ,  $F(z_0, z_1)$  as follows:

$$\begin{aligned} C(z_0, z_1) &= 1 + z_0^{-1}z_1^{-2} \\ F(z_0, z_1) &= (1 + z_0^{-1})(1 + z_1^{-1}) \end{aligned}$$

and use the following sampling matrix:

$$\mathbf{M} = \begin{bmatrix} 2 & 0 \\ 0 & 3 \end{bmatrix}. \quad (56)$$

Then, the output  $X(z_0, z_1)$  will be

$$X(z_0, z_1) = (1 + z_0^{-2}z_1^{-6})(1 + z_0^{-1})(1 + z_1^{-1}) \quad (57)$$

which is clearly not separable, since it cannot be separated into  $X(z_0, z_1) = X_0(z_0)X_1(z_1)$ .

In order to demonstrate the idea, consider the following example. We take  $F_0(z) = F_1(z) = (1 + z^{-1})^6/2^6$  and define  $F(z_0, z_1) = F_0(z_0)F_1(z_1)$ . The sampling matrix  $\mathbf{M}$  is assumed to be the following diagonal matrix:

$$\mathbf{M} = \begin{bmatrix} 2 & 0 \\ 0 & 2 \end{bmatrix}. \quad (58)$$

By feeding a proper driving signal  $c(k_0, k_1)$  into the model in Fig. 14, we obtained the bivariate PDF  $x(n_0, n_1)$  in the top of Fig. 16 as the output. Based on this joint PDF  $x(n_0, n_1)$ , we made 5000 measurements of  $(n_0, n_1)$  and computed the PDF  $h(n_0, n_1)$  from these observations. The resulting two-dimensional histogram is shown in the center of Fig. 16. We can see that there are many peaks in the histogram, which were not present in the original PDF, indicating that the estimation error has degraded the estimate considerably. Now, let us define  $G_0(z)$  and  $G_1(z)$  as the least squares partners of  $F_0(z)$  and  $F_1(z)$ , respectively, as in (52). The analysis filter in Fig. 15 is chosen to be  $G(z_0, z_1) = G_0(z_0)G_1(z_1)$ . The histogram  $h(n_0, n_1)$  is passed

Fig. 15. Estimation of a multivariate PDF.

Fig. 16. Multivariate PDF estimation. (Top) Original PDF. (Center) Histogram estimate. (Bottom) Model-based estimate.

through the single channel filterbank in Fig. 15, which results in the PDF estimate  $\hat{x}(n_0, n_1)$ . This is shown in the bottom plot in Fig. 16. It clearly shows that the model-based approach yields a much better estimate of the original PDF by removing most of the peaks in the histogram to give us a smoother output. The estimation error of each PDF estimate was

$$\sum_{n_0} \sum_{n_1} |h(n_0, n_1) - x(n_0, n_1)|^2 = 0.00019012 \quad (59)$$

and

$$\sum_{n_0} \sum_{n_1} |\hat{x}(n_0, n_1) - x(n_0, n_1)|^2 = 0.00003194. \quad (60)$$

We can see that the proposed method results in a considerably smaller estimation error, which is only 16.80% compared to that of the histogram method.

## VII. OPTIMIZATION OF $F(z)$

### A. Optimizing $F(z)$ for PDF Estimation

We have seen in the previous discussion, that the model-based approach has many advantages over the traditional histogram method. Knowing that the original PDF  $x(n)$  belongs to  $\mathcal{V}_0$ ,

we could reduce the estimation error dramatically. Moreover, the model-based approach yielded an unbiased estimate with a smaller variance. However, in general we do not know in advance what the subspace  $\mathcal{V}_0$  will look like. Unless there is a way to choose the interpolation filter  $f(n)$  such that it includes all the PDFs of interest, the estimation procedure elaborated in the previous sections may not result in a satisfactory PDF estimate. Therefore, the need for optimizing the filter coefficients of the interpolation filter  $f(n)$  arises naturally.

Let  $\mathcal{W}_0$  be a set of  $I$  PDFs  $\{x_i(n) | i = 0, 1, \dots, I-1\}$  belonging to a certain class (e.g., samples from Laplacian PDFs, samples from Poisson PDFs, etc.). We would like our PDF subspace  $\mathcal{V}_0$  to be such that the orthogonal projections  $\hat{x}_i(n)$  of  $x_i(n)$  onto  $\mathcal{V}_0$  are as close as possible to the original PDFs  $x_i(n)$  when averaged over all elements in the given set  $\mathcal{W}_0$ . That is, we would like to minimize the sum of the  $\ell_2$  norms

$$\sum_i \|x_i(n) - \hat{x}_i(n)\|^2 \quad (61)$$

by choosing  $\mathcal{V}_0$  or, equivalently, by designing  $f(n)$ . Since  $\hat{x}_i(n) \in \mathcal{V}_0$  and  $x_i(n) - \hat{x}_i(n) \in \mathcal{V}_0^\perp$ , we have

$$\|x_i(n)\|^2 = \|\hat{x}_i(n)\|^2 + \|x_i(n) - \hat{x}_i(n)\|^2. \quad (62)$$

Therefore, minimizing the sum of  $\|x_i(n) - \hat{x}_i(n)\|^2$  is equivalent to maximizing the sum of the energies of the projection  $\|\hat{x}_i(n)\|^2$ . This is, in fact, an energy compaction problem, which is similar to the problems addressed in [21]–[23].

In order to make this a well-posed optimization problem, let us consider the  $i$ th sample PDF  $x_i(n)$ . Let  $\hat{x}_i(n)$  be the orthogonal projection of  $x_i(n)$  onto  $\mathcal{V}_0$ , as before. This projection  $\hat{x}_i(n)$  can be obtained by passing  $x_i(n)$  through the model in Fig. 5, where  $G(z)$  is the least squares partner of  $F(z)$ . Suppose we let the error  $\xi_i$  be

$$\xi_i = \|x_i(n) - \hat{x}_i(n)\|^2 = \sum_n |x_i(n) - \hat{x}_i(n)|^2. \quad (63)$$

Then small  $\xi_i$  implies that the sample PDF  $x_i(n)$  can be represented by the model in Fig. 2 satisfactorily. Now, the optimization problem can be stated as follows. We want to find the filter coefficients  $f(n)$  that minimize the following objective function

$$J = \sum_{i=0}^{I-1} \alpha_i \xi_i \quad (64)$$

where the error  $\xi_i$  is defined as in (63), and  $\alpha_i$  is a weighting factor that satisfies  $\sum_i \alpha_i = 1$  and  $\alpha_i \geq 0$ .

When minimizing  $J$ , there are several constraints that have to be taken into account. We may first limit the length of the

filter to be  $\leq R$ , so that  $f(n)$  is zero outside  $0 \leq n \leq R - 1$ . Secondly, we restrict the filter coefficients to be non-negative, i.e.,  $f(n) \geq 0, \forall n$ . This is necessary in order to make the PDF estimate non-negative. Third, we impose the constraint on  $f(n)$  such that the zeros of  $[\hat{F}(z)F(z)]_{\downarrow M}$  are not too close to the unit circle. If this condition is not satisfied, the least squares partner  $G(z)$  will have poles that are close to the unit circle (or even on the unit circle), in which case, the FIR truncation approach is no longer practical. We may also impose other constraints such as  $f(0) \neq 0$  and  $\sum_n f(n) = 1$  in order to make the optimal solution unique.

### B. Optimization Results for Commonly Used PDFs

In order to demonstrate the idea, we now optimize the coefficients of  $f(n)$  for commonly used PDFs such as the Laplacian and the Poisson PDF. We assume that a set of density functions that belong to the same class—based on some criterion, which is not necessarily known—are given. This set of density functions will serve as the training set for optimizing  $f(n)$ . Next, another PDF that belongs to the same group but was not included in the training set will be chosen in order to test the performance of the model-based estimator.

Let us first consider a set of Laplacian PDFs. The continuous Laplacian density function is defined as

$$p(x) = \frac{1}{\sqrt{2}\sigma} e^{-\sqrt{2}|x-\mu|/\sigma}. \quad (65)$$

We may obtain a discrete PDF  $x(n)$  by sampling and truncating the above function and then normalizing it in order to make the coefficients add up to unity. We obtained several discrete PDFs from continuous Laplacian density functions with different mean and variance. These are shown in Fig. 17. Five density functions were used as the training set for optimizing  $f(n)$ , and the remaining one was used for evaluating the performance of the model-based PDF estimation.

*Choice of M:* When computing the optimal  $f(n)$  based on this training set, we assumed that  $M = 2$  and that the length of  $f(n)$  was restricted to be  $\leq 5$  for simplicity. In general, a larger  $M$  results in increasing the minimum value of the weighted projection error  $J$ . However, if the PDFs of our interest can be well represented by the model in Fig. 2 with the given  $M$  and the optimized  $f(n)$ , a larger  $M$  can result in a smaller estimation error. Therefore, there is a tradeoff in choosing the value of  $M$ , and it should be chosen according to the given training set. Once  $M$  is decided, choosing the length of the filter  $f(n)$  to be around  $2M + 1$  usually yields a satisfactory estimation result. After the optimization process, if the error (64) is too large compared with  $\sum_{i=0}^{I-1} \alpha_i \|x_i(n)\|^2$ , we may have to decrease  $M$  as well as allow the filter  $f(n)$  to have a longer length.

In our simulations, we used a sequential quadratic programming (SQP) method [24] to optimize the filter coefficients. Once we obtained the optimal  $f(n)$ , the corresponding least squares partner  $g(n)$  was computed as in (13). Next, we took the test PDF in Fig. 17 to make 300 measurements of the r.v.  $n$  and constructed the histogram based on these observations. Finally, this histogram was passed through the system in Fig. 5 to get the

Fig. 17. Discrete Laplacian PDFs that are used for optimizing  $f(n)$  and testing the performance.

Fig. 18. (Top) Original Laplacian PDF and the histogram. (Bottom) Original PDF and the model-based estimate.

PDF estimate  $\hat{x}(n)$ . The result is shown in Fig. 18, which shows that the model-based approach results in an excellent PDF estimate, whereas the histogram estimate is not very satisfactory. The estimation errors were

$$\sum_n |h(n) - x(n)|^2 = 0.00260485 \quad (66)$$

$$\sum_n |\hat{x}(n) - x(n)|^2 = 0.00048105 \quad (67)$$

where the error of the model-based estimate was only 18.47% of the error of the histogram-based estimate. There is another important point that has to be noted. Although the model-based estimation procedure reduces the estimation error by a considerable amount, it does not compromise the sharpness of the original PDF, as can be seen in Fig. 18. This is indeed another advantage of the model-based approach, making it more attractive compared to the traditional histogram based density estimation.

 Fig. 19. Poisson PDFs used for optimizing  $f(n)$  and testing the performance.

Fig. 20. (Top) Original Poisson PDF and the histogram. (Bottom) Original PDF and the model-based estimate.

A similar experiment has been performed based on a set of Poisson PDFs. The training PDFs and the test PDF are shown in Fig. 19. Fig. 20 shows the histogram and the model-based estimate. The estimation errors were

$$\sum_n |h(n) - x(n)|^2 = 0.001\,706\,09 \quad (68)$$

$$\sum_n |\hat{x}(n) - x(n)|^2 = 0.000\,244\,54 \quad (69)$$

hence, the estimation error of the model-based estimate was only 14.33% when compared to that of the histogram estimate. Table I summarizes the estimation results for several class of density functions. The filter coefficients  $f(n)$  were optimized for each class of PDFs, and we estimated the test PDFs using this  $f(n)$ . The estimation errors have been averaged for ten simulations. This result shows that the optimization of  $f(n)$  yields satisfactory PDF estimates that are significantly better than the histograms.

 TABLE I  
ESTIMATION RESULTS USING OPTIMIZED  $f(n)$  FOR VARIOUS CLASS OF PDFS

PDF	Average Estimation Error	
	Histogram	Model-Based
Laplacian	0.00289717	0.00115754
Gaussian	0.00304934	0.00103529
Rayleigh	0.00298871	0.00119290
Poisson	0.00292003	0.00094862

## VIII. CONCLUDING REMARKS

Although many researchers in the mathematics as well as the signal processing communities have been interested in estimating the PDF of a random variable  $v$ , most of the results were focused on the continuous case. In this paper, we proposed a new method for the estimation of discrete PDFs. The proposed method is based on multirate signal processing theory, and it makes extensive use of the notion of biorthogonal partners. This model-based approach has several advantages over the traditional histogram approach. It guarantees a smaller estimation error, and it provides an efficient denoising scheme when the observations are corrupted by additive noise. Furthermore, the analysis of the model-based estimates shows that they are unbiased and have a smaller variance than the histogram estimates. It was also shown that the proposed model can be used for modeling and estimating multivariate PDFs. Finally, it was demonstrated that the interpolation filter  $f(n)$  could be optimized for a class of density functions. Simulation results show that the use of an optimized filter can decrease the estimation error dramatically. There are many interesting extensions of the proposed ideas, which remain to be considered. For example, we may consider modeling and estimating multivariate PDFs with a nonseparable filter  $F(\mathbf{z})$  and a nondiagonal matrix  $\mathbf{M}$ . This will require the concept of multidimensional biorthogonal partners. Another interesting problem is the estimation of a PDF when the noise is dependent on the original samples. These are topics for future research.

## APPENDIX

In this Appendix, we provide the detailed derivation of (41). Let us first compute  $\mathcal{E}[t(k_1)t(k_2)]$ . If  $k_1 = k_2$ , then

$$\begin{aligned} \mathcal{E}[t(k_1)t(k_2)] &= \mathcal{E}[t^2(k_1)] \\ &= \text{Var}[t(k_1)] + (\mathcal{E}[t(k_1)])^2 \\ &= Nx(k_1)(1 - x(k_1)) + N^2x^2(k_1) \\ &= Nx(k_1)(1 + (N - 1)x(k_1)). \end{aligned} \quad (70)$$

Now, if  $k_1 \neq k_2$ , then

$$\begin{aligned} \mathcal{E}[t(k_1)t(k_2)] &= \sum_{m=0}^N P\{t(k_1) = m\} \cdot m \cdot \mathcal{E}[t(k_2)|t(k_1) = m] \\ &= \sum_{m=0}^N P\{t(k_1) = m\} \cdot m \cdot (N - m) \frac{x(k_2)}{1 - x(k_1)} \end{aligned}$$

$$\begin{aligned}
&= \frac{x(k_2)}{1-x(k_1)} \left( N \cdot \mathcal{E}[t(k_1)] \right. \\
&\quad \left. - \left[ \text{Var}[t(k_1)] + (\mathcal{E}[t(k_1)])^2 \right] \right) \\
&= \frac{x(k_2)}{1-x(k_1)} \left( N^2 x(k_1) - \left[ N x(k_1)(1-x(k_1)) \right. \right. \\
&\quad \left. \left. + N^2 x^2(k_1) \right] \right) \\
&= N(N-1)x(k_1)x(k_2). \tag{71}
\end{aligned}$$

Since  $\mathcal{E}[h(k_1)h(k_2)] = \mathcal{E}[t(k_1)t(k_2)]/N^2$ , we obtain (41) by dividing (70) and (71) by  $N^2$ .

**Byung-Jun Yoon** (S'02) was born in Seoul, Korea in 1975. He received the B.S.E. (summa cum laude) degree from Seoul National University (SNU) in 1998 and the M.S. degree from California Institute of Technology (Caltech), Pasadena, in 2002, both in electrical engineering. He is currently pursuing the Ph.D. degree in electrical engineering at Caltech.

His research interests include filterbank theory, multirate signal processing and applications, wavelets, signal regularization, bioinformatics, and genomic signal processing.

Mr. Yoon received the Killgore fellowship in 2001 from Caltech, and he was selected as a Microsoft Research fellow for the year 2004–2005. In 2003, he was awarded a prize in the student paper contest at the 37th Asilomar Conf. Signals, Systems, and Computers.

**P. P. Vaidyanathan** (S'80–M'83–SM'88–F'91) was born in Calcutta, India, on October 16, 1954. He received the B.Sc. (Hons.) degree in physics and the B.Tech. and M.Tech. degrees in radiophysics and electronics, all from the University of Calcutta, in 1974, 1977, and 1979, respectively, and the Ph.D. degree in electrical and computer engineering from the University of California, Santa Barbara, in 1982.

He was a post doctoral fellow at the University of California, Santa Barbara, from September 1982 to March 1983. In March 1983, he joined the Electrical Engineering Department, California Institute of Technology (Caltech), as an Assistant Professor, where since 1993, he has been Professor of electrical engineering. His main research interests are in digital signal processing, multirate systems, wavelet transforms, and signal processing for digital communications. He is a consulting editor for the journal *Applied and Computational Harmonic Analysis*.

Dr. Vaidyanathan served as Vice-Chairman of the Technical Program committee for the 1983 IEEE International Symposium on Circuits and Systems and as the Technical Program Chairman for the 1992 IEEE International Symposium on Circuits and Systems. He was an Associate Editor for the IEEE TRANSACTIONS ON CIRCUITS AND SYSTEMS FROM 1985 to 1987 and is currently an associate editor for the IEEE SIGNAL PROCESSING LETTERS. He was a guest editor in 1998 for special issues of the IEEE TRANSACTIONS ON SIGNAL PROCESSING and the IEEE TRANSACTIONS ON CIRCUITS AND SYSTEMS II on the topics of filterbanks, wavelets, and subband coders. He has authored a number of papers in IEEE journals and is the author of the book *Multirate Systems and Filter Banks* (Englewood Cliffs, NJ: Prentice-Hall, 1993). He has written several chapters for various signal processing handbooks. He was a recipient of the Award for Excellence in Teaching from the California Institute of Technology for the years 1983–1984, 1992–1993, and 1993–1994. He also received the NSF's Presidential Young Investigator Award in 1986. In 1989, he received the IEEE ASSP Senior Award for his paper on multirate perfect-reconstruction filterbanks. In 1990, he was recipient of the S. K. Mitra Memorial Award from the Institute of Electronics and Telecommunications Engineers, India, for his joint paper in the *IETE Journal*. He was also the coauthor of a paper on linear-phase perfect reconstruction filterbanks in the IEEE TRANSACTIONS ON SIGNAL PROCESSING, for which the first author (T. Nguyen) received the Young Outstanding Author Award in 1993. He received the 1995 F. E. Terman Award of the American Society for Engineering Education, sponsored by Hewlett Packard Co., for his contributions to engineering education, especially the book *Multirate Systems and Filter Banks*. He has given several plenary talks including the Sampta'01, Eusipco'98, SPCOM'95, and Asilomar'88 conferences on signal processing. He was chosen as a distinguished lecturer for the IEEE Signal Processing Society for the year 1996–1997. In 1999, he received the IEEE CAS Society's Golden Jubilee Medal, and in 2002, he received the IEEE Signal Processing Society's Technical Achievement Award.
