## ABSTRACT

We report on the discovery and characterization of the transiting planet K2-39b (EPIC 206247743b). With an orbital period of 4.6 days, it is the shortest-period planet orbiting a subgiant star known to date. Such planets are rare, with only a handful of known cases. The reason for this is poorly understood but may reflect differences in planet occurrence around the relatively high-mass stars that have been surveyed, or may be the result of tidal destruction of such planets. K2-39 (EPIC 206247743) is an evolved star with a spectroscopically derived stellar radius and mass of  $3.88^{+0.48}_{-0.42} R_{\odot}$  and  $1.53^{+0.13}_{-0.12} M_{\odot}$ , respectively, and a very close-in transiting planet, with  $a/R_{\star} = 3.4$ . Radial velocity (RV) follow-up using the HARPS, FIES, and PFS instruments leads to a planetary mass of  $50.3^{+9.7}_{-9.4} M_{\oplus}$ . In combination with a radius measurement of  $8.3 \pm 1.1 R_{\oplus}$ , this results in a mean planetary density of  $0.50^{+0.29}_{-0.17} \text{ g cm}^{-3}$ . We furthermore discover a long-term RV trend, which may be caused by a long-period planet or stellar companion. Because K2-39b has a short orbital period, its existence makes it seem unlikely that tidal destruction is wholly responsible for the differences in planet populations around subgiant and main-sequence stars. Future monitoring of the transits of this system may enable the detection of period decay and constrain the tidal dissipation rates of subgiant stars.

**Key words:** planetary systems – planets and satellites: detection – planets and satellites: dynamical evolution and stability – stars: fundamental parameters – stars: individual (K2-39)

## 1. INTRODUCTION

In comparison to main-sequence stars, subgiant and giant stars have a higher observed occurrence of exoplanets but have fewer close-in giant planets (Bowler et al. 2010; Johnson et al. 2010; Reffert et al. 2015). To explain the lack of close-in

planets orbiting these stars, there are currently two main theories. In one scenario the close-in planets are destroyed by tidal evolution: they spiral into their host stars as they transfer angular momentum, a process that is expected to be stronger for evolved stars than for main-sequence stars (e.g., Rasio et al. 1996; Villaver & Livio 2009; Schlaufman & Winn 2013). In another scenario the lower occurrence rate of short-period gas giant planets orbiting evolved stars is a result of the systematically higher mass of the observed evolved stars compared to the observed main-sequence stars. The shorter lifetime of the inner protoplanetary disks around these more massive stars

\* Based on observations made with the NOT telescope under program ID. 50-022/51-503, 50-213(CAT), 52-201 (CAT), 52-108 (OPTICON), 51-211 (CAT), and ESOs 3.6 m telescope at the La Silla Paranal Observatory under program ID 095.C-0718(A).

<sup>21</sup> NASA Sagan Fellow.

causes the lower occurrence rate of gas giant planets at short orbital periods (e.g., Burkert & Ida 2007; Currie 2009; Kretke et al. 2009).

Detections of planets around evolved stars are challenging because of additional noise sources in the stellar Radial Velocity (RV) signal (see e.g., Reffert et al. 2015), and because the larger stellar radii result in shallower planetary transits. There are currently only four evolved stars ( $R \geq 3.5 R_{\odot}$ ) known to host short-period ( $\leq 100$  days) transiting planets.

One example is Kepler-91b (Lillo-Box et al. 2014b), whose validity as a genuine planet was debated (e.g., Sliski & Kipping 2014) until RV confirmation ruled out false positive scenarios (Lillo-Box et al. 2014a; Barclay et al. 2015). Kepler-56 is host to two short-period transiting planets (Huber et al. 2013). Kepler-391 is likely an evolved star with two short-period planets (7 and 20 days) that were statistically validated (Rowe et al. 2014). Finally, Kepler-432b is an eccentric Jupiter-sized planet that orbits its giant star in 52 days (Ciceri et al. 2015; Ortiz et al. 2015; Quinn et al. 2015).

Here we report on the discovery and characterization of K2-39b (EPIC 206247743b), a transiting planet in a 4.6 day orbit around a subgiant star, making it the shortest period planet orbiting such a star known to date. Its transits were observed by the K2 mission (Howell et al. 2014) in Campaign 3. The transits in this system have also been recently reported by Vanderburg et al. (2015a), who assigned it the status of “planetary candidate.” We conducted RV follow-up observations using HARPS (Mayor et al. 2003), FIES (Telting et al. 2014), and PFS (Crane et al. 2010), which result in a  $5\sigma$  measurement of the mass, both confirming the planetary nature of the system and constraining its bulk density. This work is part of the *Equipo de Seguimiento de Planetas Rocosos INterpretando sus Tránsitos (ESPRINT)* project (see Hirano et al. 2016; Sanchis-Ojeda et al. 2015; Van Eylen et al. 2016).

In Section 2 we describe the observations used in this work. In Section 3 we describe the way these data were modeled. In Section 4 we present the results, and in Section 5 we discuss and conclude.

## 2. OBSERVATIONS

### 2.1. Photometry

The K2 observations (Howell et al. 2014) are extracted from the raw pixel files, detrended, reduced, and searched for planets following the procedure outlined in Van Eylen et al. (2016), and used the pipeline publicly available on GitHub.<sup>22</sup> We summarize the important features here.

The aperture that was used to generate a light curve for K2-39 is shown in Figure 1, and includes all pixels that have a flux level that is at least six times the median flux value in the pixel mask. The light curves are detrended using a polynomial fit of time,  $T$ , and flux,  $F$ , to the centroid positions ( $X_c$  and  $Y_c$ ) to remove instrumental effects. Specifically we fit the model,  $M$ , with fitting parameters  $t_i$ ,  $x_i$ ,  $y_i$ , and  $z_1$ :

$$M = t_0 + t_1 T + x_1 X_c + x_2 X_c^2 + y_1 Y_c + y_2 Y_c^2 + z_1 X_c Y_c.$$

We note that this is a lower-order polynomial than was used by Van Eylen et al. (2016), which we found to result in higher-quality photometry in this case. The light curve was fitted in

**Figure 1.** Pixel mask for K2-39. The gray scale indicates the electron count, going from black (high) to white (low). The red line encircles the aperture used to generate the photometry, which includes all pixels with counts more than six times the median flux value.

**Figure 2.** Reduced and phase-folded K2 transit photometry. The best fitted model is shown with a solid line, as well as the residuals after subtracting the model. Error bars are omitted for clarity, but a representative error bar is shown in the top panel.

chunks of 650 data points each. We also compared the resulting light curve with one obtained following Sanchis-Ojeda et al. (2015), and found it to be consistent. An initial orbital period is determined using a box least-square search algorithm (e.g., Kovács et al. 2002), which is later refined during the fitting procedure (see Section 3.3). The final, phase-folded transit light curve is shown in Figure 2.

### 2.2. Imaging Follow-up Observations

The photometric aperture of K2-39 contains many pixels (28 in total, see Figure 1) and each K2 pixel spans  $3.98 \times 3.98$

<sup>22</sup> <https://github.com/vincentvaneylen>

**Figure 3.** Top: shift-and-add FastCam image of K2-39 constructed by combining the 50% best individual TCS/FastCam frames. The orientation is north-up and east-right. Bottom: stars observed just before (left) and just after (right) the target during the same night. The image on the left shows the same distortion, indicating that the distortion is likely caused by instrument defocus.

arcsec. This implies that ground-based imaging is needed to assess the presence of nearby contaminant stars that may be associated with the system or aligned by chance.

We performed lucky imaging observations with the FastCam camera (Oscoz et al. 2008) at the 1.55 m Telescopio Carlos Sánchez (TCS). FastCam is a very low noise and fast readout speed EMCCD camera with  $512 \times 512$  pixels (with a physical pixel size of 16 microns, a scale of 42.5 mas per pixel, and an FoV of  $21''.2 \times 21''.2$ ) and it is cooled down to  $-90^\circ\text{C}$ . On 2015 July 30, 10,000 individual frames of K2-39 were collected in the I-band, with an exposure time of 50 ms for each frame. In order to construct a high resolution, long-exposure image, the individual frames were bias-subtracted, aligned, and co-added. In Figure 3 we present a high resolution image that was constructed by co-adding the best 50% of images so that it has a 5 s total exposure time.

We find no evidence for a contaminant star within the field of view. The target star shows a deviation from spherical symmetry. To assess if it may be instrumental in nature, we looked at other targets observed during the same night. The target observed just before EPIC 20624774 shows the same elongated shape (see Figure 3), indicating that the cause of the asymmetry is likely instrumental in nature due to a defocus.

We further gathered an Adaptive Optics (AO) image using the Subaru telescope’s Infrared Camera and Spectrograph (IRCS), which is shown in Figure 4 together with the achieved  $5\sigma$  contrast limits. The seeing without AO was estimated at 0.4 arcsec, but a cirrus clouds may have degraded the AO performance at the 0.1 arcsec level, as suggested by the PSF of a standard star (FS151) observed during the same night (see Figure 4).

The AO image reveals no companion objects but shows a distortion to the north–east of about 0.2 arcsec. The standard star FS151 shows a distortion as well, suggesting that the cause for this effect may be instrumental. This asymmetry in the AO observations does not follow the same orientation as the

**Figure 4.** Adaptive optics image using the Subaru telescope. The orientation is north-up and east-left, as in Figure 3. In the top figure the image for K2-39 is shown. The middle figure shows a standard star (FS151) observed during the same night, which has a slightly non-circular shape, suggesting a degraded AO performance. The bottom image shows the  $5\sigma$  contrast ratio the image provides.

asymmetry in the lucky imaging and does not have the same scale, so they are unlikely to have the same origin.

An alternative explanation for the observed asymmetry in the AO image is the presence of a very nearby companion star. If this is the case, such a companion would influence our measurement of the planetary radius by diluting the transit light

curve. Assuming the distortion is caused by a stellar companion, we can estimate its flux by fitting two two-dimensional Gaussian functions to the image. This method is not ideal because the “companion star” is not well-separated from the target star, but after trying different fitting methods and Gaussian function parameters, we consistently find it to be four to seven times fainter than the target star. Assuming the companion is associated with the target star so that it has the same distance implies that the companion star would likely be less evolved than the target star, which explains the lower flux contribution. As discussed in detail in Section 4.2, we find no evidence of such a star (or any other star) in the spectroscopic observations. Therefore we proceed here under the assumption that no companion star is present. We caution that if there is indeed a nearby star, this would influence the derived planetary parameters.

### 2.3. Spectroscopic Follow-up Observations

We carried out high-precision RV follow-up observations of K2-39 using the HARPS, FIES, and PFS instruments.

We started our observations using the FIES spectrograph (Frandsen & Lindberg 1999; Telting et al. 2014) mounted at the 2.56 m Nordic Optical Telescope (NOT) of Roque de los Muchachos Observatory (La Palma, Spain). We used the FIES high-res mode ( $R \approx 67\,000$ ) and collected 17 high-resolution spectra from 2015 July until 2016 January. We set the exposure time to 15–20 minutes, which resulted in an average signal-to-noise ratio (S/N) of 40 per pixel at 5500 Å. We acquired long-exposed ( $T_{\text{exp}} \sim 30$  s) ThAr spectra right before and after each science exposure to trace the RV drift of the instrument. We used the method by Gandolfi et al. (2015) to analyze the data.

Between 2015 August 21 and September 13 we observed the system using the HARPS spectrograph at the ESO 3.6 m telescope at La Silla. We acquired seven high-resolution spectra, using an exposure time of 10 minutes per data point. At order 50 they have an average S/N of 30. The HARPS observations were analyzed using the standard data reduction pipeline (Baranne et al. 1996; Pepe et al. 2000).

We also acquired data using the PFS at the *Magellan* II Telescope at Las Campanas Observatory. Between 2015 August 23 and September 4 we obtained six high-resolution spectra. Each exposure lasted 20 minutes and resulted in an S/N of 80–100. PFS uses the iodine technique for calibration, and the radial velocities were derived using an updated version of the algorithm outlined in Butler et al. (1996).

All RV data points and their observation times are listed in Table 3.

## 3. MODELING

### 3.1. Stellar Parameters

We co-added the HARPS spectra and determined the atmospheric parameters following Takeda et al. (2002). We find the effective temperature  $T_{\text{eff}} = 4881 \pm 20$  K, surface gravity  $\log g = 3.44 \pm 0.07$  (cgs), metallicity  $[\text{Fe}/\text{H}] = 0.32 \pm 0.04$ , and a microturbulent velocity of  $\xi = 0.97 \pm 0.11$  km s $^{-1}$ , based on the measurement of equivalent widths of iron lines, and on the excitation and ionization equilibria. Following Hirano et al. (2012), we also derive the stellar rotation velocity by fitting the combined HARPS spectrum to obtain  $v \sin i_* = 2.0 \pm 0.5$  km s $^{-1}$ .

**Figure 5.**  $Y^2$  isochrones for  $[\text{Fe}/\text{H}] = 0.32$ , where the blue lines represent the evolution tracks for different stellar masses and the black curves are curves of constant radius. K2-39 is shown as the red point with its error bars.

From the stellar atmospheric parameters we then determine the stellar physical parameters using  $Y^2$  isochrones (Yi et al. 2001), as shown in Figure 5. K2-39 is found to be a metal-rich subgiant star ( $M_* = 1.53^{+0.13}_{-0.12} M_{\odot}$ ,  $R_* = 3.88^{+0.48}_{-0.42} R_{\odot}$ ) with an age of  $3.09^{+0.92}_{-0.70}$  Gyr.

Since the stellar parameters of evolved stars are known to be sensitive to the adopted isochrones (evolutional tracks), we also checked the consistency of the derived parameters in two ways. First we derived the stellar atmospheric parameters using the VWA software<sup>23</sup> (Bruntt et al. 2012). Again using the effective stellar temperature ( $T_{\text{eff}}$ ), surface gravity ( $\log g$ ), and metallicity ( $[\text{Fe}/\text{H}]$ ) as input, we inferred the stellar mass, radius, and age using BaSTI evolution tracks<sup>24</sup> following the SHOTGUN method (Stello et al. 2009). We found the results to be consistent. Second, we check the results by employing the empirical relations of Torres et al. (2010). Consequently, we found  $M_* = 1.39^{+0.11}_{-0.10} M_{\oplus}$  and  $R_* = 3.69^{+0.43}_{-0.38} R_{\oplus}$ , which agree with the isochrone-based values within  $1\sigma$ . We adopt the values derived using the  $Y^2$  isochrones for the remainder of this work, and list these parameters in Table 1.

### 3.2. Asteroseismology

Because the star is evolved and relatively bright, we searched the frequency power spectrum of the corrected light curve for indications of stellar oscillations. We performed a search for indications of a seismic power excess using frequency-power spectra prepared using corrected light curves from the K2-Photometry-Pipeline (K2P<sup>2</sup> Lund et al. 2015) and the KASOC filter (Handberg & Lund 2014). No such signal was found. This agrees with the spectroscopic parameters, from which we estimate a frequency of maximum power ( $\nu_{\text{max}}$ ) of  $\sim 338 \pm 55$   $\mu\text{Hz}$  using the  $\nu_{\text{max}} \propto g/\sqrt{T_{\text{eff}}}$  scaling relation (Brown et al. 1991; Kjeldsen & Bedding 1995). This is above the Nyquist frequency of  $\nu_{\text{Nyq}} \approx 283$   $\mu\text{Hz}$  for K2 long-cadence observations, and conforms with the detection limits presented in Stello et al. (2014) for K2 observations.

With an independent estimate of the effective temperature one may use such a non-detection of seismic signal to place a lower limit on  $\log g$  (see Campante et al. 2014). However, without observations in short-cadence, we are limited by the Nyquist

frequency and can only set a lower limit of  $\log g > 3.36$  dex. However, the fact that no signal is seen from back-reflected seismic power in the “super-Nyquist” regime (i.e., above  $\nu_{\text{Nyq}}$ ) could indicate that  $\nu_{\text{max}}$  is as high as 400  $\mu\text{Hz}$  (Chaplin et al. 2014), hence  $\log g \geq 3.5$  dex (consistent with findings from spectroscopy, see Section 3.1).

**3.3. Orbital and Planetary Parameters**

We derive the planetary parameters following the procedure outlined in detail in Van Eylen et al. (2016). We highlight the key points here.

*Photometric model:* we model the planetary transits assuming a constant orbital period (linear ephemeris), without transit timing variations, and using the analytical model by Mandel & Agol (2002). The model was binned to 30 minutes to match the finite integration time of the observations (20 hr of observations around each transit were used), and contains the following parameters: orbital period ( $P$ ), mid-transit time ( $T_{\text{mid}}$ ), stellar radius divided by semimajor axis ( $R_*/a$ ), planetary radius divided by stellar radius ( $R_p/R_*$ ), the cosine of the orbital inclination ( $\cos i_o$ ), and two limb darkening parameter ( $u_1$  and  $u_2$ ) which determine a quadratic law.

*RV model:* we model the RV observations by fixing the eccentricity to zero and modeling the projected stellar reflex motion ( $K_*$ ). In addition, we fit for a systemic velocity offset between the different spectrographs ( $\gamma_{\text{spec}}$ ). We furthermore include a quadratic drift (using two parameters,  $\phi_1$  and  $\phi_2$ ) as a function of time relative to an arbitrary zero point ( $t_0$ ). We tested whether allowing non-zero orbital eccentricity would affect the derived parameters, and found that not to be the case (see also Section 4.1). As a result, the RV model we fit for is

$$\text{RV}(t) = \phi_1(t - t_0) + \phi_2(t - t_0)^2 + \gamma_{\text{spec}} + \text{RV}_{\text{planet}} \quad (1)$$

To account for our incomplete knowledge of stellar activity, we add stellar “jitter” to the internal uncertainties of the RV points, so that the minimum reduced  $\chi^2$  for the data obtained by each spectrograph is close to unity. Note that two data points were observed in-transit, and we assume the star is aligned with the planet in our model. Even if the star and planet were misaligned, the effect of this would be below the photon noise.

*Prior information:* we place a Gaussian prior with a width of 0.1 and a center value derived from the tables by Claret & Bloemen (2011) on the sum of the limb darkening parameters ( $u_1 + u_2$ ), while holding the difference ( $u_1 - u_2$ ) fixed at the tabulated value. For the K2 bandpass we find  $u_1 = 0.5902$  and  $u_2 = 0.1395$ , using  $T_{\text{eff}} = 5000$  K,  $\log g = 3.5$  (cgs) and  $[\text{Fe}/\text{H}] = 0.3$ . When we try an eccentric fit, the stellar density (see Section 3.1) is used as a Gaussian prior and helps constrain  $e$  and  $\omega$  (see, e.g., Van Eylen & Albrecht 2015). In this case we furthermore assume an eccentricity prior of  $\frac{dN}{de} \propto \frac{1}{(1+e)^4} - \frac{e}{2^4}$  (see Shen & Turner 2008), and require that the orbits of planet and star do not cross, and sample uniformly in  $\sqrt{e} \cos \omega$  and  $\sqrt{e} \sin \omega$  to avoid a positive bias (see e.g., Lucy & Sweeney 1971). All other parameters have flat (uniform) priors.

*Parameter estimation:* we model the planetary transit and the stellar RV signal simultaneously using a Markov Chain Monte Carlo (MCMC) method (Tegmark et al. 2004), and following the Metropolis–Hastings algorithm. We run three chains of  $10^6$  steps each, with a step size adjusted to obtain an acceptance rate of approximately 25%. We employed a burn-in phase of  $10^4$  points, which were removed from each chain prior to the analysis. We checked for convergence using the Gelman and Rubin diagnostic (Gelman & Rubin 1992).

The chains are merged and uncertainty intervals encompassing 68.3% of the total probability are calculated by excluding the 15.85% quantiles on both sides, while median values are used as best estimates. All parameters are reported in Table 1.

**Figure 6.** RV observations over time (left) and phased (right). The best fitting model is shown with a solid line, as are the residuals after subtracting the model. The internal RV uncertainties are indicated by the black error bars; the gray error bars include an additional “stellar jitter” term, as explained in the text.

## 4. RESULTS

### 4.1. Planet Confirmation and Properties

We determine a planetary radius of  $8.2^{+1.1}_{-1.1} R_{\oplus}$  and a planet mass of  $50.3^{+9.7}_{-9.4} M_{\oplus}$ . We obtain a planetary bulk density of  $0.50^{+0.29}_{-0.17} \text{ g cm}^{-3}$ . The planet is very close to its star, with  $R_{*}/a = 0.293^{+0.045}_{-0.030}$ . We note that if there is an unseen companion star contaminating the light curve (see Section 2.2), then the planet would be larger and its density would be lower.

During the fitting procedure we assumed a circular orbit because the orbital period of 4.6 days suggests that tidal effects have circularized any initial eccentricity. Out of caution we also try a solution in which we allow non-circular orbits. We find that a circular orbit is favored, with an upper limit (at 95% confidence) of  $e = 0.24$ . The resulting planetary mass,  $53.8^{+10}_{-9.9} M_{\oplus}$ , is consistent with the circular fit. We adopt the values from the circular solution in Table 1. The best transit fit is shown in Figure 2, and the RV observations are shown in Figure 6. The rms values of the RVs from each spectrograph after the best fitting model is subtracted are  $8.6 \text{ m s}^{-1}$  (HARPS),  $7.3 \text{ m s}^{-1}$  (FIES), and  $4.4 \text{ m s}^{-1}$  (PFS).

For a circular orbit, the transit duration directly constrains the mean stellar density. Following the procedure used by Van Eylen & Albrecht (2015) to validate Kepler-449b/c and Kepler-450b/c/d, we find that a transit fit constrains the bulk density of the host star to  $[0.026, 0.14] \text{ g cm}^{-3}$  at 95% confidence, assuming the planet has a circular orbit. The stellar density derived from the transit for a circular orbit is furthermore fully consistent with the bulk density of K2-39 derived from spectroscopy ( $0.036 \pm 0.011 \text{ g cm}^{-3}$ ), giving further credibility to the fact that this star is indeed the host of the planet. More generally, the transit duration provides independent evidence that the planet is orbiting an evolved star. For example, we find that if the planet would orbit a star with a solar mean density ( $1.408 \text{ g cm}^{-3}$ ), then it would require the planet to have an eccentricity in the interval  $[0.78, 0.94]$  at 95% confidence. Given the short orbital period, we find such a scenario not to be feasible.

We find evidence of a long-period companion, which we modeled as a quadratic trend with  $\phi_1 = -0.313 \pm 0.052 \text{ m s}^{-1} \text{ d}^{-1}$  and  $\phi_2 = 0.0063 \pm 0.0012 \text{ m s}^{-1} \text{ d}^{-1}$ , with  $t_0 = 2457300$  BJD. We check whether the data warrants the

inclusion of both parameters, and find this to be the case. Including the quadratic term, we find  $\chi^2 = 552.1$ , while only including a linear term  $\chi^2 = 579.6$ . Calculating the Bayesian Information Criterion (BIC) with 12 and 11 degrees of freedom, respectively, and 30 RV data points, we find that the quadratic term is clearly favored (with a BIC of 593, versus 617 for the linear case). If we count all photometry data points as well, the BIC numbers change but the quadratic term remains clearly favored. Nevertheless, the trend is dependent on the two latest observations, so that more observations are needed to fully interpret it. Assuming the trend is caused by a companion object, it has a period that is longer than the time span of the data. As a result, its true orbit and amplitude are difficult to constrain. We attempted to do so by allowing a second body in the MCMC fit rather than the quadratic trend, but find that the orbit is consistent with all orbital periods longer than 125 days, and amplitudes corresponding to objects at least as massive as Jupiter. Further observations may help determine if the trend is caused by an additional planet or a self-luminous companion object. We note that the AO image (see Section 2.2) suggests that there may be a nearby companion star. If we roughly estimate this potential companion to be at an angular distance of about 0.2 arcsec, and use 255 pc as the distance between an observer and the star as estimated by RAVE distance calibrations (Francis 2013; Kordopatis et al. 2013), this would imply a minimum distance of  $\sim 50$  au between the two stars. This would imply an orbital period of order of a hundred years, making it unlikely that the quadratic trend observed in a time span of only a few months is caused by such an orbit.

### 4.2. Stellar Activity and Light Blending

We check if any observed RV signal could be caused by stellar activity by calculating the bisectors (BIS) as defined by Queloz et al. (2001) for the HARPS and FIES observations. The results are shown in Figure 7. We calculate the Pearson correlation coefficient. For HARPS this is 0.66 with a  $p$ -value of 0.11, with seven data points and five degrees of freedom. For FIES this is  $-0.03$  with a  $p$ -value of 0.91, with 17 data points and 15 degrees of freedom. This implies that in neither of the data sets is there any evidence for a correlation at a significance level of 0.01.

**Figure 7.** Bisectors (BIS) from HARPS (top) and FIES (bottom) CCFS are plotted vs. the stellar RVs. The color code indicates the signal-to-noise ratio in the stellar spectra obtained around a wavelength range of 5560 Å. There is no evidence for correlations. The BIS uncertainties are taken to be three times the RV uncertainties. The mean BIS values for HARPS and FIES are  $49 \text{ m s}^{-1}$  and  $-4.6 \text{ m s}^{-1}$ , respectively.

We further check if there are any correlations between the Mount Wilson activity index and the RV observations. For the HARPS observations we have seven data points, and find a Pearson correlation coefficient of 0.23 with a  $p$ -value of 0.66, indicating no evidence for correlation. For the PFS data we have six data points, and find a Pearson correlation coefficient of 0.24 with a  $p$ -value of 0.64. As for the bisector data discussed above, the Mount Wilson measurements show no evidence that the RV variation is caused by stellar activity.

We checked the K2 light curve for evidence of a rotational modulation signal but could not clearly determine any period of stellar rotation. This may be due to systematic effects in the photometry.

If an unseen stellar contaminant would have a  $v \sin i$  and RV that are very similar to that of K2-39, then this may remain undetected in the measured bisectors. However, such a hypothetical companion would still influence the shape of the cross-correlation function (CCF), which can be measured through the Full-Width at Half Maximum (FWHM, see e.g., Santerne et al. 2015). We calculate these values for the HARPS and FIES observations and compare them with the RV

**Figure 8.** Full-width at half maximum (FWHM) from HARPS (top) and FIES (bottom) CCFS are plotted vs. the stellar RVs. The color code indicates the signal-to-noise ratio in the stellar spectra obtained around a wavelength range of 5560 Å. There is no evidence for correlations. The mean FWHM values for HARPS and FIES are  $6,813 \text{ m s}^{-1}$  and  $11,552 \text{ m s}^{-1}$ , respectively.

measurements, as shown in Figure 8. For HARPS, we find a Pearson correlation coefficient of 0.10 with a  $p$ -value of 0.83, while for FIES we find a Pearson coefficient of 0.12 and a  $p$ -value of 0.64, implying there is no evidence for a correlation in either data set. We also checked if the FWHM measurements showed any correlation with the long-term trend seen in Figure 6, but found no evidence for that either.

We further checked the high-resolution spectroscopic observations (see Section 2.3) for the presence of a second set of spectral lines, which would be caused by a companion star of a different stellar type. To do so we looked at the cross-correlation function and found no evidence of any companion star. We furthermore did a visual inspection of the  $H_\alpha$  lines for any features caused by a contaminant star, and found no evidence of this. We have also visually inspected the spectrum at 6079–6084 Å, and again found no evidence of any secondary features as deep as  $>10\%$  of the spectrum continuum.

#### 4.3. Optical Phase Curve

The K2 photometry also provides some information on the out-of-transit variation. In general, such variations can be

**Figure 9.** Reduced and phase-folded K2 photometry for K2-39b (transit excluded). Top: the K2 observations are shown in gray, with 100-point bins in black circles. Bottom: as before, the bins are in black circles, the best fitted model is shown with a solid red line, and the photometry extracted by Vanderburg et al. (2015b) are shown in gray squares. The duration of the occultation is fixed to the duration of the transit, which is the case for circular orbits.

caused by light emitted or reflected by the planet, the ellipsoidal modulation of the star caused by the planet, and Doppler beaming (see e.g., Esteves et al. 2015). The latter two effects are very small for this system. However, given the quality of the data, we neglect them here. We model the emitted and reflected light by a Lambert sphere model, and fix the nightside temperature to zero. By assuming a circular orbit, we fix the occultation to occur at  $\phi = 0.5$ , with a duration equal to that of the primary transit. In this simple model we fit the light curve (out of the transit and occultation) for a single parameter, the amplitude  $F_0$ :

$$F = F_0 \frac{\sin z + (\pi - z) \cos z}{\pi}, \quad (2)$$

where  $z$  is defined as  $\cos z = -\sin i \cos(2\pi\phi)$ , with  $\phi$  describing the orbital phase calculated from mid-transit. To remove long-term residual trends in the photometry, we run a moving median filter with a width of twice the orbital period before modeling the data. After doing so, a simple MCMC analysis results in  $F_0 = 26.0_{-5.3}^{+5.3}$  ppm, and this model is shown in Figure 9. Such an amplitude would imply a maximum geometric albedo of the planet  $A_g = F_0(a/R_p)^2$  in the interval  $[0.64, 0.98]$  within 68% confidence, or a maximum brightness temperature of the planet of  $3050 \pm 100$  K. However, it is clear from the figure that this simple model does not adequately describe the observations, in particular around  $\phi = 0.25$ . We know of no astrophysical effect that can easily explain the observed dip at this phase, so that the origin is likely instrumental. To check if a different analysis method can avoid this, we compare our data with the photometry extracted by Vanderburg et al. (2015b) using a different method. However, as shown in Figure 9, we find that these data show a similar trend.

## 5. DISCUSSION AND CONCLUSIONS

We reported on the discovery and characterization of a giant transiting planet orbiting a subgiant star with a short period.

There are only a few known cases of such systems, which are thought to be rare. Of these systems, K2-39b, reported here, has the shortest orbital period.

By combining the K2 transit photometry with high resolution spectroscopic measurements from HARPS, FIES, and PFS we are able to measure the planetary mass and mean density. The system shows a long-term quadratic trend indicative of an additional body in the system. The current data do not span enough time to characterize the properties of this body.

We now discuss the importance of this planet in the context of planet (re)inflation in Section 5.1, and in the context of planet evolution in Section 5.2.

### 5.1. (Re)inflation?

Measuring the inflation of planets orbiting giant stars is interesting, as it may help distinguish between inflation mechanisms (Lopez & Fortney 2016). Lopez & Fortney (2016) suggest that planets with an orbital period of 10–20 days are likely not inflated while their host star is on the main sequence, but may become inflated as their host star evolves.

Despite its low density, K2-39b is not inflated in the sense that its radius is not larger than what would be expected for a pure H/He planet (Fortney et al. 2007) with this mass. With a mass of  $50.3_{-9.4}^{+9.7} M_{\oplus}$ , the planet is likely too small to fall into the regime where inflation is important. With an orbital period of 4.6 days, the planet has received high radiation even when the host star resided on the main sequence, unless its orbital period used to be longer. We note that the adaptive optics image presented in Figure 4 cannot rule out a nearby self-luminous companion, although we find no evidence of such a hypothetical companion contributing significant flux in the high-resolution spectroscopic observations. However, if a companion star nevertheless exists, this may affect the planet mass and radius, and its derived mean density. Extreme adaptive optics observations would be needed to rule out such a close companion star.

### 5.2. Tidal Evolution

K2-39b joins a small sample of short-period transiting planets orbiting (subgiant) stars. This is illustrated in Figure 10, where K2-39b is shown together with Kepler-91b, Kepler-56b/c, Kepler-391b/c, and Kepler-432b. The only non-transiting planet in the same part of the diagram is HD 102956b (Johnson et al. 2010). Of all these planets, K2-39b has the lowest semimajor axis and the shortest orbital period. K2-39b is closer to its host star than Kepler-91b, which orbits a more evolved star.

Because the scarcity of short-period planets orbiting subgiant stars may be a result of tidal destruction (Rasio et al. 1996; Villaver & Livio 2009; Schlaufman & Winn 2013), it is interesting to investigate how long K2-39b can survive. Under the assumption that the planet remains in its current orbit, the stellar surface will reach the planet once  $R_* \approx 14 R_{\odot}$ . Based on the stellar mass of  $1.53_{-0.12}^{+0.13} M_{\odot}$ , the isochrones suggest this will happen in  $150 \pm 90$  Myr. This provides a conservative upper limit on the remaining lifetime of the planet.

In addition to the evolution of the stellar surface, the planet may spiral inwards as its orbital period decays due to tides. Following Schlaufman & Winn (2013), and Equation (11)

**Figure 10.** K2-39b vs. other confirmed planets, with transiting planets (open circles) and non-transiting planets (open stars) taken from exoplanets.org (accessed on 2016 February 20, with the error bars omitted for clarity). Short-period transiting planets orbiting evolved stars are indicated with filled blue circles, with values taken from: Kepler-91 (Lillo-Box et al. 2014b), Kepler-56 (Huber et al. 2013), Kepler-391 (Rowe et al. 2014), Kepler-432 (Ciceri et al. 2015), and HD 102956b (Johnson et al. 2010). Left: stellar radius vs. semimajor axis, where the dotted line indicates  $R_* = a$ . Of all evolved stars, K2-39 has a planet with the shortest semimajor axis. Right:  $\log g$  vs. semimajor axis. The dotted line indicates the (empirical) border line defined by Nowak et al. (2013). Only Kepler-91b orbits inside of the line, while K2-39b falls exactly on top of it.

therein, we can estimate the timescale of orbital decay:

$$t = 10 \text{ Gyr} \frac{Q_*/k_*}{10^6} \left( \frac{M_*}{M_\odot} \right)^{1/2} \left( \frac{M_p}{M_{\text{Jup}}} \right)^{-1} \left( \frac{R_*}{R_\odot} \right)^{-5} \left( \frac{a}{0.06 \text{ au}} \right)^{13/2}. \quad (3)$$

Here,  $Q_*$  is the tidal quality factor of the star, and  $K_*$  is its tidal Love number. These values are highly uncertain, but assuming a canonical value of  $Q_*/k_* = 10^6$ , we find that the decay time is  $\approx 100$  Myr. If, however,  $Q_*/k_* = 10^2$ , as Schlaufman & Winn (2013) suggest may be the case for subgiant stars, then  $t \approx 10,000$  years. With such a short time scale it would be an interesting coincidence to observe the planet in its current state. Interestingly, Kepler-91b (e.g., Lillo-Box et al. 2014b) has a tidal decay timescale that is of the same order of magnitude, but slightly shorter, because it orbits at a slightly higher semimajor axis but around a more evolved, larger star. Consequently, the existence of K2-39b and Kepler-91b appears to argue against the strong tidal dissipation suggested by Schlaufman & Winn (2013) to explain the under-abundance of short-period planets orbiting subgiant stars.

K2-39b may allow a direct test of the tidal dissipation strength in the future. Because  $t = a/\dot{a} = P/\dot{P}$ , we find that  $\dot{P} = -4 \text{ ms/yr}$  for  $Q_*/k_* = 10^6$ , and  $\dot{P} = -40 \text{ s/yr}$  for  $Q_*/k_* = 10^2$ . Very recently,  $\dot{P} = (-2.56 \pm 0.40) \times 10^{-2} \text{ s yr}^{-1}$  was measured for WASP-12b, based on ten years of transit observations, corresponding to a tidal quality factor of  $2.5 \times 10^5$  for the (main-sequence) host star (Maciejewski et al. 2016).

To aid future measurements of  $\dot{P}$  for K2-39b, we report the times of the 15 individual transits observed by K2 in Table 2. These times were measured by fitting the best transit model to individual transit observations, while the uncertainties were estimated through a bootstrap procedure in which the residuals after the fit were resampled. The times and uncertainties reported in Table 2 are the mean and standard deviation of 4000 such fits to each transit.

**Table 2**  
Times of Individual Transits

Time (BJD)
2456980.8237 $\pm$ 0.0076
2456985.4232 $\pm$ 0.0081
2456990.010 $\pm$ 0.011
2456994.6438 $\pm$ 0.0086
2456999.2504 $\pm$ 0.0093
2457003.899 $\pm$ 0.011
2457008.4569 $\pm$ 0.0074
2457013.0664 $\pm$ 0.0083
2457017.6455 $\pm$ 0.0093
2457022.2631 $\pm$ 0.0081
2457026.8919 $\pm$ 0.021
2457031.475 $\pm$ 0.010
2457036.084 $\pm$ 0.017
2457040.715 $\pm$ 0.020
2457045.292 $\pm$ 0.013

We also fitted the current transit times to place an upper limit on period decay. Modeling the time of each transit ( $T_n$ ) as

$$T_n = T_0 + nP + \frac{1}{2}n^2P\dot{P}, \quad (4)$$

we fit for  $T_0$ ,  $P$ , and  $\dot{P}$  using an MCMC algorithm (Foreman-Mackey et al. 2013), with uniform priors on  $T_0$  and  $\dot{P}$ , and a Gaussian prior on  $P$  based on the simultaneous transit and RV fit reported in Table 1. Within 95% confidence, we find that  $\dot{P} > -0.000071$ , corresponding to a period decay less than 37 minutes  $\text{yr}^{-1}$ .

This provides a weak lower limit of  $Q_*/k_* > \approx 1.8$ . A longer baseline of observations could improve this constraint by orders of magnitude. Given the transit depth of  $\approx 400$  ppm, observing future transits is difficult to do using ground-based observations. However, the TESS mission (Ricker et al. 2014), planned to observe in  $\sim 2018$ –2019, or the CHEOPS mission (Broeg et al. 2013), planned to observe in 2018–2020, should easily be able to observe the transits if they target this star. By this time the tidal strengths suggested by Schlaufman & Winn

(2013) could lead to a period decay of several minutes, which should be well within reach of detectability.

Finally, we note that as K2 continues to observe, it may discover other rare systems similar to K2-39, allowing us to further constrain stellar structure and planet formation and evolution.

We thank the referee, Alexander Santerne, for helpful comments and suggestions which significantly improved this manuscript. We thank Saul Rappaport for helpful comments during the early stages of this project. We acknowledge kind help by Masayuki Kuzuhara for the analysis of Subaru IRCS data. This article is based on observations obtained with the Nordic Optical Telescope, operated on the island of La Palma jointly by Denmark, Finland, Iceland, Norway, and Sweden, in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias. Further observations made with the 1.55 m Carlos Sánchez Telescope operated on the

island of Tenerife by the Instituto de Astrofísica de Canarias in the Spanish Observatorio del Teide. Observations with the HARPS spectrograph at ESO's La Silla observatory (095.C-0718(A)). Data gathered with the 6.5 meter *Magellan* Telescopes located at Las Campanas Observatory, Chile. Funding for the Stellar Astrophysics Centre is provided by The Danish National Research Foundation (Grant agreement no.: DNR106). The research is supported by the ASTERISK project (ASTERoseismic Investigations with SONG and Kepler) funded by the European Research Council (Grant agreement no.: 267864). We acknowledge A.S.K. for covering travels in relation to this publication. The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2013-2016) under grant agreement No. 312430 (OPTICON). This research has made use of the Exoplanet Orbit Database and the Exoplanet Data Explorer at [exoplanets.org](http://exoplanets.org).
