Abstract

We present stellar and planetary properties for 1305 *Kepler* Objects of Interest hosting 2025 planet candidates observed as part of the California-*Kepler* Survey. We combine spectroscopic constraints, presented in Paper I, with stellar interior modeling to estimate stellar masses, radii, and ages. Stellar radii are typically constrained to 11%, compared to 40% when only photometric constraints are used. Stellar masses are constrained to 4%, and ages are constrained to 30%. We verify the integrity of the stellar parameters through comparisons with asteroseismic studies and *Gaia* parallaxes. We also recompute planetary radii for 2025 planet candidates. Because knowledge of planetary radii is often limited by uncertainties in stellar size, we improve the uncertainties in planet radii from typically 42% to 12%. We also leverage improved knowledge of stellar effective temperature to recompute incident stellar fluxes for the planets, now precise to 21%, compared to a factor of two when derived from photometry.

Key words: planets and satellites: fundamental parameters – planets and satellites: general – stars: abundances – stars: fundamental parameters – techniques: spectroscopic

1. Introduction

The prime *Kepler* mission (2009–2013; Borucki et al. 2010) revealed over 4000 planet candidates (Mullally et al. 2015). The vast majority of these planet candidates, formally known as *Kepler* Objects of Interest (KOIs), are *bona fide* planets (Morton & Johnson 2011; Lissauer et al. 2012). This large sample of planets with high purity enabled studies of planet occurrence (Howard et al. 2012; Fressin et al. 2013; Petigura et al. 2013) and planetary architectures (Lissauer et al. 2011; Fabrycky et al. 2014), and when coupled with spectroscopy, enabled determination of planet masses, densities, and interiors (Marcy et al. 2014; Weiss & Marcy 2014; Rogers 2015; Wolfgang & Lopez 2015). However, the inferred properties of extrasolar planets are often limited by uncertainties in stellar properties. The *Kepler* Input Catalog (KIC; Brown et al. 2011) was the first homogeneous catalog of properties of *Kepler* field stars. However, stellar radii (R_*) in the KIC, based solely on photometric constraints, have fractional uncertainties of

$\sigma(R_*)/R_* \approx 40\%$, which limits the precision with which one can measure planetary radii and densities.

The California-*Kepler* Survey (CKS) is a large spectroscopic survey conducted with Keck/HIRES of KOIs. This survey was conducted with the aim of improving knowledge of host star properties, which translate into higher precision measurements of planetary properties including planet radius (R_p) and incident stellar flux (S_{inc}). The CKS project and goals are described in detail in Paper I of this series (Petigura et al. 2017). In brief, between 2012 and 2015, we obtained high-resolution ($R \approx 50,000$) spectra of 1305 stars identified as KOIs with Keck/HIRES (Vogt et al. 1994). We used an exposure meter to achieve a uniform signal-to-noise ratio ≈ 45 per HIRES pixel on blaze near 5500 Å. Using these spectra, we derived effective temperature (T_{eff}), surface gravity ($\log g$), metallicity ($[\text{Fe}/\text{H}]$), and projected stellar rotation velocity ($v \sin i$).

In this work (Paper II of the CKS series), we convert the observed spectroscopic properties of Paper I into physical stellar and planetary properties. In Section 2, we convert T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ into stellar masses, radii, and ages. We assess the integrity of these measurements through comparisons with asteroseismology and trigonometric parallaxes from *Gaia*. We find that the typical fractional uncertainties in M_* and R_* are 4% and 11%, respectively. Stellar ages are constrained to 30%. In Section 3, we recompute planetary parameters including R_p and S_{inc} . We offer some concluding thoughts in Section 4 and introduce subsequent papers in the CKS series that leverage these improved stellar and planetary properties.

* Based on observations obtained at the W. M. Keck Observatory, which is operated jointly by the University of California and the California Institute of Technology. Keck time has been granted by the University of California, and California Institute of Technology, the University of Hawaii, and NASA.

2. Stellar Properties

2.1. Isochrone Modeling

Several groups have used theoretical models of stellar structure and evolution to compile grids of stellar properties (R_* , T_{eff} , etc.) as functions of M_* , $[\text{Fe}/\text{H}]$, and age. A set of models at constant metallicity and age is commonly called an “isochrone.” We used the Dartmouth Stellar Evolution Program (DSEP) models (Dotter et al. 2008) to convert the spectroscopic properties of T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ into M_* , R_* , and age. To facilitate this conversion, we used the publicly available Python package *isochrones* (Morton 2015),¹³ which interpolates between the discrete grid of DSEP models to derive properties at off-grid values.

One feature of *isochrones* is the capability to use Markov Chain Monte Carlo (MCMC) sampling¹⁴ to compute the range of physical parameters (M_* , R_* , age, and other parameters), consistent with a set of user-defined observational constraints. In order to facilitate convergence, we seeded the sampler with initial guesses of M_* and age, which we computed using the publicly available Python package *isoclassify* (Huber et al. 2017),¹⁵ which uses the MESA Isochrones and Stellar Tracks (MIST) database (Paxton et al. 2011, 2013, 2015; Choi et al. 2016). Because *isoclassify* is a grid-based code, initializing *isochrones* takes only a few CPU-seconds per star. We then performed the more computationally expensive MCMC exploration of the likelihood surface using *isochrones*, which requires several CPU-minutes per star.

For each star, *isochrones* returned the set of stellar masses, radii, and ages consistent with the spectroscopic T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ from Paper I. While the stellar parameters of interest could be derived solely from the spectroscopic parameters, we included a single photometric band in order to estimate distances and to facilitate a comparison with *Gaia* parallaxes (Section 2.4). We used *K*-band from 2MASS (Skrutskie et al. 2006) because it was the reddest band available and thus the least sensitive to interstellar extinction.

We elected against including broadband photometry from multiple bands because doing so could have the deleterious effect of biasing our results away from the spectroscopic values. For *Kepler* target stars, typical uncertainties for 2MASS *K* and *J* apparent magnitudes are 0.02 mag. However, for a G2 star, an error in $J - K$ color of 0.02 mag corresponds to the difference in T_{eff} of ≈ 100 K, which is larger than the 60 K precision of the CKS effective temperatures (Casagrande et al. 2010; Pecaute & Mamajek 2013). The potential for such biases is compounded by uncertain line-of-sight extinction and photometric zero-point errors. We thus used only a single photometric band to avoid such biases. Interstellar extinction or zero-point errors in the input *K*-band magnitudes could influence the implied source distance, but not the derived M_* , R_* , and age, which are constrained solely from spectroscopy.

We list our derived M_* , R_* , and age measurements and uncertainties in Table 1, which are computed from the 16%, 50%, and 84% of the posterior samples. During the modeling, *isochrones* also sample T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$. Typically, these parameters reflect the input T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ from spectroscopy with our adopted uncertainties. In some cases,

where, by fluctuations or other errors, the spectroscopic constraints extend into regions of the HR diagram that are not populated by the DSEP models. In these cases, *isochrones* only sample T_{eff} , $\log g$, $[\text{Fe}/\text{H}]$, etc. that are allowed by the physics incorporated in the DSEP models. The behavior occurs most often in cool dwarf stars ($T_{\text{eff}} \lesssim 5300$ K), where the main sequence has a narrow spread in $\log g$. Following the notation of Valenti & Fischer (2005), we also list these isochrone-constrained properties, $T_{\text{eff,iso}}$, $\log g_{\text{iso}}$, $[\text{Fe}/\text{H}]_{\text{iso}}$ in Table 1.

The DSEP models also tabulate absolute stellar magnitudes in various band passes. By comparing stellar apparent magnitude to the theoretical absolute magnitude, one can compute an “isochrone parallax,” modulo line-of-sight extinction to the target star. In Table 1, we list this implied parallax, which we denote $\pi_{*,\text{iso}}$, to distinguish from trigonometric parallax, $\pi_{*,\text{trig}}$. We perform a comparison of $\pi_{*,\text{iso}}$ and $\pi_{*,\text{trig}}$ in Section 2.4.

2.2. Uncertainties

The *isochrones* framework computes the range of physical parameters (M_* , R_* , age, etc), consistent with the spectroscopic input constraints. The formal uncertainties on the stellar parameters are set by the uncertainties associated with T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$. The median formal uncertainties are 3.3%, 10.7%, and 0.10 dex in M_* , R_* , and age, respectively. The formal uncertainties associated with an individual star depend on its position in the HR diagram. We list the ranges of these uncertainties in Table 2. For M_* and R_* , the fractional errors are smallest for cool ($T_{\text{eff}} \lesssim 5300$ K) main-sequence stars because these quantities are constrained mainly by T_{eff} and $[\text{Fe}/\text{H}]$, which are known to high precision from spectroscopy. There is little dispersion in the DSEP models as a function of stellar age, due to the long timescales associated with the evolution of low-mass stars. Consequently, the formal uncertainties on stellar age are largest for these low-mass stars. The formal uncertainties on M_* and R_* are largest for evolved stars, because a larger variety of (M_* , R_* , age) combinations are consistent with the spectroscopic observables.

The formal errors from *isochrones* do not incorporate model-dependent uncertainties associated with the DSEP models. Quantifying the extent to which stellar models can accurately reproduce the physical properties of real stars involves detailed comparisons with stars that have physical parameters measured through some model-independent means such as eclipsing binary systems or interferometry (e.g., Boyajian et al. 2012). Such comparisons are an active area of research and are beyond the scope of this paper.

Here, we make an estimate of the size of such errors by comparing the physical parameters derived using two sets of models. In addition to interpolating between the DSEP tracks, *isochrones* can also interpolate between models from MESA Isochrones and Stellar Tracks (MIST) database (Paxton et al. 2011, 2013, 2015; Choi et al. 2016). We performed a parallel analysis of our spectroscopic parameters using the MIST models and compared the derived parameters. We found that M_* and age computed using these methods were consistent to 2% and 10%, respectively. For R_* , the degree of agreement between the models depended on whether a star had evolved off the main sequence. The radii were consistent to 2% and 10% for dwarfs and evolved stars, respectively. In this paper, we have adopted $\log g = 3.9$ dex as a convenient dividing line between dwarfs and evolved stars.

Note. Stellar parameters for the 1305 stars in the California-*Kepler* Survey (CKS) catalog. We provide the Tycho-2 identifier, where available. K is the apparent K -band magnitude from the Two Micron All Sky Survey (2MASS, Skrutskie et al. 2006). We used the `isochrones` Python package to derive the following physical parameters: $T_{\text{eff,iso}}$, $\log g_{\text{iso}}$, $[\text{Fe}/\text{H}]_{\text{iso}}$, M_* , R_* , $\log_{10}(\text{age})$, and $\pi_{*,\text{iso}}$. `isochrones` return posterior distributions on effective temperature, surface gravity, and metallicity, which we distinguish from the purely spectroscopic measurements as $T_{\text{eff,iso}}$, $\log g_{\text{iso}}$, $[\text{Fe}/\text{H}]_{\text{iso}}$. We list the trigonometric parallax ($\pi_{*,\text{trig}}$) for stars listed in the Tycho-*Gaia* Astrometric Solution (TGAS).

(This table is available in its entirety in machine-readable form.)

Table 2
Summary of Parameter Uncertainties

Parameter	Formal			Adopted		
	5%	50%	95%	5%	50%	95%
$\sigma(M_*)/M_*$	2.6%	3.3%	7.5%	3.3%	3.9%	7.8%
$\sigma(R_*)/R_*$	3.1%	10.7%	16.6%	3.7%	11.0%	17.3%
$\sigma(\log \text{age})$	0.05 dex	0.10 dex	0.30 dex	0.07 dex	0.11 dex	0.30 dex

Note. Summary of the uncertainties associated with stellar mass, radius, and age. The “formal” uncertainties returned by the `isochrones` framework do not incorporate model-dependent errors associated with the DSEP models. The uncertainties depend on a star’s position in the HR diagram and we summarize the range of errors by quoting the 5%, 50%, and 95%. The “adopted” uncertainties incorporate additional error terms, described in Section 2.2.

To account for model-dependent uncertainties, we added the following fractional uncertainties in quadrature to our CKS parameters: we added 2% to the mass uncertainties; we added 2% and 10% to the radius uncertainties for dwarfs and evolved stars respectively; and we added 10% to the age uncertainties.

Our adopted uncertainties are summarized in Table 2. Because the model-dependent uncertainties are typically smaller than the formal uncertainties, the inclusion of model-dependent errors affects only a small number of stars.

2.3. Comparison with Asteroseismology

To verify the integrity of our derived stellar masses and radii, we performed a comparison with values computed by Huber et al. (2013; H13 hereafter) using asteroseismology for 72 stars in common. H13 used the power in different Fourier modes in the *Kepler* light curves to derive M_* and R_* with precisions of 7% and 3%, respectively. Aside from a weak dependence on T_{eff} , which is determined from spectroscopy, asteroseismology relies on an independent set of observations and offers a good check on the precision and accuracy of our derived parameters. Furthermore, H13 relied on a suite of six stellar structure models¹⁶ that reduce the risk of systematic offsets in M_* or R_* common to both H13 and CKS.

In Figure 1, we compare M_* determined from spectroscopy and asteroseismology. On average, the spectroscopic M_* values are 1.7% smaller than the asteroseismic values with a 6.3% rms scatter in the ratio. We assessed the degree to which the errors associated with the CKS and H13 masses can account for the observed dispersion by computing the “reduced-chi-square” statistic:

$$\chi_r^2 = \frac{1}{N} \sum \frac{(M_{*,2} - M_{*,1})^2}{\sigma_1^2 + \sigma_2^2},$$

where subscripts 1 and 2 refer to the CKS and H13 parameters, respectively. A $\chi_r^2 = 1$ indicates that the quoted uncertainties can account for the observed dispersion. For the CKS–H13 M_* comparison, $\chi_r^2 = 0.6$, indicating reasonable errors.

Figure 1 also shows the agreement between spectroscopic and asteroseismic R_* . The median uncertainty on the spectroscopic radii is 11.0%, while the asteroseismic radii are measured to 3% (Huber et al. 2013). When examining both dwarf and giant stars, we observe an rms scatter of 11.2%. For dwarf stars (94% of the CKS sample), the agreement is slightly tighter, with an rms scatter of 9.7%. For the CKS–H13 R_* comparison, we find $\chi_r^2 = 1.0$, indicating that the reported uncertainties can account for the observed scatter.

We note a systematic trend in the ratio of the CKS and H13 R_* in the range of 1–3 $R_\odot$. While one could, in principle, improve the agreement between spectroscopic and asteroseismic radii with an

¹⁶ ASTEC (Christensen-Dalsgaard 2008), BaSTI (Pietrinferni et al. 2004), DSEP (Dotter et al. 2008), Padova (Marigo et al. 2008), Yonsei-Yale (Demarque et al. 2004), and YREC (Demarque et al. 2008).

Figure 1. Stellar masses (M_*) and radii (R_*) derived from asteroseismology (Huber et al. 2013; H13) and spectroscopy (this work) for 72 stars in common. Left: comparison of spectroscopic and asteroseismic M_* (linear scale). Equality is represented by the green line. We note that the spectroscopic M_* are 1.7% smaller on average and that there is a 6.3% rms dispersion in the ratios. Right: comparison of spectroscopic and asteroseismic R_* (log scale). For dwarf stars (94% of the CKS sample), we find that the spectroscopic R_* are 4.8% smaller on average and there is a 9.7% rms dispersion in the ratios.

ad hoc correction, we elect against adding this additional complication. The observed trend may raise some concern regarding the accuracy of R_* for stars smaller than $1.0 R_\odot$, where few asteroseismic anchor points exist. However, the spread in main-sequence stellar radii rapidly shrinks toward later type stars. For the cool dwarfs in the CKS sample, the stellar radii are primarily constrained by the spectroscopic effective temperatures, which are precise to 60 K.

Spectroscopy and isochrone modeling provide some information regarding the stellar age, though this parameter is not as well-constrained as either M_* or R_* in a fractional sense. For the CKS sample, the median uncertainty is 0.11 dex. Here, we assess the integrity of these uncertainties with comparisons to asteroseismology. As stars evolve, nuclear fusion changes the radial distribution of stellar mass, $\rho(r)$. In some cases, the frequencies of individual oscillation modes can be measured from photometry, and asteroseismology can probe $\rho(r)$. In these cases, asteroseismology provides additional leverage on stellar age beyond T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$.

In Figure 2, we show a comparison between CKS ages and ages from asteroseismic modeling of individual modes performed by Silva Aguirre et al. (2015; S15 hereafter) for 32 stars in common. S15 report median fractional age uncertainties of 0.056 dex. On average, the CKS ages are 0.02 dex with a scatter of 0.10 dex. For the CKS–S15 age comparison, we find $\chi_r^2 = 0.6$, which indicates that adopted errors can reasonably account for the observed scatter. We note that the quality of the CKS age constraints varies across the HR diagram. For cool dwarf stars, age is only constrained to a factor of two.

2.4. Comparison using Gaia Parallaxes

While we treat asteroseismology as the preferred benchmark with which to assess our spectroscopic parameters and uncertainties, we performed an additional assessment of the quality of the derived CKS stellar radii using trigonometric parallaxes, $\pi_{*,\text{trig}}$, from the Tycho–Gaia Astrometric Solution (TGAS; Michalik et al. 2015; Gaia Collaboration et al. 2016a, 2016b; Lindegren et al. 2016). As discussed in Section 2.1, one of the outputs of our isochrone modeling is a parallax measurement, $\pi_{*,\text{iso}}$. Comparing the two measurements of parallax is a good check on the quality of the CKS measurements of R_* . For example, if the CKS stellar radii were systematically large, the inferred distance to the stars would be systematically large, resulting in measurements of $\pi_{*,\text{iso}}$ that are systematically smaller than $\pi_{*,\text{trig}}$.

We compare $\pi_{*,\text{iso}}$ and $\pi_{*,\text{trig}}$ in Figure 2. On average $\pi_{*,\text{iso}}$ is 0.16 mas larger than $\pi_{*,\text{trig}}$. The two measurements of parallax have an rms dispersion of 0.51 mas, consistent with the typical uncertainties. We note that for the most distant objects in this sub-sample (having $\pi_{*,\text{trig}} < 2$ mas), $\pi_{*,\text{iso}}$ is often larger than the TGAS $\pi_{*,\text{trig}}$. As discussed in Paper I, the CKS program achieved uniform signal-to-noise on targets brighter than $K_p = 14.2$, regardless of distance, i.e., all stars in common. Therefore, we consider the possibility of an onset of systematic errors in the CKS parameters at parallaxes of less than 2 mas unlikely.

The possibility of systematic offsets in the TGAS distance scale has been the subject of considerable interest in the past year. Stassun & Torres (2016) found that the TGAS parallaxes were on average 0.25 mas smaller than those constrained from

Figure 2. Left: comparison of stellar ages derived from asteroseismology (Silva Aguirre et al. 2015; S15) and spectroscopy (this work). On average, the CKS ages are 0.02 dex with a scatter of 0.10 dex in the ratios. Right: comparison stellar parallax derived from spectroscopy, isochrones, K -band photometry ($\pi_{*,\text{iso}}$), and parallaxes from the Tycho-*Gaia* Astrometric Solution ($\pi_{*,\text{trig}}$). The majority of the sample is consistent within errors, with a possible systematic offset for the most distant stars.

eclipsing binaries. Similar offsets were also reported by Jao et al. (2016), who compared TGAS parallaxes to literature values of nearby stars, and by Silva Aguirre et al. (2017), who compared TGAS parallaxes against asteroseismic parallaxes for 66 main-sequence stars. In contrast, Huber et al. (2017), who performed a comparison of TGAS and asteroseismic parallaxes for 2200 stars, observed no offset, nor did Casertano et al. (2017), who compared TGAS parallaxes to parallaxes derived from Cepheids.

The small number of comparison stars with $\pi_{*,\text{trig}} < 2$ mas combined with the large fractional errors in the TGAS for such stars prevents a detailed assessment of systematics in the TGAS. We expect that this offset will diminish in future *Gaia* data releases that will rely solely on *Gaia* measurements. In the near future, *Gaia* will provide parallaxes for all stars in the CKS sample. Comparisons between the CKS parallaxes and *Gaia* parallaxes will enable detailed assessments of systematics inherent to both CKS and *Gaia* and constrain dust extinction in the direction of the *Kepler* field.

2.5. Comparison with Photometric Parameters

We compare our new stellar parameters to those in the Q1-Q16 KOI catalog (Mullally et al. 2015), which we accessed via the NASA Exoplanet Archive (Akeson et al. 2013)¹⁷ on 2016 December 12. The Q1-Q16 KOI catalog (Q16 hereafter) contains the stellar properties of Huber et al. (2014), which were derived from various literature sources based on asteroseismology, spectroscopy, and photometry.

The vast majority, 969/1305 (74%) of the stars in the Huber et al. (2014) catalog that appear in the CKS sample have only

photometric constraints on $\log g$. However, only 88/1305 (7%) of CKS stars had previous asteroseismic constraints, and 220/1305 (17%) had previous spectroscopic constraints on $\log g$. Our new spectroscopic constraints on $\log g$ and stellar radius are generally more precise than the previous photometric or spectroscopic constraints, but we do not improve the stellar radius precision for stars that already had asteroseismic constraints.

Median uncertainties in the Q16 catalog are 13.4% and 38% for stellar mass and radius respectively, while the median uncertainties presented in this work are 3.9% and 11.0% for stellar mass and radius respectively. We computed the fractional differences in stellar radii,

$$\frac{\Delta R_{\star}}{R_{\star}} = \frac{R_{\star,\text{CKS}} - R_{\star,\text{Q16}}}{R_{\star,\text{CKS}}},$$

to assess the offset and scatter between the two samples. When considering all CKS stars, we found a modest offset between the CKS and Q16 radii, $\text{mean}(\Delta R_{\star}/R_{\star}) = 2.8\%$ and a scatter of $\text{rms}(\Delta R_{\star}/R_{\star}) = 28.2\%$ after removing seven outliers with radii differing by more than a factor of two. We computed the fractional differences in stellar masses,

$$\frac{\Delta M_{\star}}{M_{\star}} = \frac{M_{\star,\text{CKS}} - M_{\star,\text{Q16}}}{M_{\star,\text{CKS}}}.$$

On average, the CKS masses had a small offset with respect to the Q16 masses, $\text{mean}(\Delta M_{\star}/M_{\star}) = 1.8\%$ with a scatter $\text{rms}(\Delta M_{\star}/M_{\star}) = 11.2\%$ after removing nine outliers with masses differing by more than a factor of two.

We compare the Q16 and CKS radii as a function of effective temperature in Figure 3. Although the average CKS

¹⁷ <http://exoplanetarchive.ipac.caltech.edu/>

Figure 3. Top left: R_* and T_{eff} from the Q1-Q16 KOI Catalog (Q16; Mullally et al. 2015) for the stars in the CKS sample. The parameters are primarily based on broadband photometry, with a small number from astroseismology and previous spectroscopic studies. The green bar reflects the median uncertainties. Top right: same but showing spectroscopic parameters from this work. Bottom: enlarged representation of the CKS and Q16 parameters to highlight differences between the two samples. We identify stars having Q16 properties that fall within each of the black boxes and the circles represent the mean Q16 (T_{eff} , R_*). The lines point to the mean CKS (T_{eff} , R_*) for these same stars to highlight the systematic offsets in between two catalogs as a function of T_{eff} and R_* . The largest difference is for the hottest stars, which have systematically lower spectroscopic temperatures. A number of stars that the Q16 catalog designates as subgiants are reclassified as dwarfs, which account for the downward shift in the upper right grid cell.

Figure 4. Left: number of CKS planet candidates having different sizes. Here, the planet radii are taken from the Q1-Q16 KOI catalog (Q16; Mullally et al. 2015). The error bar shows the median uncertainty in planet radius. Right: same but showing planet radii computed using the CKS spectroscopic parameters. We note the emergence of structure in the CKS histogram of radii, the statistical significance of which requires further work, presented in Fulton et al. (2017).

Table 3
Summary of Typical Parameter Uncertainties

Source Method	Q16				CKS Spec.
	All	AS	Spec.	Phot.	
N_*	1277	88	220	969	1305
$\sigma(M_*)/M_*$	14%	6.9%	7.1%	16%	3.9%
$\sigma(R_*)/R_*$	39%	2.9%	17%	42%	11.0%
$\sigma(\log \text{ age})$	...	...	...	...	0.11 dex
$\sigma(R_p)/R_p$	38%	2.8%	17%	42%	12%
$\sigma(S_{\text{inc}})/S_{\text{inc}}$	113%	12%	48%	124%	21%
$\sigma(a)/a$	...	...	...	...	1.7%

Note. Summary of median quoted uncertainties for Q1-Q16 KOI catalog (Q16; Mullally et al. 2015) and the CKS sample. We also list uncertainties for the sub-samples of the Q16 parameters based on asteroseismology, spectroscopy, or photometry. The CKS survey contains a few dozen stars not included in the Q16 catalog.

and Q16 radii agree at the few percent level, we note significant temperature-dependent systematics for stars having $T_{\text{eff}} \gtrsim 6000$ K. For dwarf stars ($R_p < 1.5 R_\odot$), the CKS parameters prefer cooler and slightly larger stars. For slightly evolved stars ($R_p > 1.5 R_\odot$) the CKS stellar properties favor cooler and smaller stars. For the hottest stars, the typical offset between the spectroscopic and photometric T_{eff} reaches 200 K.

Measuring T_{eff} and $\log g$ from photometry introduces systematics, which are discussed in previous stellar classification papers (e.g., Pinsonneault et al. 2012; Huber et al. 2014). These systematics are due to the fact that photometry provides little independent leverage on T_{eff} , $\log g$, and reddening. Both Pinsonneault et al. (2012) and Huber et al. (2014) apply *ad hoc* corrections to the photometric T_{eff} which grow to 400 K at 6500 K. Given that we observe offsets of 200 K, we conclude that these *ad hoc* corrections did not completely remove the systematic errors associated with photometric T_{eff} .

3. Planet Properties

We used our newly measured stellar parameters to recalculate several important planetary parameters. We began with the transit fit parameters from the Q16 KOI catalog (Mullally et al. 2015). We recomputed planet radii (R_p) using the published transit depths and the CKS R_* . Given that the planet radii are limited by uncertainties in the stellar radii, the

CKS stellar radii enable an improvement of planet radii R_p from $\sigma(R_p)/R_p \approx 38\%$ to 12%.

Figure 4 shows the distribution of planet radii from the Q16 catalog and from this paper. The general features of the two histograms are similar. We note apparent structure in the histogram of the CKS radii that is not apparent in the Q16 histogram. The statistical significance of this structure in the planet radius distribution will be explored in detail in Paper III of this series (Fulton et al. 2017).

Using our updated stellar properties, we recomputed planet semimajor axes a , incident stellar flux S_{inc} , and equilibrium temperature T_{eq} , assuming circular orbits. Semimajor axes are computed using *Kepler's* Third Law. Because orbital periods are measured very precisely from *Kepler* photometry, uncertainty in a is set by the uncertainty in M_* according to

$$\frac{\sigma(a)}{a} = \frac{1}{3} \frac{\sigma(M_*)}{M_*} \approx 1.7\%. \quad (1)$$

One could, in principle, compute a from R_*/a , measured from the transit profile, and R_* . However, R_*/a has large uncertainties due to the assumption of a circular orbits and degeneracies with impact parameter. At a minimum, the uncertainty in semimajor axis computed according to this second method is

$$\frac{\sigma(a)}{a} \gtrsim \frac{\sigma(R_*)}{R_*} \approx 10\%, \quad (2)$$

which is far less precise than the calculation using *Kepler's* Third Law.

We compute the incident flux as

$$\frac{S_{\text{inc}}}{S_\oplus} = \left(\frac{T_{\text{eff}}}{5778 \text{ K}} \right)^4 \left(\frac{R_*}{R_\odot} \right)^2 \left(\frac{a}{\text{au}} \right)^{-2}. \quad (3)$$

For convenience, we also provide planetary equilibrium temperature, T_{eq} , defined according to

$$\left(\frac{T_{\text{eq}}}{280 \text{ K}} \right) = \left(\frac{S_{\text{inc}}}{S_\oplus} \right)^{1/4} \left(\frac{1 - \alpha}{4} \right)^{1/4}, \quad (4)$$

assuming a Bond albedo α of 0.3, typical for super-Earth-size planets (Demory 2014). Because S_{inc} depends on T_{eff}^4 and R_*^2 our spectroscopic improvements T_{eff} and R_* result in a substantial

Table 4
CKS Planet Parameters

improvement in S_{inc} from $\sigma(S_{\text{inc}})/S_{\text{inc}}$ of 113% to 21%. We summarize the uncertainties associated with CKS and Q16 stellar and planetary properties in Table 3. The updated planetary parameters for the 2025 planet candidates in the CKS sample are listed in Table 4.

4. Conclusion

In this work, we converted the measured spectroscopic stellar parameters presented in Paper I to the physical stellar masses, radii, and ages for 1305 stars in the CKS sample. We used these properties to improve knowledge of the physical properties of 2025 planet candidates including R_p and S_{inc} .

These improved stellar and planet properties will yield new insights into the *Kepler* sample of planets, some of which will be explored in subsequent papers in this series. Paper III (Fulton et al. 2017) examines the planet radius distribution, brought into sharper focus by the improved uncertainties in planet size. In Paper IV (E. A. Petigura et al. 2017, in preparation), we explore the extent to which host star metallicity is connected to other planet properties. Paper V (Weiss et al. 2017), explores the connection between stellar and planet properties in the context of planetary multiplicity and system architectures.

Finally, we encourage the community to use the CKS data set. The spectra are available on the CFOP.¹⁸ The spectroscopic parameters are given in Paper I and are also available in machine readable form on GitHub¹⁹ along with the derived parameters and the code used compute the derived parameters. We expect and anticipate that these data will prove useful for many additional projects.

The CKS project was conceived, planned, and initiated by A.W.H., G.W.M., J.A.J., H.T.I., and T.D.M. A.W.H., G.W.M., J.A.J. acquired Keck telescope time to conduct the magnitude-limited survey. Keck time for the other stellar samples was acquired by J.N.W., L.A.R., and G.W.M. The observations were coordinated by H.T.I. and A.W.H. and carried out by A.W.H., H.T.I., G.W.M., J.A.J., T.D.M., B.J.F., L.M.W., E.A.

P., E.S., and L.A.H. A.W.H. secured CKS project funding. SpecMatch was developed and run by EAP and SME@XSEDE was developed and run by L.H. and P.A.C. E.A.P. computed derived planetary and stellar properties with assistance from B.J.F. This manuscript was largely written by E.A.P. with significant assistance from A.W.H., G.W.M., and B.J.F.

We thank Jason Rowe, Dan Huber, and Jeff Valenti for helpful conversations and Roberto Sanchis-Ojeda for his work on the Ultra-Short Period planet sample. We thank the many observers who contributed to the measurements reported here. We gratefully acknowledge the efforts and dedication of the Keck Observatory staff, especially Randy Campbell, Scott Dahm, Greg Dopmann, Marc Kassiss, Jim Lyke, Hien Tran, Josh Walawender, and Greg Wirth for support with HIRES and with remote observing. Most of the data presented here are based on spectra obtained at the W. M. Keck Observatory, which is operated as a scientific partnership among the California Institute of Technology, the University of California, and NASA. We are grateful to the time assignment committees of the University of Hawaii, the University of California, the California Institute of Technology, and NASA for their generous allocations of observing time that enabled this large project. *Kepler* was competitively selected as the tenth NASA Discovery mission. Funding for this mission is provided by the NASA Science Mission Directorate. We thank the *Kepler* Science Office, the Science Operations Center, Threshold Crossing Event Review Team (TCERT), and the Followup Observations Program (FOP) Working Group for their work on all steps in the planet discovery process ranging from selecting target stars and pointing the *Kepler* telescope to developing and running the photometric pipeline to curating and refining the catalogs of *Kepler* planets. E.A.P. acknowledges support from Hubble Fellowship grant *HST*-HF2-51365.001-A awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc. for NASA under contract NAS 5-26555. A.W.H. acknowledges NASA grant NNX12AJ23G. T.D.M. acknowledges NASA grant NNX14AE11G. P.A.C. acknowledges NSF grant AST-1109612. L.H. acknowledges NSF grant AST-1009810. L.M.W. acknowledges support from Gloria and Ken Levy and from the the Trotter Family. E.S. is supported by a post-

graduate scholarship from the Natural Sciences and Engineering Research Council of Canada. This work made use of the SIMBAD database (operated at CDS, Strasbourg, France), NASA's Astrophysics Data System Bibliographic Services, and the NASA Exoplanet Archive, which is operated by the California Institute of Technology, under contract with the National Aeronautics and Space Administration under the Exoplanet Exploration Program. This work has made use of data from the European Space Agency (ESA) mission *Gaia*, processed by the *Gaia* Data Processing and Analysis Consortium. Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement.

Finally, the authors wish to recognize and acknowledge the very significant cultural role and reverence that the summit of Maunakea has always had within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain.

Facilities: Keck:I (HIRES), *Kepler*.
