Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

Abstract

A multi-scale hybrid quantum/classical approach using classical electrodynamics and a collection of discrete three-level quantum systems is used to simulate the coupled dynamics and spectra of a malachite green monolayer adsorbed to the surface of a spherical gold nanoparticle (NP). This method utilizes finite difference time domain (FDTD) to describe the plasmonic response of the NP within the main FDTD framework and a three-level quantum description for the molecule via a Maxwell/Liouville framework. To avoid spurious self-excitation, each quantum molecule has its own auxiliary FDTD subregion embedded within the main FDTD grid. The molecular parameters are determined by fitting the experimental extinction spectra to Lorentzians, yielding the energies, transition dipole moments, and the dephasing lifetimes. This approach can be potentially applied to modeling thousands of molecules on the surface of a plasmonic NP. In this paper, however, we first present results for two molecules with scaled oscillator strengths to reflect the optical response of a full monolayer. There is good agreement with experimental extinction measurements, predicting the plasmon and molecule depletions. Additionally, this model captures the polariton peaks overlapped with a Fano-type resonance profile observed in the experimental extinction measurements. This technique can be generalized to any nanostructure/multi-chromophore system, where the molecules can be treated with essentially any quantum method.

Keywords

plasmons, polaritons, Fano resonance, quantum/classical modeling, electrodynamics, quantum mechanics, finite-difference time-domain

1 Introduction

Noble metal nanoparticles (NPs) possess unique chemical, electronic, and optical properties with important applications spanning molecular sensing, catalysis, metamaterials, and

biologically-relevant technologies.^{1–10} Many of these applications exploit field enhancements due to localized surface plasmon resonances, which are coherent oscillations of the free electrons at the NPs surface.^{11–14} Changing the composition, size, shape, and surrounding medium allows for tunable optical properties of these plasmonic NPs. These broadly tunable NPs show promise for the molecular detection, metamaterials, and novel dispersion properties.¹⁵ Plasmonic gold and silver nanoparticles can be functionalized with biological molecules and polymers through thiolation for applications in biolabeling,^{16,17} drug delivery,^{11,18} and photothermal therapy.^{19–21}

Nonlinear responses of plasmonic nanoparticles such as second harmonic generation (SHG) and sum frequency generation (SFG) can be significantly enhanced due to these plasmon resonances.^{22–29} Additionally, interactions between plasmonic nanoparticles and chromatic dyes give rise to molecular and plasmonic resonance coupling, which can be measured via extinction spectroscopy. When the plasmon frequency is in resonance with a molecular excitation, strong coupling can lead to the formation of hybrid states, resulting in exciton-polariton peaks separated by a splitting energy. Additionally, this coupling leads to characteristic Fano-type resonances with corresponding plasmon and molecular spectral depletions.^{30–32,32–38}

The near-field dynamics and coupled dynamics of molecules, such as light harvesting dyes adsorbed to the surface of plasmonic nanostructures,¹¹ show promise in the fields of photovoltaics, catalysis, and chemical sensing. For example, the strong fields near the surface of metal nanoparticles can boost the response of nearby adsorbates in low concentrations which is ideal for sensing applications such as surface enhanced Raman spectroscopy (SERS), or conversely, the optical responses of molecules at the surface of metallic nanostructures can induce plasmonic modes via surface-enhanced fluorescence. There has been much recent progress towards modeling these hybrid molecular/plasmonic systems. Some of the many approaches to model the dynamics between plasmons and molecules include point-plasmon/random phase approximation (RPA),^{39,40} a molecule treated with time-dependent

Hartree Fock coupled to a continuous dielectric metal nanoparticle,⁴¹ resonant energy transfer via quantum molecules embedded in a classical continuum background,^{42,43} coupled Liouville/Maxwell equations,⁴⁴ electrodynamics coupled to a density matrix master equation,³³ extended Mie Theory on plasmonic nanospheres coupled to a two-level quantum model,⁴⁵ finite-difference time-domain/real time-TDDFT,^{46–49} and quantum electrodynamics coupled with time-dependent Hartree-Fock.³²

Quantum/classical approaches based on a finite-difference time-domain (FDTD) solution to Maxwell's equations, with embedded quantum oscillators, are especially versatile as they can describe arbitrary geometries of nanostructures with a nearby quantum emitter (e.g., molecule or quantum dot), potentially with solvent effects included. Typically these approaches involve a single quantum point source, but in many real systems there is coupling between nanoparticles (NPs) and thousands of nearby dyes (e.g., adsorbed on the surface). This requires an extensible approach capable of describing an arbitrary number of quantum sub-regions within the FDTD main grid. In this paper, we present a method for modeling a monolayer of molecules on the surface of a spherical plasmonic nanoparticle using two "super molecules" and compare these results to experimental extinction measurements. The method can readily be extended to an arbitrary number of molecules. We use a phenomenological N -level Hamiltonian for each molecule, but this approach can be extended to accommodate any quantum description.

The remainder of the paper is structured as follows: In Sec. 2, we present expressions for the FDTD evolution of the electric fields, magnetic fields, currents and polarizations for a combined plasmon/molecule system, followed by an explanation of how to implement a combined FDTD/ N -level approach. Sec. 3 presents validation simulations including: single gold NP extinction spectra, long-range resonant energy transfer (FRET) between two molecules, and finally difference extinction spectra for malachite green monolayers adsorbed on a Au NP (See Fig. 1). Comparison of these spectra with experiment allows us to extract approximate transition dipole angles and monolayer separation distances. Finally, conclusions and

Figure 1: Schematic of the gold/dye interface. The cationic malachite green (MG) molecules are held at the surface via electrostatic interactions with the anionic mercaptosuccinic acid (MSA) with a small water solvation layer between the MG and MSA. The transition dipole moment for the brightest absorption is tilted with respect to the normal of the surface by angle η . Assuming roughly two water shells, the overall separation ℓ between the Au surface and the MG center of mass is roughly 25.4 Å. For simplicity, in this paper we approximate the molecular monolayer as two supermolecules with scaled oscillator strengths.

future extensions are presented in Sec. 4.

2 Theory

In this section, we outline an approach for coupling multiple quantum oscillators within a classical electrodynamics background described using FDTD. Broadly, this involves five components:

1. Describe the electric and magnetic fields in the vacuum (or background medium), and the fields and currents on the metal nanoparticle, using FDTD.
2. Partition an auxiliary FDTD subregion around each quantum oscillator (molecule) to remove spurious self-excitation of the molecules with their radiated fields. This uses a total-field/scattered-field (TF/SF) approach.
3. Propagate each quantum molecule in time under the influence of the external field

from the FDTD. This can be done using any quantum method, but here we use phenomenological N -level molecules.

4. The quantum currents on each molecule act as source terms for the main FDTD grid via the TF/SF boundary around each molecular subregion.

2.1 Basic FDTD Considerations

In the finite-difference time-domain (FDTD) approach, the fields and currents are discretized on a grid and solved in time and space using a “leap-frog” integrator.⁵⁰ The spatial and frequency-dependent permittivity $\varepsilon(r)$ and permeability, $\mu(r)$ are typically fit to experimental bulk values. Neglecting magnetization effects in the metal (i.e., $\mu = \mu_0$), the Maxwell’s equations are:

$$\varepsilon_{\text{eff}}(\mathbf{r}) \frac{\partial}{\partial t} \mathbf{E}(\mathbf{r}, t) = \nabla \times \mathbf{H}(\mathbf{r}, t) - \mathbf{J}(\mathbf{r}, t) \quad (1a)$$

$$\mu_0 \frac{\partial}{\partial t} \mathbf{H}(\mathbf{r}, t) = -\nabla \times \mathbf{E}(\mathbf{r}, t) \quad (1b)$$

where $\mathbf{E}(\mathbf{r}, t)$ is the electric field, $\mathbf{H}(\mathbf{r}, t)$ is the magnetic field, and $\mathbf{J}(\mathbf{r}, t)$ is the electric current density. Note that in this paper, $\mathbf{J}$ is only present on the metal nanostructure.

To avoid issues with “hard sources,” where propagated fields interact in non-physical ways with the source, we use a total-field scattered-field (TF/SF) approach.^{51–53} Here, an auxiliary 1D simulation with a specified pulse is propagated separately from the main 3D grid. To excite the system, the 1D incident field is projected to 3D and added uniformly to one side of the TF/SF boundary. The pulse is then subtracted out as it reaches the opposite side, resulting in purely scattered fields outside the TF/SF boundary. By subtracting the incident field, the resulting simulation outside the total-field region contains only scattered fields. This technique is commonly used to calculate the scattering cross sections of arbitrary objects via the outgoing flux (outside the TF/SF) along with a near-to-far-field transform (NTFF).⁵⁴ The corresponding absorption cross section can be computed inside the TF region using flux monitors, but this approach can be somewhat sensitive to monitor position and

grid spacing. Details on calculating the absorption and scattering cross sections are outlined in the Supporting Information.

2.2 Coupling between Quantum Mechanics and FDTD

The electron dynamics in molecules must be described using quantum mechanics, which necessitates a multiscale coupling between the main FDTD grid and multiple quantum sub-regions. We assume that each molecule only occupies one FDTD grid point. This can be justified for both the absorption and emission of the molecule as follows: For absorption, when the wavelength of light is much greater than the size of the molecule, the applied field on a molecule is essentially constant. Thus, the coupling is dominated by dipolar coupling and the molecule can be treated as experiencing a uniform electric field with the value given by the FDTD field at a single point in space (at the center of mass of the molecule). For the molecular radiation, the fields near the molecule may not be dipolar (especially for long chromophores) but will become dipolar far enough away from the molecule. Given the relatively large distances between the NP and molecules (~ 25 Å), this is also a reasonable approximation. Extensions to close molecule-molecule distances may require going beyond this dipolar emission approximation. This can be accomplished by solving the FDTD and QM on the same (or overlaid) grids.⁴⁸ Thus, the FDTD electric field at that point acts as an external field on the molecule, and the molecular current acts as a source for the FDTD. Direct application of this, however, results in spurious self-excitation of the molecule, as the radiated field can immediately “re-excite” the emitting molecule. One way of overcoming this is to use a full auxiliary FDTD grid for each molecule,⁴⁰ but this is not tractable for a large number of molecules. A better alternative is to instead partition a small FDTD region around each molecule using a TF/SF-like coupling, such as the approach developed by Seideman and coworkers.⁴⁴ By propagating the fields in this small region using the analytical expression for a radiating dipole, the radiated fields from the molecule do not interact with the molecule itself, but are instead coupled back into the main grid some distance away

using a “reverse” TF/SF boundary. In this paper we instead propagate using a FDTD with a point source, which is valid for any quantum emitter.

Figure 2: Schematic of the multiscale quantum/classical approach. A main finite-difference time-domain (FDTD) region contains the background and any potential metal nanostructures, while each quantum molecule is contained within its own FDTD subregion. These molecules are excited via the electric field in the main region, but emit into their own auxiliary sub-region to prevent self-excitation. These emitted fields are then introduced into the main region using reverse total-field/scattered-field (TF/SF)-like interfaces (arrows). This approach allows for an arbitrary number of quantum molecules treated using any quantum method.

Fig. 2 shows a schematic of the approach for the case of two molecules. The main FDTD has two regions: a total field (TF) region which contains all nanostructures and molecules, and a scattered field (SF) region which contains only the scattered fields (i.e., no incident pulse). The boundary of the main FDTD region was taken to be a second-order Mur absorbing boundary to remove non-physical reflections.⁵² The system is excited with a broadband pulse via the TF/SF interface, as described in the previous section. This electric field then acts as an external applied source for each quantum molecule in the region. Rather

than radiate back into the TF region, which would allow the molecule to nonphysically excite itself, instead each molecule radiates into its own auxiliary FDTD region centered around the molecule (see Fig. 2). After propagating some distance from the molecule, this molecular field is then added back to the main FDTD grid via a “reverse” TF/SF boundary. These interfaces act as sources for the TF region. Finally, each molecular subregion has its own absorbing boundary to prevent reflections.

An approach based on point polarizable dipole molecules, parameterized to either experiment or QM calculations, would likely give a similar result for this application. Our embedded time-dependent quantum method, however, can be extended to other nontrivial cases. Because this method propagates the quantum molecules in the time domain, it can capture nonlinear responses such as strong field excitations (e.g., Rabi cycling, tunnel ionization,⁵⁵ etc), and multiphoton processes (e.g., hyperpolarizabilities,⁵⁶ high harmonic generation, etc.). Additionally, it allows for extension to molecular photochemistry under plasmonic fields via non-adiabatically⁵⁷ (beyond Born-Oppenheimer) coupled electron/nuclear dynamics simulations (e.g., surface hopping).

This technique has three advantages: (1) It does not assume any analytic form for the molecular fields and is thus valid for any quantum point source (e.g., non-dipolar), (2) if the grid parameters are consistent between the main and molecular FDTD regions, artifacts from the interfaces will be minimal, and (3) it can be extended to a large number of molecules, as the computational cost associated with each subregion is insignificant compared to the main grid, and each region can be computed in parallel.

2.3 *N*-Level System with Dephasing

The above-described embedding technique is valid for virtually any quantum treatment of the molecules (e.g., time-dependent Schrödinger equation, time-dependent density functional theory, etc). For simplicity, here we will use a phenomenological *N*-level picture for the quantum dynamics. In the density matrix representation, the equation of motion is governed

by the von Neumann equation:

$$i\frac{\partial\rho(t)}{\partial t} = [\rho(t), H(t)] \quad (2)$$

where for a N -level system H and ρ are $N \times N$ matrices. To incorporate dephasing, it is convenient to instead use a Liouville representation:

$$i\frac{\partial||\rho(t)\rangle\rangle}{\partial t} = \mathcal{L}||\rho(t)\rangle\rangle, \quad (3)$$

where $||\rho(t)\rangle\rangle$ is the density vector (length N^2) and $\mathcal{L}$ is the Liouville operator (matrix size $N^2 \times N^2$)

$$||\rho(t)\rangle\rangle = \begin{pmatrix} \rho_{11}(t) \\ \rho_{12}(t) \\ \vdots \\ \rho_{1N}(t) \\ \rho_{21}(t) \\ \vdots \\ \rho_{NN}(t) \end{pmatrix} \quad (4)$$

The Liouville operator can be constructed from the Hamiltonian by converting from 2-index to 4-index form:

$$\mathcal{L}_{jklm} = H_{jl}\delta_{km} - H_{mk}\delta_{jl} \quad j, k, l, m \in [1, N] \quad (5)$$

where, without dephasing, the Hamiltonian is given by

$$\mathbf{H}(t) = \mathbf{H}^0 - \boldsymbol{\mu} \cdot \mathbf{E}(t) \quad (6)$$

and μ is the transition dipole (tensor) operator, $\mathbf{E}(t)$ is a time dependent electric field, and $\mathbf{H}_{kl}^0 = \varepsilon_k \delta_{kl}$. The transition dipole matrix elements in direction d are

$$\mu_{kl}^d = -\langle k|d|l\rangle, \quad (d = \{x, y, z\}) \quad (7)$$

The 4-index $\mathcal{L}^0$ operator ($N \times N \times N \times N$) is then reshaped to 2-index for ($N^2 \times N^2$). For example, if $N = 2$

$$\mathcal{L}^0 = \begin{pmatrix} 0 & \mu_{12} \cdot E & -\mu_{12} \cdot E & 0 \\ \mu_{12} \cdot E & -\Delta\varepsilon_{2-1} + \Delta\mu_{2-1} \cdot E & 0 & -\mu_{12} \cdot E \\ -\mu_{12} \cdot E & 0 & \Delta\varepsilon_{2-1} - \Delta\mu_{2-1} \cdot E & \mu_{12} \cdot E \\ 0 & -\mu_{12} \cdot E & \mu_{12} \cdot E & 0 \end{pmatrix} \quad (8)$$

where the energy of the transition is defined as $\Delta\varepsilon_{l-k} = \varepsilon_l - \varepsilon_k$ (e.g., $\Delta\varepsilon_{2-1} = \varepsilon_2 - \varepsilon_1$), and the difference in static dipole moments is defined as $\Delta\mu_{l-k} = \mu_l - \mu_k$. For a three level

system (N=3), we get

$$\mathcal{L}^0 = \begin{pmatrix} 0 & \mu_{12} \cdot E & \mu_{13} \cdot E & -\mu_{12} \cdot E & 0 \\ \mu_{12} \cdot E & -\Delta\varepsilon_{2-1} + \Delta\mu_{2-1} \cdot E & \mu_{21} \cdot E & 0 & -\mu_{12} \cdot E \\ \mu_{13} \cdot E & \mu_{23} \cdot E & -\Delta\varepsilon_{3-1} + \Delta\mu_{3-1} \cdot E & 0 & 0 \\ -\mu_{12} \cdot E & 0 & 0 & \Delta\varepsilon_{2-1} - \Delta\mu_{2-1} \cdot E & \mu_{12} \cdot E \\ 0 & -\mu_{12} \cdot E & 0 & \mu_{12} \cdot E & 0 \\ 0 & 0 & -\mu_{12} \cdot E & \mu_{13} \cdot E & \mu_{23} \cdot E \\ -\mu_{13} \cdot E & 0 & 0 & -\mu_{23} \cdot E & 0 \\ 0 & -\mu_{13} \cdot E & 0 & 0 & -\mu_{23} \cdot E \\ 0 & 0 & -\mu_{13} \cdot E & 0 & 0 \\ 0 & -\mu_{13} \cdot E & 0 & 0 & 0 \\ 0 & 0 & -\mu_{13} \cdot E & 0 & 0 \\ -\mu_{12} \cdot E & 0 & 0 & -\mu_{13} \cdot E & 0 \\ \mu_{13} \cdot E & -\mu_{23} \cdot E & 0 & 0 & 0 \\ \mu_{23} \cdot E & 0 & -\mu_{12} \cdot E & 0 & 0 \\ -\Delta\varepsilon_{3-2} + \Delta\mu_{3-2} \cdot E & 0 & 0 & -\mu_{23} \cdot E & 0 \\ 0 & \Delta\varepsilon_{3-1} - \Delta\mu_{3-1} \cdot E & \mu_{12} \cdot E & \mu_{13} \cdot E & 0 \\ 0 & -\mu_{12} \cdot E & \Delta\varepsilon_{3-2} - \Delta\mu_{3-2} \cdot E & \mu_{23} \cdot E & 0 \\ -\mu_{23} \cdot E & \mu_{13} \cdot E & \mu_{23} \cdot E & 0 & 0 \end{pmatrix} \quad (9)$$

Now if we want to introduce dephasing of the coherences (i.e., T_2 lifetimes) in a Redfield-like picture,⁵⁸ we add an imaginary part to the Liouville operator

$$\mathcal{L} = \mathcal{L}^0 + i\mathcal{L}^d \quad (10)$$

In 4-index form:

$$\mathcal{L}_{j,k,l,m}^d = \gamma_{jk} \delta_{jk,jk}, \quad j \neq k \quad (11)$$

where $\gamma_{jk} = \gamma_{kj}$ and the dephasing parameters are the inverse of the T_2 lifetimes:

$$T_{2,jk} = \frac{1}{\gamma_{j,k}} \quad (12)$$

Note that we have not included T_1 lifetimes here (energy loss/damping) although this is easily done. E.g. for $N = 2$

$$\gamma_{12} = \gamma_{21} = -\frac{i}{T_{2,12}} \quad (13)$$

and zero for other terms.

For a three level system, the 4-index dephasing Liouvillian is:

$$\mathcal{L}_{12,12}^d = \mathcal{L}_{21,21}^d = -i\gamma_{12} \quad (14a)$$

$$\mathcal{L}_{13,13}^d = \mathcal{L}_{31,31}^d = -i\gamma_{13} \quad (14b)$$

$$\mathcal{L}_{23,23}^d = \mathcal{L}_{32,32}^d = -i\gamma_{23} \quad (14c)$$

(other terms are zero). In the 2-index form:

$$\mathcal{L}^d = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -i\gamma_{12} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -i\gamma_{13} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -i\gamma_{12} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -i\gamma_{23} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -i\gamma_{13} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -i\gamma_{23} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \quad (15)$$

Now, if we assume the system starts purely in the ground state

$$||\rho(0)\rangle\rangle = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (16)$$

we can propagate $||\rho(t)\rangle\rangle$ by integrating the equation of motion:

$$||\rho(t + \Delta t)\rangle\rangle = \hat{U} ||\rho(t)\rangle\rangle \quad (17)$$

where the propagator $\hat{U} \equiv e^{-i\mathcal{L}(t)\Delta t}$. In simple cases, the matrix exponentiation can be done using diagonalization, but other methods, such as power series expansion, can be used.^{59,60}

Now, the expectation value of the polarization can be computed from the density vector:

$$\langle p^d(t) \rangle = p^d(t) = \langle \langle \mu^d | \rho(t) \rangle \rangle \quad (18)$$

where μ^d is the dipole superoperator in the d -direction:

$$\mu^d = \begin{pmatrix} \mu_{11}^d \\ \mu_{12}^d \\ \mu_{13}^d \\ \vdots \\ \mu_{1N}^d \\ \vdots \\ \mu_{NN}^d \end{pmatrix} \quad (19)$$

Note, this includes on-diagonals μ_{kk} which represent static dipole moments of the ground and excited states. The time derivative of the polarization (Eq. 18) is required for coupling

to the FDTD:

$$\frac{\langle p(t) \rangle}{dt} = \frac{d}{dt} \langle \langle \mu | \rho(t) \rangle \rangle \quad (20a)$$

$$\frac{d}{dt} \langle p(t) \rangle = \langle \langle \mu | \frac{d\rho(t)}{dt} \rangle \rangle \quad (20b)$$

Since

$$\frac{d\rho(t)}{dt} = -i\mathcal{L}\rho(t) \quad (21)$$

Eq. 20a becomes

$$\frac{dp}{dt} = -i \langle \langle \mu | \mathcal{L}\rho \rangle \rangle \quad (22)$$

This single molecule (microscopic) polarization is scaled by the volume of a simulation voxel ($\Delta V = \Delta x \times \Delta y \times \Delta z$) to obtain the macroscopic current density:

$$\frac{dP}{dt} = \frac{dp}{dt} \Delta V = J(t) \quad (23)$$

This becomes a current source term in Maxwell's equations via Eq. 1a.

3 Results

3.1 Validation of FDTD

Before discussing the coupled plasmon/molecule case, we validate the electrodynamics and FDTD/QM approaches separately. For the electrodynamics, we developed our own FDTD code to allow for ease of integration with the quantum code. For each simulation, the total volume was approximately $2281 \times 2281 \times 2281 \text{ nm}^3$. Convergence with grid spacing was testing for $\Delta x = \Delta y = \Delta z = 16, 12, 8 \text{ au} = 8.47, 6.35, 4.23 \text{ \AA}$. For the finest grid, this corresponds to 539^3 total grid points. The time step was taken to be 0.8 times the Courant stability limit which corresponds to $0.036 \text{ a.u.} = 8.71 \times 10^{-4} \text{ fs}$. Each simulation was allowed to continue until the fields decayed to 0.1% of the maximum intensity, corresponding to about

3500 au of time. This required roughly 9.72×10^4 time steps, which took about 20 hours on 16 processors (OpenMP parallelized) and used approximately 160 GB of RAM.

For each simulation, the system was initialized using the TF/SF boundary with an x -directed, z -polarized broadband plane-wave excitation centered on the plasmon frequency. The pulse was chosen to be a discrete Ricker Wavelet to minimize grid artifacts:

$$f_r[q] = \left(1 - 2\pi^2 \left[\frac{S_c q}{N_p} - M_d\right]^2\right) \exp\left(-\pi^2 \left[\frac{S_c q}{N_p} - M_d\right]^2\right) \quad (24)$$

where S_c is the Courant stability number, which is a dimensionless quantity representing the ratio of the chosen simulation time step to the largest stable time step. Here, $\Delta t_{max} = c\Delta x/\text{sqrt}(3)$, is the Courant stability limit for a cubic 3D grid ($\Delta x = \Delta y = \Delta z$), i.e., the maximum possible time step for which the Yee FDTD propagation is stable.⁶¹ N_p is the number of points per wavelength at the center frequency ω_0 and is defined by

$$N_p = \frac{S_c}{\omega_0 \Delta t} \quad (25)$$

and the temporal delay M_d is the delay multiple. This pulse contains no DC component, and its spectral content is set by a single parameter (i.e., ω_0).⁶² After excitation, the energy flow into and out of the system is measured as a function of time via a scattering flux monitor located outside the total field region (in the scattering region) and an absorption flux monitor located inside the total field region. By collecting the outgoing electric and magnetic fields on these flux monitors, we can obtain extinction properties of the system (molecule, nanoparticle, combined, etc). See Supporting Information for details.

Before progressing to the coupled quantum/FDTD case, we first validate our FDTD implementation for a single gold nanoparticle. As is commonly done, the frequency-dependent

permittivity of the metal is modeled as a sum of Lorentzians

$$\varepsilon(\omega) = \varepsilon_{\infty} + \varepsilon_0 + \sum_{j=1}^{N_L} \frac{\beta_j}{\omega_j^2 - i\alpha_j\omega - \omega^2} \quad (26)$$

where α_j , ω_j , and β_j are real material-dependent parameters. These parameters can be directly incorporated through the auxiliary difference equation technique.⁶¹ For the parameters, we use the $N_L = 9$ Lorentzian fit to experimental bulk values obtained by Neuhauser et al.⁶³ This fit is valid over the energy range between 0.6 – 6.7 eV.

Figure 3: Comparison of FDTD computed and experimentally measured extinction (absorption + scattering) for a 80 nm diameter gold nanoparticle. The computed spectra are insensitive to grid and are consistent with experiment.

For this validation we computed the extinction (absorption + scattering) of a single 80 nm diameter gold nanosphere in water with various grid spacings and compared it to the experimental extinction measured with a UV/Vis spectrophotometer. Additionally, we can change the background medium through $\varepsilon_{eff} = \varepsilon_0\varepsilon_r$ in Eq. 1a. For these simulations, we used $\varepsilon_r = 1.782$, which corresponds to a water solvent. Fig. 3 shows the spectra for various grid spacings. Overall the spectrum is relatively insensitive to grid, and agrees well

with experiment in the region of the plasmon resonance. Deviations at lower (~ 1.8 eV) and higher (~ 2.5 eV) are likely due to polydispersity in the experiment. Based on these results, we henceforth use a grid spacing of $\Delta x = 8$ au = 4.23 Å for subsequent calculations of this size nanoparticles.

3.2 Energy coupling between two molecules

Figure 4: Computed resonant energy transfer between a pair of two-level chromophores as a function of separation (R). The transition dipole moments are shown with arrows. The fractional energy transfer from an excited (donor) molecule to the acceptor follows a $1/R^6$ trend, consistent with a Förster-like process (dipole-dipole coupling).

To validate our multi-molecule embedding scheme, we computed resonant energy transfer between a pair of spatially separated two-level molecules with aligned transition dipole moments. Here, to emphasize the effect, we chose each to have a non-physical transition dipole moment of 57 au = 144 D. The frequency was chosen to be 0.073 au = 2.0 eV. For this simulation, the subregion around each molecule was 30 au wide with an absorbing boundary beyond each TF/MF boundary. The left molecule was initialized via a delta kick excitation. The transfer was quantified by computing the maximum energy on the right molecule as a

fraction of the maximum energy on the left molecule. Figure 4 shows this fractional energy transfer as a function of intermolecular separation R . The observed $1/R^6$ behavior is characteristic of a Förster-like resonance energy transfer (FRET) mechanism, which arises from long-range dipole-dipole interactions.^{64–66} The energy transfer between the two embedded molecules is mediated by the propagation of the electric fields through the FDTD background. This yields the dipole-dipole coupling without additional distance-dependent terms in the Liouvillian (or corresponding operator for other QM methods). This type of interaction can be modeled using purely quantum approaches such as TDDFT transition-dipoles⁶⁷ or transition density cube methods.⁶⁸ Embedded QM schemes like previous work^{40,44,47} and our approach here have a few advantages. Since the molecules and intermediate fields are propagated explicitly in time and space, these methods can be extended to FRET in environments with non-trivial frequency responses (e.g., near plasmons and surfaces, certain solvents, etc). Additionally, they open the door to resonant energy transfer under intense fields.

3.3 Plasmon/Molecule Coupling

Now we turn to the main topic of this paper, namely computing the coupled excitations of plasmons with multiple nearby chromophores. Here we study the system consisting of a 80 nm gold NP with a full monolayer of malachite green molecules adsorbed on the surface (See Fig. 1). Previous experimental studies on this system have exhibited strong coupling between the plasmons and excitations on the dyes, which can be observed via a difference UV-visible extinction spectrum.³⁴ These systems have well-characterized nanoparticle sizes (via transmission electron microscopy) and known surface coverage (via second harmonic generation isotherms). Questions remain, however, about the physical origins of the observed features in the coupling spectra, as well as the orientation (transition dipole angle) and distance of the dyes molecules from the NP surface. In this section, we present simulations for interpreting these difference spectra and approximating the geometries of the dyes with

respect to the NP.

3.3.1 Parametrizing Monolayer of Quantum Molecules

We model malachite green as a three-level molecule, focusing only on the transitions at 2.02 eV and 2.13 eV. The molecular parameters were determined by fitting the experimental spectrum to the sum of two Lorentzian functions, with the peak positions yielding $\Delta\epsilon_{2-1} = 0.07423$ au = 2.020 eV and $\Delta\epsilon_{3-1} = 0.07822$ au = 2.129 eV, respectively. The oscillator strengths were found by integrating the extinction, which gives the transition dipole moments $\mu_{12} = 1.985$ au = 5.046 D and $\mu_{13} = 1.575$ au = 4.003 D. Here, we are only interested in modeling the two lowest excitations of the malachite green molecule: $|1\rangle \rightarrow |2\rangle$ and $|1\rangle \rightarrow |3\rangle$. Since the $|2\rangle$ states will be negligibly populated (due to low field intensities), the $|2\rangle \rightarrow |3\rangle$ is not experimentally observable and can be neglected. We thus turn off the excited state absorption ($|2\rangle \rightarrow |3\rangle$) by setting $\mu_{23} = 0$. For the lifetimes, it is generally impossible to deconvolute an experimental absorption peak into T_1 (damping) and T_2 (dephasing) contributions. A more sophisticated approach would be to use time-resolved techniques, such as pump-probe transient absorption spectroscopy, to measure the T_1 and T_2 contributions. For simplicity we assume only dephasing, with the corresponding lifetimes fit to the full width half maximum of the experiment. Here, $T_{12} = 481.4$ au = 11.65 fs and $T_{13} = 291.9$ au = 7.061 fs, corresponding to the dephasing times between states $|1\rangle$ and $|2\rangle$ and $|1\rangle$ and $|3\rangle$, respectively.

Experimentally, we previously determined that each 80 nm Au NP had $M \approx 9200$ molecules adsorbed to the surface.³⁴ Although the formalism could be applied to directly model this system, for simplicity we instead model the monolayer as two “super” molecules with scaled-up transition dipole moments. This allows us to mimic the response of malachite green covering the entire gold surface using only two quantum molecules. A super molecule approach implicitly assumes a particular orientation of each molecule with respect to the surface and neglects coupling between molecules. These super molecules then couple indirectly

Figure 5: Computed extinction spectra for a single malachite green molecule, modeled as a three-level system with parameters fit to match experiment.

through the plasmonic fields. Additionally, we experimentally determined the adsorption site area of malachite green to be approximately 2.19 nm^2 , where the average molecule-molecule distance is 1.14 nm . Although these molecules are potentially within the strong coupling regime,⁶⁹ we believe the overall spectra are dominated by the plasmon/molecule coupling as evidenced by our good agreement with experiment. For smaller NP's (i.e., $< 50 \text{ nm}$), higher site densities, or molecules with higher oscillator strengths, we suspect that the molecule/molecule interaction will play a more important role in the coupling.

We determined the super molecule transition dipole moments such that the absorption of the pair matches the expected response of a fully covered nanoparticle. Neglecting molecule/molecule coupling, the scaling factor can be approximated from the experimentally measured surface coverage M . Since absorption scales linearly with the number of molecules, the total absorption of a collection of independent oscillators is given by:

$$\tilde{\sigma} = \widetilde{M}\sigma \quad (27)$$

where σ is the absorption of a single molecule, $\tilde{\sigma}$ is the absorption of the collection of molecules, and $\tilde{M}$ is an effective number of molecules. For an isotropic arrangement, $\tilde{M}$ is simply the number of molecules in solution. For the case of molecules adsorbed to a spherical nanoparticle with a well-defined angle with respect to the normal, and for a particular light polarization (say z), this becomes an orientational average. This is a surface integral of the transition dipoles dotted into the normal, which accounts for alignment of the molecules with respect to the z -polarized light field:

$$\tilde{M} = M \int_0^\pi d\theta \sqrt{\frac{\langle \cos^2(\theta) \rangle}{\langle \cos^2(0) \rangle}} = M \frac{1}{\sqrt{2}} \quad (28)$$

Now, since absorption is directly proportional to the square of the transition dipole, $\tilde{\sigma} \propto \tilde{\mu}^2$, the effective “super” transition dipole moment is given by:

$$\tilde{\mu} = \sqrt{\tilde{M}} \mu \quad (29)$$

A single molecule is unable to capture molecule-plasmon-molecule polariton modes so we instead used two super dyes positioned at the $\theta = 0$ and $\theta = 180^\circ$ poles of the nanoparticle. Before proceeding to the nanoparticle case, we first validated the super molecule approach by comparing the z -polarized extinction of two dyes with purely z -oriented dipole moments against that of four dyes, each located at some angle θ with respect to the z -axis. For a pair, the transition dipole is scaled by an additional $\frac{1}{\sqrt{2}}$ such that the absorption cross section is the same (see Eq. 29). Fig. 6 shows the calculated extinction spectra for these two systems. Note here, for molecules the scattering is negligible so the extinction is predominantly absorption. The two are essentially identical, demonstrating that two super molecules can represent an arbitrary number of molecules, at least in the limit of no molecular coupling.

Figure 6: Computed z -polarized extinction of four molecules ($\theta = 30^\circ, 150^\circ, 210^\circ$, and 330°) is captured correctly by two “super” molecules ($\theta = 0^\circ, 180^\circ$). Here, the long axis of the red ovals point along the direction of the transition dipole. This can be extended to modeling an arbitrary number of molecules using only two oscillators, at least in the limit of negligible molecule-molecule interactions.

3.3.2 Au Nanoparticle/Malachite Green Difference Spectra

Using this approach we now model the coupled plasmon-molecule polariton response of Au NP with malachite green adsorbed on the surface. This is a follow up on our previous experimental results.³⁴ For these coupled nanoparticle/molecule simulations, we parameterized our grid using the best grid spacing from the convergence test of gold in Fig. 3 (i.e., $\Delta x = 8$ au). The malachite green monolayer was modeled using a pair of three-level super molecules, with the molecular parameters fit to experiment (See Sec. 3.3.1). For the surface coverage, we use our experimentally determined value of $M \approx 9200$, which was obtained using second harmonic generation (SHG) isotherm for a 80 nm gold nanoparticle.³⁴

The physical distance between the NP surface and dye monolayer (ℓ), as well as the angle of the transition dipole with respect to the normal (η) both remain unknown. As a first approximation, we estimate the distance by measuring the length of mercaptosuccinic acid (MSA) (i.e., 9 – 12 Å), the capping agent molecule, which is chemically bound to the surface of gold, and the length from the edge of the dye to its center (i.e., 7 – 10 Å). Additionally, since these dyes are held at the surface via electrostatic interactions, we estimate that there are at least 1-2 water shells between the dye and MSA (i.e., ~ 6 Å). Therefore, we estimate the distance from the NP surface to the center of the dye to be 25 Å. (Figure 1) For the angle, previous studies attribute observed results to a tilt angle of the dyes, but the angle remains unclear. Moreover, the molecular tilt angle is potentially different from the transition dipole angle. Thus for this paper, we compute the plasmon-molecule spectra for a range of separations (ℓ) and transition dipole angles (η) to determine rough values.

First, we explore the effect of transition dipole angle on the coupling. To start, we pick the monolayer distance to be $\ell = 48$ au = 25.4 Å. This is consistent with approximately 1-2 shells of water between the surface and the center of the dye. Figure 7 shows resulting z -polarized coupling spectra for a range of transition dipole angles. As in experiment, this extinction spectrum was obtained by computing the spectrum of the NP+molecule system, then subtracting the extinction spectrum of the lone gold nanoparticle, as well as that of

a solution of M molecules. For the molecule subtraction, to be consistent with experiment we used an ensemble average of molecular orientations, which corresponds to $\frac{1}{3}M$ for the z -polarization.

Figure 7 shows the difference in extinction as a result of the molecule-plasmon interactions, that is, in the absence of plasmon/molecule coupling, the difference extinction would be zero. In this case, the residuals reveal a Fano-like resonance centered at the molecular frequency $\Delta\varepsilon_{2-1}$, which results in two additional peaks. The lower energy peak corresponds to an in-phase coupled polaritonic mode $|P-\rangle$ involving the primary dye absorption ($|1\rangle \rightarrow |2\rangle$ transition) and the plasmon. This mode is significantly red-shifted from the uncoupled molecular mode. The complimentary out-of-phase polariton $|P+\rangle$ is blue-shifted and lower in magnitude. Additionally, there is a prominent negative feature at ~ 2.02 eV which corresponds to depletion of the main molecular mode at $\omega_m = \Delta\varepsilon_{2-1}$, i.e., energy transferred from the molecule to the plasmon, forming the polaritonic states $|P-\rangle$ and $|P+\rangle$. The corresponding plasmon depletion and second molecular mode (i.e., $\Delta\varepsilon_{3-1}$) overlap the $|P+\rangle$ polariton and are not clearly visible due to the small μ_{13} transition dipole for this molecular mode. These signals would likely be more prominent for the case of a smaller nanoparticle, where the cross section of the molecules would be closer in magnitude to that of the plasmon.

The effect of transition dipole angle η on these polaritonic states is also shown in Figure 7. Regardless of angle, the frequency of the $|P+\rangle$ polariton is ~ 2.14 eV, while the magnitude decreases with increasing η . In contrast, the $|P-\rangle$ frequency blue-shifts and the magnitude decreases with increasing η . At a distance of $\ell = 25.4$ Å, for example, a transition dipole angle of $\eta = 60^\circ$ gives the best agreement with experiment, for both the frequency (~ 1.89 eV) of the modes as well as the relative magnitudes. The energy difference between the two polariton peaks, ΔE_P , corresponds to the splitting energy. This is a measure of the coupling strength between the molecular and plasmon excitations. Our model predicts an approximate splitting energy of $\Delta E_P = 263$ meV for malachite green and a 80 nm Au NP. This is in

Figure 7: Comparison of FDTD computed and experimentally measured difference extinction spectra (coupled system – pure Au NP – dye solution) for a 80 nm diameter Au nanoparticle (NP) surrounded by malachite green molecules. The difference spectra reveals the coupling between the plasmon and molecular excitations. The system is modeled using two “super” dye molecules by fixing either the separation distance from the NP surface (Panel A) or transition dipole angle (Panel B) and varying the other (e.g., Panel A $l = 25.4 \text{ \AA}$ and vary η). The residual Fano-type resonances correspond to an in-phase polariton $|P-\rangle$ (lower energy) and an out-of-phase polariton $|P+\rangle$ (higher energy). The depletion in the brightest molecular mode is visible at 2.02 eV (ω_m). The corresponding plasmon depletion and second molecular mode overlap the $|P+\rangle$ polariton and are not clearly visible.³⁴

agreement with our experimental difference extinction measurements (Fig. 7C).³⁴

Additionally, since the exact distance ℓ between the metal surface and the malachite green monolayer is not implicitly known, we also explored its effect on the splitting energy ΔE_P . Figure 7B shows the difference spectra with a fixed transition dipole angle ($\theta = 60^\circ$) and various monolayer distances ($\ell = 48, 60, 80, 100$ au). The splitting energy decreases with increasing ℓ , as evidenced by a blue-shifting $|P-\rangle$ (in-phase) polariton frequency. The magnitude, on the other hand, is relatively insensitive to ℓ . This is likely due to the relatively large separation from the surface, where the exponentially decaying electric field has a shallow gradient. The $|P+\rangle$ (out-of-phase) polariton frequency and magnitude appears relatively insensitive with increasing ℓ . From these results, however, it is clear that the splitting energy ΔE_P decreases with ℓ .

Since both η and ℓ affect the splitting energy, there is some ambiguity in using these simulations to determine the molecular geometry. Without some experimental measure of either of the parameters, it is difficult to conclusively approximate their values. In principle, a full 2D parameter scan might be illustrative, but choosing a “best” angle and distance by matching ΔE_P might still be ambiguous. Regardless, assuming $\ell = 25.4$ Å gives a transition dipole angle of $\eta = 60^\circ$ which is consistent with a tilted malachite green molecule. Future molecular simulation studies will give more insight into the geometry of malachite green adsorbed to the surface of Au NP.

4 Conclusions

In conclusion, we have presented a multiscale method for computing the coupled plasmon/molecule excitations for systems containing an arbitrary number of molecules on the surface of a metal. This uses finite-difference time-domain (FDTD) for the classical fields and quantum mechanical for the electron dynamics on each molecule. In this paper, we derive the expression for an N -level Hamiltonian with dephasing via a Redfield-like treatment,

but this approach can also be extended to use any time-dependent quantum method.

We validated our results for the simple cases of a lone gold nanoparticle, as well as resonant energy transfer between two isolated molecules. The technique was then extended to model the extinction spectra of gold nanoparticles with an adsorbed monolayer of malachite green described using two “super molecules.” This was used to predict the orientation of the dye molecules (or at least that of their transition dipole), as well as the separation of the monolayer from the gold surface. Our results capture the experimentally observed polariton modes (coupled plasmon/molecule excitations) and agree with the observed experimental splitting energy of ~ 263 eV, with a “best guess” for the distance of $\ell \sim 25.4$ Å, and a transition dipole angle of $\eta \sim 60^\circ$.

Both quantities ℓ and η are difficult to measure experimentally, but are crucial for interpreting spectra and for applications spanning molecular sensing, plasmonic photovoltaics, and near-field photocatalysis. As the coupling depends simultaneously on both transition dipole angle of the molecule, as well as the separation from the surface, it is difficult to conclusively assign their values from these simulations. Nevertheless, this ambiguity can be remedied if one parameter is known, either from experimental measurements, or computed using molecular simulations. In subsequent studies, to include potential molecule/molecule interactions, we will use a larger number of oscillators rather than two “super molecules”. The agreement of these results, however, with experiment suggests that primary mechanism of coupling is due to the interaction between the molecule and plasmon, rather than inter-molecular effects. The role of molecule-molecule coupling on the spectra will be explored in future studies. Finally, this method can be extended beyond the simple N -level model using real-time quantum chemistry techniques such as time dependent Hartree-Fock,^{70–72} time-dependent density functional theory,^{60,73–76} configuration interaction,^{77,78} coupled cluster,^{79,80} and two-electron reduced density matrix methods.⁸¹ Moreover, to mitigate the computational cost of multiple molecules, the FDTD as well as each molecule can be computed in parallel, either using traditional MPI-like parallelization, or by using accelerator cards.

Finally, spectral acceleration techniques such as filter diagonalization^{82,83} or Padé approximants,⁸⁴ can significantly decrease simulations times.
