Seawater-driven magnesium based Janus micromotors for environmental remediation†

Wei Gao,† Xiaomiao Feng,‡ Allen Pei,‡ Yonge Gu, Jinxing Li and Joseph Wang*

We describe the use of seawater as fuel to propel Janus micromotors. The new micromotors consist of biodegradable and environmentally friendly magnesium microparticles and a nickel–gold bilayer patch for magnetic guidance and surface modification. Such seawater-driven micromotors, which utilize macrogalvanic corrosion and chloride pitting corrosion processes, eliminate the need for external fuels to offer efficient and prolonged propulsion towards diverse applications in aquatic environments.

The propulsion of synthetic nanoscale objects represents a great challenge and opportunity, and has thus stimulated considerable research efforts in recent years.1–3 Self-propelled micromotors offer promise for diverse practical applications, such as drug delivery,4,5 biomaterials isolation,6–8 surface patterning9 and environmental remediation.10 Bubble-propelled catalytic micromotors are particularly attractive due to their efficient propulsion in relevant biological fluids and high ionic-strength media.11–16 Unfortunately, the requirement of the hydrogen peroxide fuel greatly impedes many practical applications of such catalytic micro/nanoscale motors.7 New micro/nanomotors that can harvest energy from their own surrounding environment, i.e., use the sample matrix itself as their fuel source, are highly desired for eliminating the need for adding external fuels. For example, Gao et al. illustrated hydrogen-bubble-propelled micromotors that can be powered in acidic or alkaline media.17–20 However, water is the obvious ideal choice of fuel for the majority of practical nanomachine applications compared to extreme acidic or alkaline media. Recently we described the first example of a water-driven micromotor, based on Al/Ga microparticles, which displayed efficient propulsion in aqueous solutions.21 However, due to the toxicity of aluminum and gallium, more biocompatible and environmentally friendly materials are highly desired for different applications of water-driven micromotors.

Here we demonstrate a new hydrogen-bubble-propelled Janus micromotor, based on the magnesium–water reaction, which can be self-propelled in seawater without an external fuel. Common active metals (e.g., Li, Na, K, Ca), can lead to efficient hydrogen evolution from the water–metal reaction, but are too reactive for a safe operation and are not stable in air. Magnesium, in contrast, is an attractive candidate material for the design of water-driven micromotors as it is a biocompatible ‘green’ nutrient trace element, vital for many bodily functions and enzymatic processes. In addition, Mg is a low cost metal and Mg2+ is present in different natural environments (e.g., seawater). The Mg–water reaction is commonly hindered in ambient atmospheres due to the formation of a compact hydroxide passivation surface layer. Accordingly, Mg cannot continuously reduce water to generate hydrogen bubbles.22,23 However, we demonstrate in the following sections that the micromotor can display efficient and prolonged propulsion in chloride-rich environments (such as seawater) owing to the combination of macrogalvanic corrosion and chloride pitting corrosion processes (discussed below). The new seawater-driven micromotors can be guided magnetically (through the incorporation of a magnetic Ni layer) and be functionalized to perform various important tasks. For example, modification of the outer gold patch with long-chain alkanethiols leads to a super-hydrophobic surface that can be used for environmental oil remediation.

Fig. 1 displays the schematic of the hydrogen-bubble-propelled seawater-driven Janus Mg-based micromotors. The Mg particles have an average size of ~30 μm and are asymmetrically coated by e-beam evaporation with Ti, Ni and Au layers to form the Janus micromotors (with the Ti layer providing a good contact between the Ni–Au layers and the Mg surface). Upon immersion into seawater, a spontaneous redox reaction occurs, involving the oxidation of the Mg surface to reduce water to hydrogen bubbles.
Mg(s) + 2H₂O(aq) → Mg(OH)₂(s) + H₂(g)  

While the rapidly formed oxide passivation layer on the Mg surface can hinder the process, we found that the presence of the gold layer and chloride ions allows the reaction to proceed (by combination of macrogalvanic corrosion and pitting corrosion processes, respectively), hence leading to continuous formation of hydrogen bubbles to propel the microparticles.

Fig. 2 displays time-lapse images, taken from ESI Video 1, of the movement of the Janus Mg micromotor in seawater over a 4 s period at 1 s intervals. These images illustrate the continuous stream of hydrogen microparticles released from the exposed Mg surface. The micromotor is self-propelled at a high speed of over 90 μm s⁻¹, which corresponds to a relative speed of nearly 3 body lengths per s. The Mg Janus micromotor follows predetermined trajectories under the magnetic guidance. As illustrated in Fig. 2b-e and ESI Video 1, such magnetic guidance steers the micromotor along different trajectories to offer high spatial and temporal resolution essential for a variety of applications. The micromotor thus executes sharp and rapid turns and travels in a square pattern.

The presence of the gold layer plays a crucial role in the self-propulsion of the Mg-based micromotor, as was demonstrated by various control experiments. Fig. 3A and corresponding ESI Video 2† clearly indicate that the bare Mg particles and Mg–Ti Janus particles display no bubble generation and net displacement in seawater. Some bubble formation, with no directional propulsion, is observed using the Mg–Ti–Ag microparticle in the seawater. In contrast, replacing the Ag layer with a Au layer leads to efficient motion in seawater, reflecting the enhanced Mg–water reaction. The important role of the gold in the increased reaction rate and propulsion efficiency is associated with the macrogalvanic corrosion mechanism, which is an electrochemical process in which one metal corrodes preferentially to another one when both metals are in electrical contact and immersed in an electrolyte. When the Janus micromotor is immersed into seawater, a short-circuited galvanic cell is formed. The anodic indexes for gold and silver are −0.0 V and −0.15 V, respectively, while magnesium has a very low potential of −1.75 V. The Au–Mg system thus has a larger electrochemical potential difference, compared to the Ag–Mg couple, resulting in a considerably faster and preferential dissolution of magnesium in the presence of gold.

Additionally, we observed that such macrogalvanic corrosion of Mg (and the corresponding propulsion) is strongly influenced by co-existing anions. For example, Fig. 3B and ESI Video 3† compare the bubble generation and motion of Mg–Ti–Au Janus micromotors in the presence of different electrolytes (NaNO₃, Na₂SO₄, and NaCl). No bubble generation is observed on the micromotors in pure water and sodium nitrate solutions, while very slow bubble generation is observed in the sodium sulfate medium; in contrast, a fast and strong bubble generation is observed in the sodium chloride solution. Overall, Fig. 3B clearly indicates that the chloride-induced pitting corrosion on the Mg surface plays a critical role in the observed bubble generation and propulsion (in addition to the galvanic corrosion). Pitting corrosion commonly occurs in metals that are protected by a passivation layer (e.g., Mg with a Mg(OH)₂ layer). It is well known that chloride ions promote the corrosion of Mg in aqueous solutions. Aggressive anionic species, such as chlorine, are able to penetrate the passivation layer and are further electrostatically transported into the pit, where they serve to balance the charge within the corrosion pits as the Mg²⁺ cation concentration builds up. As the Mg corrosion continues, the OH⁻ is depleted within the pit, preventing the passivation of the pit surfaces. The pit environment becomes weakly acidic due to the build-up of Mg²⁺ and Cl⁻ levels, further promoting the Mg dissolution in the pit. The intermediate Mg²⁺ near the surface of the pit then reacts to form H₂ gas:  

\[ 2\text{Mg}^⁺(aq) + 2\text{H}_2\text{O}(aq) \rightarrow 2\text{Mg}^{2⁺}(aq) + 2\text{OH}⁻(aq) + \text{H}_2(g) \]
level of Cl\(^-\) in seawater (546 mmol kg\(^{-1}\)) thus strongly promotes this reaction mechanism. Sulfate ions can still facilitate the reaction but display a much weaker effect (compared to the chloride ions),\(^{31,32}\) which is consistent with the experimental results shown in Fig. 3B; nitrate ions, in contrast, have no apparent effects on the reaction rate,\(^{31,32}\) and hence no bubbles are observed in NaNO\(_3\).

It appears that the macrogalvanic corrosion and pitting corrosion effects – when coupled together as in these Mg motors – work synergistically to enhance the overall rate of Mg dissolution and reaction. The galvanic coupling of the Mg particle with the Au layer leads to an enhanced preferential corrosion and anodic dissolution of Mg at the exposed regions, along with the cathodic evolution of \(\text{H}_2\) gas at the Au surface. However, the control experiments clearly illustrate that the \(\text{H}_2\) bubbles, generated at the Mg surface in the presence of chloride ions due to the pitting corrosion mechanism, have a dominating effect upon the observed propulsion. In fact, the intrinsic galvanic cell (macrogalvanic and microgalvanic effects from the gold coating and impurities of the Mg particles, respectively) serves to further increase the anodic dissolution of Mg, assisting in the pitting corrosion.\(^{27}\) Thus, the rapidly evolving hydrogen bubbles at the Mg surface provide the thrust essential for the directional propulsion of the Janus micromotors.

The autonomous motion performance of the new Mg-based Janus micromotors depends strongly upon the chloride ion concentrations in the aqueous media (Fig. 4 and ESI Video 4†). As was discussed earlier, the presence of chloride ions increases the amount of dissolved intermediate Mg\(^+\) that can react to form hydrogen. The reaction of the Mg–Ti–Ni–Au particles can be observed from the evolution of a clear bubble tail even in the 0.001 M sodium chloride media, reflecting the strong pitting corrosion effect of the chloride ions. As expected,\(^{33}\) higher chloride concentrations induce faster reaction rates. For example, the micromotors display an efficient speed of 90 \(\mu\text{m s}^{-1}\) in 0.3 M sodium chloride (b), and an even higher speed of 300 \(\mu\text{m s}^{-1}\) in 3 M sodium chloride (c). This increased rate of bubble generation in chloride solution further confirms the presence of the pitting corrosion mechanism. Despite the continuous dissolution of the Mg microparticle, the Janus Au–Ti–Ni–Mg micromotors display a lifetime of over one min in seawater. Various factors, including the particle size and shape and the exact fuel composition are currently being examined towards extending the motor lifetime.

We also examined the influence of the solution pH and the presence of a metal complexing agent (EDTA) upon the speed of the micromotors. The micromotors displayed a comparable propulsion behavior in weak acidic or alkaline seawater of pH values ranging from pH 4 to pH 10, indicating minimal effect of these media upon the efficiency of the Mg-water reaction. Even faster Mg dissolutions and propulsions were observed in strongly acidic environments (pH < 2), while strongly alkaline media (pH > 12) resulted in nearly complete hindrance of the Mg-water reaction.\(^{27}\) Adding 0.1 mM EDTA to the natural seawater resulted in a decreased speed (to 40 \(\mu\text{m s}^{-1}\)), possibly due to chelation of Mg\(^+\) ions, and hence hindrance of the hydrogen evolution reaction (eqn (2)).

Fig. 4 Motion of the Mg–Ti–Ni–Au micromotors in the presence of different levels of chloride ions: 0.001 M (a), 0.5 M (b) and 3 M NaCl (c) solutions. Scale bar, 50 \(\mu\text{m}\).

micromotors in seawater), indicating that the SAM layer does not affect the galvanic role of the gold layer. Upon contacting the pair of oil droplets (of 20 μm diameter each), the micromotor instantaneously captures them. As expected, the speed of the motor greatly decreases to around 44 μm s⁻¹ while carrying the droplets, reflecting the larger drag force. In contrast, control experiments involving unmodified micromotors (i.e., without the alkanethiols) displayed no affinity to such droplets after direct contact (ESI Video 6†).

Conclusions

In conclusion, we have presented a new chemically powered magnesium-based Janus micromotor that propels autonomously using seawater as the sole fuel source and a hydrogen bubble thrust generated from the Mg-water reaction. The hydrogen-bubble propulsion mechanism has been attributed to the combination of galvanic corrosion and pitting corrosion effects, and the important related roles of the gold coating and the ionic (particularly chloride-rich) environments have been discussed. Accordingly, the Mg-based micromotors are expected to move efficiently in other biological media which contain high chloride concentrations. The new water-driven motion capability should greatly expand the scope of applications and environments of chemically powered nanomachines. The composition of the motor and the fuel makes these micromotors highly biocompatible and environmentally friendly. We also demonstrated the first example of a surface-functionalized water-driven micromotor towards practical applications in realistic environments. SAM-modified hydrophobic Mg micromotors were thus applied successfully for oil cleaning in seawater and show considerable potential for environmental remediation. Depending on the specific application, smaller Mg-based motors can be prepared using smaller Mg particles. Additional efforts should be devoted to extending the lifetime of Mg-based motors for addressing the requirements of many practical applications. We expect that the Mg-based Janus micromotor will have a profound impact upon diverse applications in various aqueous environments.

Experimental section

Synthesis of Mg-Ti–Ni–Au Janus micromotors

The micromotors were prepared using magnesium microparticles (Catalog #465666, Sigma-Aldrich, St Louis, MO, powder, ~325 mesh, 99.5% trace metals basis) as the base particles. The Mg particles were placed onto glass slides and coated with a 20 nm titanium layer at 1 Å s⁻¹, a 80 nm nickel layer at 2 Å s⁻¹, and a 10 nm gold layer at 1 Å s⁻¹ using Temescal BJD 1800 E-beam Evaporator. After a brief sonication in ethanol, the micromotors were released from the glass slide and dispersed into ethanol. The motors were stored in the pure ethanol solution until use. For the control experiments, Mg particles were similarly coated with 100 nm Ti (for Mg–Ti particles), 100 nm Ti and 10 nm Ag (for Mg–Ti–Ag particles), and 100 nm Ti and 10 nm Au (for Mg–Ti–Au particles).

Micromotor modification

The external gold surface of the micromotors was modified by immersion in 1 mM octadecanethiol (Sigma-Aldrich) in absolute ethanol (Sigma-Aldrich) for 1 hour, after which the resulting monolayer-modified micromotors were washed with ethanol and isolated by centrifugation at 6000 rpm for 2 min. All experiments were carried out at room temperature.

Equipment and experimental procedure

Seawater used as propulsion media in the experiments was collected at Torrey Pines Beach, La Jolla, CA. All the solutions (seawater, NaCl, NaNO₃ and Na₂SO₄) used in the paper contained 0.5% Triton X-100 (Fisher Scientific, Fair Lawn, NJ). For the oil remediation experiments, an emulsion of seawater-motor oil sample (20 : 1), with 0.5% Triton, was first prepared. Videos were captured by an inverted optical microscope (Nikon Instrument Inc. Ti-S/L100), coupled with 10× and 4× objectives, a Hamamatsu digital camera C11440 using the NIS-Elements AR 3.2 software.
