Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

Explanation of Dramatic pH-Dependence of Hydrogen Binding on Noble Metal Electrode: Greatly Weakened Water Adsorption at High pH.

ABSTRACT: Hydrogen oxidation reaction (HOR) and hydrogen evolution reaction (HER) are both two orders slower in alkaline electrolyte than in acidic electrolyte, but no explanation has been provided. The first step towards understanding this dramatic pH-dependent HOR/HER performance is to explain the pH-dependent hydrogen binding to the electrode, a perplexing behavior observed experimentally. In this work, we carried out Quantum Mechanics Molecular Dynamics (QMMD) with explicit considerations of solvent and applied voltage (U) to *in situ* simulate water/Pt (100) interface in the condition of under-potential adsorption of hydrogen (H_{UPD}). We found that as U is made more negative, the electrode tends to repel water, which in turn increases the hydrogen binding. We predicted a 0.13 eV increase in hydrogen binding from pH = 0.2 to pH = 12.8 with a slope of 10 meV/pH, which is close to the experimental observation of 8 to 12 meV/pH. Thus, we conclude that the changes in water adsorption are the major causes of pH-dependent hydrogen binding on a noble metal. The new insight of critical role of surface water in modifying electrochemical reactions provides a guideline in designing HER/HOR catalyst targeting for the alkaline electrolyte.

Despite the broad application of hydrogen oxidation reaction (HOR) and hydrogen evolution reactions (HER) in electrochemical catalysis,¹⁻² for yet unclear reasons the HOR/HER kinetics on noble metals are much slower in alkaline than in acid electrolytes,³ which poses enormous challenges in practical applications. For example, the HOR/HER reaction rate is as two orders of magnitude slower in strong base than that in strong acid,³ which significantly diminishes the overall performance of oxygen reduction reaction (ORR)⁴ and the oxygen evolution reaction (OER) in alkaline electrolyte.⁵⁻⁶

The slow HER rate in base than in acid has been rationalized as arising from the faster formation of H_{ad} from H^+ than from H_2O ,⁷⁻⁸ or in terms of the change in configurational entropy of the proton.⁹ However, none of these explanations are entirely satisfactory, considering that in HOR H_{ad} forms from H_2 dissociation without involving H^+ , but still the activity decreases significantly from acid to base conditions, and lower activation energy is observed for HOR/HER in acid than in base.¹⁰⁻¹¹ Instead, the pH-dependent hydrogen binding energy (HBE), derived from cyclic voltamme-

try (CV), is considered to be a more reliable descriptor. For example, Shen et al. observed a 0.15 eV increase in the HBE as the pH is increased by 13 units, which in turn changes the HOR/HER activity by two orders of magnitude.¹² However, the underlying cause of this pH-dependent behavior is still far from clear.

The HBE (ΔG_H^{ad}) is typically considered as an intrinsic property of each metal with no pH dependence.¹³

$$\Delta G_H^{ad} = \Delta G_{M-H_{ad}} - (\Delta G_{1/2H_2} + \Delta G_M) \quad (2)$$

However, the electrode surface in an aqueous electrolyte is known to be covered with water, and thus it is likely that the adsorption/desorption of hydrogen is accompanied by desorption/re-adsorption of water,¹⁴

$$\Delta G_H^{ad*} = \Delta G_{M-H_{ad}} - (\Delta G_{1/2H_2} + \Delta G_{M-H_2O} - \Delta G_{H_2O}) \quad (4)$$

Therefore, it is rational to expect that the apparent hydrogen binding energy (HBE*, ΔG_H^{ad*}), taking into account both the intrinsic HBE and the water adsorption energy, exhibits a pH-dependent behavior.¹⁴ Furthermore, one should notice that the same values of Us at different pH in the RHE scale are actually different in the SHE scale. Very possibly, the variations in Us (hereafter, all the Us are for the SHE scale unless otherwise specified) lead to the changes in water adsorption, which in turn modifies the hydrogen adsorption. Therefore, we suspect that water adsorption at different Us are the underlying cause of pH-dependent HBE*.

To prove this hypothesis, we need to answer two fundamental questions:

- First, what are the influences of different Us to water adsorption?
- Second, what are the influences of water adsorption to HBE*?

To answer the first question, we carried out QMMD with explicit solvent to directly simulate water/Pt (100) interface. We

considered U between +0.29 V to -0.46 V to cover the range of experimental condition from pH 0.2 to 12.8 at $U = +0.3$ V (RHE). The work function of water/Pt (100) predicted from QM-MD is -5.06 eV, which corresponding to $U = 0.62$ V (taking reference SHE as -4.44 eV), close to the experimental potential of zero charge (PZC) on Pt (100) of 0.41 V.¹⁵ Extra electrons were introduced to simulate more negative U , which can be achieved by either explicitly introducing sodium (Na) (as shown in Figure 1b) or combining an implicit solvation model¹⁶ on top of explicit water leading to the hybrid scheme (as shown in Figure 1c). The advantage of the hybrid scheme is that we can continuously control the work function by introducing fractional charges at explicit/implicit interface under Poisson-Boltzmann approximation.¹⁶ For example, we can simulate the work function of 4.73 eV, 4.34 eV, 4.11 eV and 3.98 eV by introducing extra charges of $0.97e^-$, $1.94e^-$, $3.06e^-$ and $3.48e^-$, resulting in $U = +0.29$ V, -0.10 V, -0.33V and -0.46V. Thus, with both the explicit and hybrid scheme, we can carry out QMMD simulations and perform *in situ* analysis at given U s of H_{UPD} from pH 0.2 to 12.8.

Figure.1 The water/Pt (100) interface in QMMD simulations. (a) Explicit model (~6 water layers) (b) Explicit + Na⁺ model (~6 water layers + 1 Na) and (c) Explicit + Implicit model (~3 water layers + Implicit solvation model). The colors are Pt in silver, O in red, H in white and Na in green.

From $U = 0.29$ V to -0.46V, we observed substantial changes in the water adsorption, which is reflected in the distribution of water along the z -axis (perpendicular to the surface). Figure 2a shows the distribution of water perpendicular to the surface along the z -axis (ZDF), in which the first peak of Pt-O is 2.15 Å, only 0.13 Å longer than estimated Pt-O valence bond of 2.02 Å.¹⁷⁻¹⁸ Thus we suspected that the water molecules within the first peak might present chemisorbed characters as observed by Schwarz et al.¹⁹ As U decreases, the height of the first peak of Pt-O decreases, which demonstrates that the electrode with increasing d -electrons tends to repel water, thus, weaken water adsorption.

The weaker Pt-water interaction causes notable reorganization of water in the first layer. Figure 2f shows a snapshot of water/Pt (100) interface at $U = 0.29$ V. We highlighted the first layer of water in the blue transparent region by plotting the vdW surface. We characterize the orientation of water molecule by measuring the angle (θ) between water plane and xy plane as shown in Figure 2c. According to θ , we distinguish water molecules with $\theta < 30^\circ$ or $\theta > 150^\circ$ as water parallel to the surface (H_2O^\parallel) (although it is not perfectly parallel to the surface). We distinguish water molecules with $\theta = 90^\circ$ as water perpendicular to the surface (H_2O^\perp). As shown in Figure 3d, H_2O^\parallel is closer to Pt and contributes to the first Pt-O peak. At $U = 0.29$ V, we find 3 H_2O^\parallel as shown in Figure 2d and 2f (as further confirmed from the distribution of water along z -direction as shown in Figure 2b). Thus, the decrease in the first peak of Pt-O radial distribution function (RDF) results from the loss of H_2O^\parallel . Figure 2g shows the snapshot of water/Pt (100) interface at $U = -0.46$ V (pH = 12.8). In this case, only one H_2O^\parallel is observed (as further confirmed from Figure 2b and 2e). Thus, at

more negative U s the electron-rich Pt surface both repels the water and reorients H_2O^\parallel . At even more negative U (such as -0.90 V), all the H_2O^\parallel disappear, with the only H_2O^\perp observed (as shown in Figure S4).

Figure. 2 The interface structures of water adsorption layers under different applied potentials from +0.29 V to -0.46 V. (a) the distribution of water perpendicular to the surface along the z -axis (ZDF) and (b) the number of water (by dividing the interface water from 2 Å to 8 Å into 8 slices). (c) Orientation of water molecules [the angles (θ s) between water plane and xy plane]. The orientation distribution of water molecules that close to surface (< 3.63 Å) at (d) $U = +0.29$ V and (e) $U = -0.46$ V (x-axis is angle, y-axis is distance to surface and z is the probability). The snapshots with atomic details of the interfaces are shown in (f) at $U = +0.29$ V and (g) at $U = -0.46$ V. We highlight the first layer of water by plotting the van der Waals surface of oxygen as blue in transparent. The blacked dashed line shows the boundary of simulation cell. We highlight the water with OH parallel to the surface (H_2O^\parallel) with colored stars.

The question now is the influence of water adsorption to HBE*. To predict the HBE*, we employed Widom insertion (WI) method²⁰ (the details of the WI calculations are in the SI) to calculate the free energies of hydrogen binding on the interface at $U = +0.29$ V, -0.01 V, -0.10 V, -0.33 V and -0.46 V. The obtained HBE* at different U s can be converted back to pH of 0.2, 5.2, 6.7, 10.7 and 12.8 at $U = 0.3$ V (RHE). Therefore, we can compare our calculated HBE* directly with the experimentally measured pH dependent HBE*.¹² As shown in Figure 3, the predictions from QMMD well reproduce the increase of HBE* as a function of pH. The largest deviation between QMMD predictions and experiment is less than 0.05 eV, which is already within the accuracy of PBE calculations. The slope predicted from QMMD is 10 meV/pH

(more details about data fitting is in SI), very close to 8 to 12 meV/pH as measured experimentally.¹² Thus, without postulating of cation or anion effects,²¹ it appears that water adsorption is the dominant cause of the pH-dependent HBE*.

Figure. 3 comparison of apparent hydrogen binding energies (HBE*) between QMMD predictions (solid black lines with hexagons) and experiment data (scatter symbols) at pH ranging from 0.2 to 12.8 (bottom x-axis) or U ranging from 0.29 to -0.46 V (top x-axis). The experimental data is from the work of Shen et al.¹²

The presence of H_2O^- could be potentially determined from experimental measurements, such as ambient pressure X-ray photoelectron spectroscopy (APXPS)²² and attenuated total reflectance infrared (ATR-IR) spectroscopy. We have calculated the O1s chemical shifts of various H_2O molecules near the surface and found that the bulk water has O1s from 506.66 eV to 507.36 eV, while the O1s for H_2O^- is 507.54 eV. Thus, we predicted -0.18 eV to -0.88 eV chemical shift of O1s as guidance to distinguish H_2O^- in APXPS experiment. Meanwhile, H_2O^- also exhibits different rotation and vibration behavior as compared with bulk water. We employed Two-phase Thermodynamic (2PT) model to predict the density of state (DOS) of water from QMMD (as shown in Figure S10).²³ We observe that H_2O^- exhibits significant blue shifts in both rotation and vibration. For example, we predict ~300 wavenumbers blue shift of H-O-H bending mode. The entropy of H_2O^- from the 2PT calculation is 38.06 J/K, about 25% decrease than that of bulk water from the PBE-D3 prediction (51.32/K),²⁴ which indicates that H_2O^- is more active and could increase the kinetic of Volmer reaction and Heyrovsky reaction.²⁵

In summary, we carried out full solvent *in situ* QMMD simulation to explicitly simulate the water/Pt (100) interface at U from +0.29 V to -0.46 V, which are equivalent to pH from 0.2 to 12.8 at U = 0.3 V (RHE). We found that Pt (100) electrode becomes more hydrophobic as U decreasing from +0.29 V to -0.46 V, which is due to the negative charged Pt (100) tends to repel water adsorption. The decrease of water adsorption, in turn, increases hydrogen bonding within the monolayer, resulting in 0.13 eV increase in HBE*. Assuming the linearly relationship between reaction energy difference and reaction energy barrier, a rough estimation is 153 times decrease in HER basing on Arrhenius equation. The slope of pH-dependend HBE* predicted from QMMD is 10 meV/pH, very close to the experimental observation of 8 to 12 meV/pH. Thus, we conclude that water adsorption is the dominant cause of pH-dependent HBE*. From QMMD, we found that the change of binding leads to dramatic water reorientations which lead to a -0.18 eV to -0.88 eV change in O1s chemical shift, and significant blue shifts in surface water vibrations (for example, ~300 wavenumbers blue shift of H-O-H bending mode). These results show the importance of including explicit solvent in QM simulations to correctly describe electrochemical catalysis.

Thus, for HOR/HER catalysis design, instead of only relying on gas phase hydrogen binding calculations, it is equally important to consider the water adsorption or surface hydrophilicity which can be achieved by alloying or introducing hydrophilic surface groups (such as OH).
