**Abstract.** The Schiff theorem is revisited in this work and the residual  $P$ - and  $T$ -odd electron–nucleus interaction, after the shielding takes effect, is completely specified. An application is made to the electric dipole moments of hydrogen-like atoms, whose qualitative features and systematics have important implication for realistic paramagnetic atoms.

**Keywords:** Schiff theorem, Schiff moment, electric dipole moment, time-reversal violation

**PACS:** 11.30.Er, 24.80.+y, 32.80.Ys

## INTRODUCTION

The permanent electric dipole moment (EDM) of a physical system is an indication of time-reversal ( $T$ ) violation which, by  $CPT$  invariance, is equivalent to  $CP$  violation, one of the most profound puzzles in elementary particle physics. Although a neutral atom is ideal for such a precision measurement, much of its EDM evades detection because of the re-arrangement of its constituents in order to screen the applied electric field and keep the whole system stationary.

As the shielding is not exact, many experiments have been performed over the years to measure these tiny, residual EDMs with gradually improved techniques and accuracy. Since an atom contains both electrons and nucleons, its EDM receives contributions from all possible  $P$ - and  $T$ -odd ( $\not{P}\not{T}$ ) dynamics in leptonic, semi-leptonic, and hadronic sectors. The first part of this work is to completely specify, after incorporating the shielding effect, the residual  $\not{P}\not{T}$  electron–nucleus ( $eN$ ) interaction,  $\tilde{H}_{eN}$ . The second part concerns an application to the EDMs of hydrogen-like (H-like) atoms where some general features and systematics of the contributions from different  $\not{P}\not{T}$  sources are extracted.

## SCHIFF THEOREM REVISITED

The so-called Schiff theorem states the following: for a nonrelativistic system made up of point, charged particles which interact electrostatically with each other and with an arbitrary external field, the shielding is complete [1]. Applying this theorem to atoms, the assumptions of this theorem are not exactly satisfied because: (1) the atomic

electrons can be quite relativistic, (2) the atomic nucleus has a finite structure, and (3) the electromagnetic (EM) interaction between  $ee$  or  $eN$  has magnetic components. Therefore, a measured atomic EDM,  $d_A$ , or any upper bound on it, is a combined manifestation of these effects. This can be best summarized by  $\tilde{H}_{eN}$ , through which  $d_A$  can be expressed as

$$d_A \equiv \langle \mathbf{d}_A \rangle \cong \sum_n \frac{1}{E_0 - E_n} \left( \langle 0 | e \mathbf{x} | n \rangle \langle n | \tilde{H}_{eN} | 0 \rangle + \text{c.c.} \right), \quad (1)$$

where  $|0\rangle$  and  $|n\rangle$  represent the atomic ground and excited states, respectively.

While the implementation of the shielding effect, which can be carried out by various ways [see, *e.g.*, 1, 2, 3, 4, 5, 6, 7] is too tedious to be shown here, a simplified example below can be used to illustrate the basic points. The key relationship is to re-write the internal EDM interaction  $\tilde{H}_{eN}^d$  as a commutator involving the unperturbed atomic Hamiltonian,  $H_0$ , plus some remaining terms, if any,

$$\tilde{H}_{eN}^d = [\mathbf{d} \cdot \nabla, H_0] + \dots \quad (2)$$

Substituting the commutator in Eq. (1), a closure sum can be performed and leads to the result:  $-\langle \mathbf{d} \rangle$ . Therefore, if there is no term left beyond the commutator,  $\tilde{H}_{eN}^d$  then contributes to the total EDM exactly opposite to  $\langle \mathbf{d} \rangle$ : this is the complete shielding.

It should be emphasized that the Schiff theorem is a quantum-mechanical description of the shielding effect, and this implies that Eq. (2) should be realized at the operator level, *i.e.*, every quantity is operator. While we obtained the similar expression for the residual interaction due to the electron EDM,  $d_e$ , as Refs. [2, 8], the residual interaction due to the nuclear EDM,  $d_N$ , differs from existing literature. These differences can be summarized in the Schiff moment,  $S$ , we found

$$S \equiv \langle \mathcal{S} \rangle = \frac{e}{10} \left( \langle r^2 \mathbf{r} \rangle - \frac{5}{3} \frac{1}{Z} \left\langle \left[ r^2 \left( 1 - \frac{4\sqrt{\pi}}{5} Y_2(\hat{r}) \right) \otimes \mathbf{r} \right]_1 \right\rangle \right), \quad (3)$$

in contrast to the usual definition [see, *e.g.*, 4, 5, 6, 7].

Besides the additional quadrupole term we include in the derivation (it was usually ignored), the main difference is a matrix element of the composite operator  $\langle r^2 \otimes \mathbf{r} \rangle$  in the former versus a product of the matrix elements  $\langle r^2 \rangle \otimes \langle \mathbf{r} \rangle$  in the latter, where " $\otimes$ " denotes the recoupling of angular momenta. This stems from the way we treat  $\mathbf{d}_N \propto \mathbf{r}$  as an operator in Eq. (2), and the previous definition already takes the matrix element  $\langle \mathbf{d}_N \rangle \propto \langle \mathbf{r} \rangle$  before the derivation. As the nucleons in the nucleus do not necessarily respond in a coherent manner after the shielding sets in, our definition accounts for these additional dynamics which is left out in the previous one. A calculation for deuteron shows quite some difference: in  $S$ , the three terms contribute as 1 :  $-5/3$  :  $-4/3$ ; in the traditional definition, supposed the quadrupole term is included as  $[\langle r^2 Y_2 \rangle \otimes \langle \mathbf{r} \rangle]_1$ , the ratio becomes 1 :  $-0.59$  :  $-0.07$ . While the huge difference in deuteron can be attributed to its loose binding, other nuclear Schiff moments should be revised, because they receive most contributions from the surface region, where the binding is usually not as strong as in the core.

Our derivation also treated the finite-size effect more carefully, following the suggestion of Ref. [7], and included all the magnetic  $eN$  interactions into account. As a result, the full form of  $\widetilde{H}_{eN}$  contains all possible nuclear moments, either long-ranged or local, charge or magnetic. The details will be presented in a later publication [9].

## ELECTRIC DIPOLE MOMENTS OF HYDROGEN-LIKE ATOMS

The parity admixture of an atomic ground state,  $|\widetilde{0}\rangle$  ( $1s_{1/2}$  for H-like atoms) can be solved from the Sternheimer equation [10]. For the cases where the Pauli approximation is valid, the results can be expressed analytically. Separating the contributions from (1)  $d_e$ , (2)  $C_{PS,S}^0$ , a representative case in the semi-leptonic  $eN$  interaction, which is isoscalar and nuclear spin independent, (3)  $S$ , and (4)  $S^{\text{mag}}$ , the magnetic equivalence of  $S$ , which contains, *e.g.*, the magnetic quadrupole moment, they roughly grow with the atomic number  $Z$  as  $Z^2$ ,  $ZA$ ,  $ZS$ , and  $ZS^{\text{mag}}$ . The common factor  $Z^1$  comes from the atomic structure calculation of  $|\widetilde{0}\rangle$ , and the remaining growth factor indicates how the corresponding  $\mathcal{PT}$  interaction scales. As  $S$  and  $S^{\text{mag}}$  both involve  $r^2$ -weighted nuclear moments, they roughly scale with  $A^{2/3}$ .

The main reason that heavy paramagnetic atoms are suitable for constraining  $d_e$  is usually justified from a  $Z^3$  enhancement factor [see, *e.g.*, 11, 12]. Based on the systematics found in H-like atoms, actually part of the enhancement,  $Z^2$ , comes with  $|\widetilde{0}\rangle$ , and can be crudely understood from the fact that it takes less energy for a  $p$ -state excitation from a  $ns_{1/2}$  state with  $n > 1$  than from  $1s_{1/2}$ . As this  $Z^2$  enhancement also applies to other  $\mathcal{PT}$  sources, the competition between the four contributors mentioned above only goes with  $Z$ ,  $A$ ,  $S$ , and  $S^{\text{mag}}$ . Suppose the semi-leptonic or hadronic  $\mathcal{PT}$  interactions are large, *i.e.*, large  $C$  or  $S$  and  $S^{\text{mag}}$ , then the dominance of the  $d_e$  contribution is questionable. In this sense, it is better to have a series of EDM measurements and use their results to constrain these  $\mathcal{PT}$  sources simultaneously, or at least, one should semi-quantitatively determine the conditions under which  $d_e$  is clearly the winner. In either case, the calculations of semi-leptonic and hadronic contributions are indispensable for a more thorough study of EDMs of paramagnetic atoms.
