Running title: Pioneering and gene control by PU.1 in pro-T cells

Keywords: SPI1, DNA accessibility, T-cell development, distal regulatory elements, promoters, repression
Abstract

SPI1 (also known as PU.1) is a dominant but transient regulator in early T-cell precursors and a potent transcriptional controller of developmentally important pro-T cell genes. Before T-lineage commitment, open chromatin is frequently occupied by PU.1, and many PU.1 sites lose accessibility when PU.1 is later downregulated. Pioneering activity of PU.1 was tested in this developmentally dynamic context, by quantitating the relationships between PU.1 occupancy and site quality and accessibility as PU.1 levels naturally declined in pro-T cell development, and by using stage-specific gain and loss of function perturbations to relate binding to effects on target genes. PU.1 could bind closed genomic sites, but rapidly opened many of them, despite the absence of its frequent collaborator, CEBPA. RUNX motifs and RUNX1 binding were often linked to PU.1 at open sites, but highly expressed PU.1 could bind its sites without RUNX1. The dynamic properties of PU.1 engagements implied that PU.1 binding affinity and concentration determine its occupancy choices, but with quantitative tradeoffs for occupancy between site sequence quality and stage-dependent site accessibility in chromatin. At non-promoter sites PU.1 binding criteria were more stringent than at promoters, and PU.1 was also much more effective as a transcriptional regulator at non-promoter sites where local chromatin accessibility depended on the presence of PU.1. Notably, closed chromatin presented a qualitative barrier to occupancy by the PU.1 DNA binding domain alone. Thus, effective pioneering at closed chromatin sites also depends on requirements beyond site recognition served by non-DNA binding domains of PU.1.
Introduction

In development, a cell’s regulatory history determines different pre-existing chromatin accessibility landscapes, which in turn may bias a transcription factor (TF) to engage different sites in different contexts (Treiber et al. 2010). However, questions remain about how much of a barrier chromatin state may pose, or whether there is a clear distinction between transcription factors that are highly chromatin-limited and other, “pioneer” factors, that might engage their sites impervious to chromatin state. SPI1 (also known as PU.1, used throughout this article) works both to mediate developmental choices of blood progenitor cells and to serve the alternative developmental fates – associated with different epigenetic landscapes – that emerge from these choices. Its role in T-cell development is confined to the early stages leading up to T-cell lineage commitment, where it occupies tens of thousands of genomic sites in uncommitted cells but disappears in a programmed way during commitment. This dynamic transition offers a rare window into the quantitative contributions of affinity, chromatin context, factor concentration, and developmental history as predictors of PU.1 function.

The best studied roles for PU.1 involve its sustained actions as a lineage-determining transcription factor in myeloid, dendritic-cell, and B cell development, where it can open closed chromatin and recruit other transcription factors including CEBPA, NF-κB complexes, and IRF4 or 8 (Escalante et al. 2002; Carotta et al. 2010; Heinz et al. 2010; Natoli et al. 2011; Ostuni et al. 2013; McAndrew et al. 2016) [reviewed in (Gosselin and Glass 2014)]. In the macrophage context, PU.1 can act as a pioneer factor, capable of evicting nucleosomes (Barozzi et al. 2014), but collaboration with known partners also affects PU.1 site choices (Heinz et al. 2013). PU.1 is also crucial for multiple other hematopoietic lineages (Back et al. 2005; Iwasaki et al. 2005; Nutt et al. 2005) including the earliest stages of T-cell development (Champhekar et al. 2015). Although most mature T cells express no PU.1, early-stage pro-T cells maintain substantial PU.1 through multiple cell divisions before downregulating it during T-cell lineage
commitment (Yui et al. 2010; Zhang et al. 2012). CEBP or IRF family factors that PU.1 cooperates with in myeloid and B cells are expressed little if at all in early T-lineage cells, which should affect PU.1 genome-wide binding profiles (Heinz et al. 2013). Yet its potential for pioneering activity in other cell types, enhanced by its unusual protein stability (Kueh et al. 2013), could make it a strong contributor to “epigenetic memory” in early pro-T cells. Here we have investigated how PU.1 sets and responds to the chromatin context in which the T-cell program emerges.

PU.1 expression is well established in multilineage lymphoid precursors before they enter the thymus. Within the thymus, pro-T cells proliferate and differentiate through stages called DN1, DN2a, DN2b, and DN3a before they express T-cell receptor proteins. They become committed to the T-cell fate only during the DN2a to DN2b transition (Fig. 1A), which follows multiple cell divisions under the influence of thymic Notch pathway signaling [rev. in (Yui and Rothenberg 2014)]. Commitment encompasses a global shift in 3-D chromatin associations (Hu et al. 2018) and in regulatory gene expression (Rothenberg et al. 2016), and this is when PU.1 expression is finally shut down. Until commitment, PU.1 binds to >30,000 sites in DN1 and DN2a pro-T cells, distinct from sites occupied in B and myeloid lineage cells (Zhang et al. 2012). It supports proliferation and restrains specific alternative lineage genes, but slows progression toward commitment, thus enforcing correct timing of access to T-lineage genes (Champhekar et al. 2015). Previously, we identified impacts of PU.1 on specific, developmentally relevant genes by acute gain and loss of function perturbations (Anderson et al. 2002; Dionne et al. 2005; Franco et al. 2006; Del Real and Rothenberg 2013; Champhekar et al. 2015). PU.1 repressed as well as activated genes (Dionne et al. 2005; Franco et al. 2006; Del Real and Rothenberg 2013), antagonizing Notch signaling in early T-cell development and delaying activation of many T-cell genes until commitment. However, PU.1 binding sites globally appeared to be associated with active chromatin and actively expressed genes (Zhang et al. 2012), leaving the repression
unexplained. Furthermore, most genes linked to PU.1 occupancy in vivo do not change expression as PU.1 levels decrease in T-cell development (Zhang et al. 2012), implying that most PU.1 binding events do not control transcription. Here, therefore, we have used gain and loss of function perturbations coupled with genome-wide analyses of the changes they induce in binding, chromatin state, and transcription of developmentally significant genes to show how PU.1 selects the sites that it will occupy in changing chromatin contexts, respecting or reshaping local chromatin states, and how its binding at certain classes of sites does control early T-cell gene expression.

Results

Dynamic PU.1 occupancy at open and closed chromatin sites in pre-commitment pro-T cells

In early, pre-commitment T-cell development (Fig. 1A), PU.1 occupancy starts at ~30,000 genomic sites in DN1 and DN2a stages, globally distinct from the PU.1 sites in non-T lineage cells, then decreases to a subset of ~5000 scorable sites in newly-committed DN2b cells (Fig. 1B), before PU.1 disappears at later stages (Zhang et al. 2012). To evaluate how PU.1 might select these sites, we examined whether chromatin status at the sites and the binding specificity of the protein itself could determine occupancy preferences. We used a sequence-agnostic criterion of regulatory site activity during the natural decrease of PU.1 during commitment (from DN1 and DN2a to DN2b and DN3). Activity states of chromatin were mapped at high resolution as changes in DNA accessibility (“openness”) using Analysis of Transposase-Accessible Chromatin (ATAC)-seq (Buenrostro et al. 2013). Fig. 1C shows examples of PU.1 occupancy patterns at the Cd34 and Bcl11a target genes, which are most highly expressed in pre-commitment DN1 cells, correlated with ATAC status of the relevant sites before (DN1) and just after commitment (DN3). Although “permissive” H3K4me2 chromatin modifications change little across these stages in general (Zhang et al. 2012), these loci are linked with specific sites
where developmental loss of PU.1 binding during commitment is accompanied by losses of ATAC accessibility and H3K4me2 (Fig. 1C, highlighted regions). Considering all sites genome-wide where PU.1 bound during any DN1-DN2b stage, ATAC criteria showed that more of these sites were likely to be “open” in DN1 stage (Fig. 1D, cyan) than in DN3 stage, when PU.1 levels were low (Fig. 1D, dark green). This suggests that PU.1 either causes these sites to open or is preferentially recruited to them because of their accessibility.

Changes in ATAC status of PU.1 sites between DN1 and DN3 stage were strongly correlated with changes in expression of the closest linked gene. As shown by an empirical cumulative distribution frequency (ECDF) plot (Supplementary Fig. S1A), genes linked to PU.1 sites that lost accessibility during commitment (“closing sites”) were more likely to be downregulated (DN3/DN2a ratio <1, padj<0.1, blue arrow) than genes without PU.1 sites. Accordingly, genes linked to sites that increased accessibility (“opening sites”) were more likely to be upregulated (DN3/DN2a ratio >1, padj<0.1, red arrow). Taken together with the enrichment of open regions among all PU.1-occupied sites, this suggests that PU.1 could positively regulate hundreds of genes specific to precommitment cells. However, PU.1 binding across the genome was not confined to open sites (Fig. 1D,E). In DN1 and DN2a cells, PU.1 occupied similar numbers of closed and open sites (Fig. 1E). Therefore, PU.1 does not simply engage sites epigenetically primed by other factors, nor does its binding always cause chromatin opening as scored by ATAC-seq.

**Distinct PU.1 affinity thresholds in open and closed chromatin and at promoter and non-promoter sites**

In macrophages, PU.1 is a pioneer factor capable of displacing nucleosomes from its binding sites (Barozzi et al. 2014). In pro-T cells, where PU.1 expression is inherited from pre-thymic precursors but its best-characterized partner factors are absent, it was not clear whether PU.1...
led or followed other factors to select its sites. The definition of pioneering (Zaret and Carroll 2011) implies that the DNA binding specificity of the factor itself guides its binding to sites in initially closed chromatin. We tested whether PU.1 intrinsic specificity guides its binding to “open” and “closed” sites by scoring PU.1 occupancy sites genome-wide for log-odds match to an optimal position weight matrix (PWM), calculated de novo (Supplementary Table S1, Supplementary Fig. S1B) from its pro-T cell binding sites (Zhang et al. 2012). The scoring pattern of sites across the genome (Fig. 1E,F) agreed well with the pattern scored using a more permissive PWM, calculated from PU.1 sites occupied in macrophages, which was reported to reflect PU.1 binding preferences on naked DNA (Pham et al. 2013)(Supplementary Fig. S1B,C). The canonical PU.1 motif was the most enriched, at all classes of sites (Supplementary Fig. S1D). However, at each stage, PU.1-occupied sites in open regions had a broader range of quality scores, with lower median and quartile quality scores, than the PU.1-bound sites in closed regions, implying that higher affinity was needed to establish binding at closed sites. The “closed” PU.1 binding sites accordingly showed a greater enrichment of a PU.1 subfamily (Sfpi1, SpiB) ETS motif than the “open” sites (Figs. 1G, S1D). On the other hand, open sites and the lower-quality half of the closed sites were distinguished from higher-quality closed sites by their high co-enrichment of RUNX family motifs (Figs. 1G, S1D).

The changes in PU.1 occupancy across the genome as PU.1 levels naturally decrease in development implied that PU.1 binding site selection is governed by its own mass action. As PU.1 tag counts at individual sites and the number of scorable binding regions genome-wide both dropped during commitment (Fig. 1B), the sites still occupied were those with higher motif quality (Figs. 1F; S1C,E). However, distinct binding criteria applied in open and closed chromatin regions. Both open and closed regions lost PU.1 occupancy at DN2b stage (Fig. 1E, left), but the site quality difference between them persisted where PU.1 remained bound (Fig. 1F, left; Supplementary Fig. S1E), consistent with a continuing affinity penalty in the closed
regions. Matching site quality distributions at “closed” DN2a and “open” DN2b sites suggested that closure reduced PU.1 sensitivity by 4-5×. In the same cell nuclei, declining PU.1 levels also differentially affected binding at promoter and non-promoter (distal) sites. Promoter sites were occupied even when they had poor quality target motifs (Fig. 1F, right), and when PU.1 fell to lower levels, the promoter sites still occupied were poorer-quality than non-promoter sites. This global difference in binding criteria at promoter and non-promoter sites was seen at all stages, and even when open and closed promoter and non-promoter sites were compared separately (Supplementary Fig. S1E). Thus, PU.1 is recruited differently to promoters and enhancer elements.

**Non-promoter PU.1 sites control chromatin configuration and function**

Genome-wide PU.1 binding dynamics were correlated with changes in local chromatin status. Fig. 2A,B shows the ~40K sites of PU.1 occupancy in the pro-T genome, clustered based on PU.1 binding, ATAC accessibility, and H3K4me2 modification status from DN1 to DN2b or DN3 stages. The majority of sites fell into either of two major groups (Fig. 2A, Group 1 and Group 2; \(k\)-means). One large group of sites comprised open sites that stayed highly accessible, independent of developmental stage or level of PU.1 binding (Fig. 2A,B, site Group 1, “static”). In contrast, about 60% of PU.1 occupancy sites in DN1 and DN2a cells lost accessibility, and sometimes even the “permissive” histone mark H3K4me2, as PU.1 expression declined in DN2b/DN3 stages (Fig. 2A,B; site Group 2, “closing”). A few sites also “opened” as PU.1 levels declined (see below), but did not cluster efficiently here. The static sites (Group 1) were highly enriched for annotated promoters (39.8% in promoter regions) (\(\chi^2\) test \(p <0.0001\)), whereas the closing sites (Group 2) were overwhelmingly in non-promoter elements (only 4.6% peaks in promoter regions). Thus, the dominant division of PU.1 occupancies was into sites with constitutive accessibility and sites whose accessibility decreased in parallel with PU.1 expression itself.
PU.1 binding at non-promoter sites, but not at promoters, was correlated with gene expression specifically before commitment. Genes linked only to Group 1 binding sites changed little in expression between DN2a (high PU.1) and DN3 (low PU.1) stages (Fig. 2C), even less (yellow arrow, p<0.0001) than genes without any PU.1 binding peaks at all (Fig. 2C, black curve). In contrast, genes linked to Group 2 PU.1 sites (Fig. 2C green) changed expression much more than genes without peaks, most of them losing expression in this developmental transition (green arrow, p<0.0001, skew to left), despite similar kinetics of retention of PU.1 between Group 1 and 2 sites (Supplementary Fig. S1F). These results suggest that PU.1 binding in pro-T cells is more stringent, more important for chromatin site accessibility, and better correlated with transcription when it binds at non-promoter regions than at promoters.

To test whether PU.1 itself was responsible for the dynamics of ATAC accessibility at these non-promoter sites, we exploited the Cas9 transgenic mouse strain (Platt et al. 2014) to provide T-cell precursors in which PU.1 could be acutely deleted at a specific developmental stage (Fig. 2D) (Hosokawa et al. 2018). Hematopoietic precursors from these mice were isolated and induced to begin T-lineage differentiation in vitro by coculture with OP9-DL1 stromal cells. When PU.1 was at its height during DN1 to DN2a stages, specific guide RNAs were introduced by retroviral transduction (sgSpi1 or sgControl), and effects on chromatin accessibility were assayed by ATAC-seq after four more days of culture. This deletes targeted exons biallelically (Supplementary Fig. S1G) and removes endogenous PU.1 expression (Hosokawa et al. 2018). While promoter sites were unaffected when PU.1 was deleted, many non-promoter sites specifically lost accessibility, far more than gained accessibility, and these affected sites were normally open in DN1 but not in DN3 stage (Fig. 2E). The sites with PU.1-dependent accessibility were indeed direct targets, for they were also significantly enriched among distal sites that normally bound PU.1 in control DN1 cells (Fig. 2F,G; p ≤ 0.0001). The whole
accessibility distribution of PU.1 binding sites in non-promoter regions shifted toward closure when Spi1 was disrupted (Fig. 2G, right). In contrast, PU.1 deletion had little if any effect on promoter sites, with or without PU.1 binding (Fig. 2E-G). Thus, sustained PU.1 activity is needed to maintain ATAC accessibility at many non-promoter PU.1 binding sites.

**PU.1 can bind its target sites independently of RUNX1**

The motifs most highly co-enriched with PU.1 motifs were for RUNX factors. In a related study, we have shown that PU.1 physically interacts with RUNX1 in pro-T cells and recruits it to PU.1 binding sites (Hosokawa et al. 2018). Supplementary Fig. S2A shows that a large fraction of endogenous PU.1 occupancy sites that were open in primary DN1 cells were in fact co-occupied by RUNX1 [data from (Hosokawa et al. 2018)], with highest RUNX1 binding enrichment among those sites with lower-quality PU.1 motifs (below median PWM score). RUNX1 co-occupancy was much lower at PU.1 sites in closed regions, consistent with motif enrichments (Fig. 1G, Supplementary Fig. S1D). These results raised the question of how much RUNX1 was contributing to the ability of PU.1 to establish occupancy at different classes of sites.

Whereas primary cell recovery is severely inhibited by combined deletion of Runx1 and forced expression of PU.1, we could test the effect of RUNX1 loss on binding of exogenous PU.1 in the Scid.adh.2C2 model cell system. These are immortal, clonal DN3-like cells that do not express endogenous PU.1, but respond sensitively to introduction of exogenous PU.1 with responses similar to those of primary pro-T cells (Dionne et al. 2005; Del Real and Rothenberg 2013)(Fig 3A). Scid.adh.2C2 cells were transduced with Cas9 followed by either control sgRNA (sgCtrl) or sgRNA against Runx1 (sgRunx1), and then transduced with exogenous PU.1 (Fig. 3B). This treatment biallelically disrupted the region around the first Met codon shared by all RUNX1 isoforms (Supplementary Fig. S2B) and eliminated RUNX1 protein expression (Hosokawa et al.
2018). Fig. 3C shows how this affected PU.1 binding to non-promoter sites. The sites bound by exogenous PU.1 were more likely to be initially open in Scid.adh.2C2 cells if near sites where RUNX1 bound previously (Hosokawa et al. 2018)(tallied below plots in Fig. 3C). However, high-quality PU.1 binding to these non-promoter sites was essentially unchanged by Runx1 disruption, whether they had been previous sites of RUNX1 occupancy (Fig. 3C, right panel) or not (left panel). Thus, although RUNX1 can be important for PU.1 function in pro-T cells (Hosokawa et al. 2018), PU.1 does not depend on RUNX1 to establish its binding at open or closed sites.

**Pioneering by PU.1 in DN3-like cells: site choice and chromatin opening in a closed epigenetic landscape**

PU.1 not only maintained the open status of its normal binding sites but could also cause sites to open in closed chromatin, as shown using the Scid.adh.2C2 cell line to provide a defined, low-background pro-T-cell context. To place PU.1 activity under tight temporal control, Scid.adh.2C2 cells were transduced stably with a vector encoding full-length PU.1 linked to the ligand-binding domain of a tamoxifen-dependent estrogen receptor (PU1-ERT2)(Fig. 3A). Most of the PU.1 expressed in these cells is tethered in the cytoplasm, but the PU.1 can translocate quickly to the nucleus in response to 4-hydroxytamoxifen (4-OHT). This downregulates the pro-T cell surface marker IL2RA (also known as CD25, used throughout this article) beginning by 24h (Supplementary Fig. S2C), and upregulates the myeloid-cell surface marker Itgam (also known as CD11b) later (Dionne et al. 2005; Del Real and Rothenberg 2013). From 0 to 24h of stimulation with 0.1 μM 4-OHT, we compared the kinetics of PU.1 binding to the genome with changes in H3K27ac and ATAC accessibility at these sites (Fig. 3D,E; Supplementary Fig. S2D). Baselines were defined by control cells transduced with an “empty” control vector encoding ERT2 only (“EV”, “EV-ERT2”)(Fig. 3B,C)(gene expression effects: Supplementary Table S2). Two site groups were seen (Groups 3 & 4). There was some background signal at
0h: in Scid.adh.2C2 cells stably expressing PU1-ERT2, low levels of PU1-ERT2 reached the nucleus even without 4-OHT, unlike EV-ERT2 samples (Fig. 3D, Supplementary Fig. S2D,E). Sites occupied in the presence of these low levels of nuclear PU.1 were restricted to already-active chromatin sites, based on ATAC accessibility and H3K27ac in non-transduced or EV-transduced cells (Fig. 3D, Group 4; Supplementary Fig. S2D,E). However, 4-OHT treatment induced nearly 5× more PU.1 binding sites within 2h (Supplementary Fig. S2D,E), and most of this new binding was to Group 3 sites (Fig. 3D) that had no PU1-ERT2 binding at 0h and were closed in unperturbed Scid.adh.2C2 cells (Fig. 3E, Supplementary Fig. S2D,E). Examples are the highlighted sites in the *Icam1* gene, which were also bound in DN1-DN2a cells by endogenous PU.1 (Fig. 3F). Like Group 1 sites of endogenous PU.1 in primary cells (Fig. 2A), 51% of Group 4 sites were at promoters, contrasting with only 3.1% of Group 3 sites ($\chi^2$ p-value < 0.0001), and the PWM match quality for Group 3 sites was much higher than for Group 4 sites (Supplementary Fig. S2F). Binding to Group 3-type sites was confirmed with another exogenous PU.1 construct, PU1WTHA (see below), which preferentially occupied “closed” sites in these cells unlike “open” sites bound by endogenous ETS1 (Supplementary Fig. S2G).

In this cell context, PU1-ERT2 exerted its main positive impact at closed, non-promoter Group 3 sites, rapidly making them ATAC accessible. This response was maximal already within 2h (Figs. 3D,E; Supplementary Fig. S2D). Slightly later, ~50% of the Group 3 sites also acquired the active histone mark H3K27ac de novo, beginning at 2 h but with most signal observed by 8-24h of PU.1 binding (Fig. 3D,E; Supplementary Fig. S2D). Genome-wide, genes responding to PU1-ERT2 binding at linked Group 3 sites also usually increased expression over the 24h period (Fig. 3G, green). In contrast, those linked only to binding at Group 4 sites showed even less increase than genes without closely linked PU.1 sites at all (Fig. 3G, yellow).
Many functionally important PU.1 sites were bound immediately: the sites occupied at 2h were as likely to predict expression of linked genes at 24h as sites that were occupied only at 8h or 24h (Supplementary Fig. S3A). However, the kinetics of transcriptional response implied a stepwise process. The pattern of expression of DEGs closely linked to new PU1-ERT2 sites began to change from 2h onward (Supplementary Fig. S3B), but only about 1/3 of the genes that were eventually activated showed upregulation by 8h, despite maximal ATAC accessibility already; most were only activated by 24h (all p<10^{-9}). Thus, PU.1 binding rapidly initiated local ATAC accessibility in previously closed chromatin sites enabling further steps resulting in local target gene activation, consistent with pioneering activity.

Whereas binding of PU.1 to non-promoter sites most often exerted positive effects, if any, on linked genes, PU.1 introduction also repressed many genes in these cells (Dionne et al. 2005; Del Real and Rothenberg 2013). Supplementary Fig. S3B shows that such repression could start early, often before most positive target genes were upregulated (2h vs. 8h; Supplementary Table S2). While much of this repression was likely indirect (Del Real and Rothenberg 2013; Champhekar et al. 2015; Hosokawa et al. 2018), some was accompanied by direct binding. For example, *Il7r* was substantially repressed as PU.1 bound to an open Group 4 site at its promoter (Supplementary Fig. S3C).

**Opening of closed chromatin by PU.1 mediates its developmental gene regulatory function**

Data in Figs. 1 and 2 have shown that PU.1 binding in steady state is correlated both with chromatin openness and with local gene expression, but correlation alone could not prove that PU.1 normally regulates these genes. Data in Fig. 3 show that PU.1 could induce chromatin opening and gene activation when introduced at high levels in a PU.1-negative cell-line context. To confirm whether PU.1 serves its normal function in pro-T cells through opening chromatin
around its non-promoter binding sites, acute perturbations of PU.1 had to be carried out in a primary-cell developmental context with dosage changes close to the normal range, and with changes in its local binding tested for direct linkage to genes showing changes in expression. The evidence is detailed in Supplementary Figs. S4, S5 and Tables S3-S7, and summarized in Fig. 4.

Briefly, we determined the RNAs changing expression after acute gains of PU.1 function at the DN2b/DN3 stages, when endogenous activity was diminishing, and reciprocally, after losses of PU.1 function (as in Fig. 2D-F; & Fig. 4A). We introduced epitope-tagged exogenous PU.1 (PU1WTHA), so that changes in transcription could be directly attributed to local binding of the exogenous PU.1 constructs. Supplementary Figs. S4A,B show the cellular features of this system. Exogenous PU1WTHA established occupancy at sites with the same site quality spectrum that the endogenous PU.1 had occupied earlier (Fig. 4B). Supplementary Fig. S4C-F show the patterns of gene expression change that resulted, and their relation both to normal pro-T development (Supplementary Tables S3, S4) and to likely physiological target genes affected by acute Spi1 deletion (Supplementary Tables S5, S6). Supplementary Fig. S4E-G show the criteria used to focus on cells affected by PU.1 within the normal pro-T developmental trajectory (“PU1WTHA25”), minimizing second-order effects. The exogenous Spi1 in these experiments was expressed at about 3-4× its endogenous DN1-cell level (Supplementary Table S3). Exogenous PU.1 in these cells altered gene expression in rough agreement with normal developmental trends of the affected genes (Supplementary Fig. S4H), and especially well in a curated “developmental index” gene set (Supplementary Fig. S4I; Supplementary Table S4). Most genes affected in PU1WTHA25 cells were upregulated, especially those with direct PU.1 binding (Supplementary Fig. S4J).
PU1WTHA established occupancy at most sites that endogenous PU.1 had occupied before (Fig. 4C, “Exo PU.1” vs. “PU.1”), at both non-promoter (Group 5) and promoter-enriched (Group 7) sites, as well as a group of sites that were normally not occupied by endogenous PU.1 (Group 6). The Group 5 and Group 7 sites respectively resembled Group 2 and Group 1 sites of endogenous PU.1 binding in chromatin dynamics and site qualities (Fig. 4C; Supplementary Fig. S5A,B). Group 6 sites had high-quality motifs but were normally closed and not bound by endogenous PU.1 (Supplementary Fig. S5A,B)(Supplementary Table S7). However, the genes upregulated in PU1WTHA25 cells were enriched not only for Group 5 sites but also for Group 6 sites (Fig. 4D; Supplementary Fig. S5C), i.e., where default chromatin states without PU.1WTHA would have been closing or closed. PU1WTHA binding to promoter-enriched Group 7 sites again resulted in minimal change.

Globally, the dynamic status of site accessibility in normal development predicted the direction of response of a linked gene (Supplementary Fig. S5D-F): PU1WTHA tended to activate genes linked to sites that normally closed as endogenous PU.1 declines (“closing sites”, Kolmogorov-Smirnov p<2.2×10^{-16}; Fig. 4E, blue arrow), while it had little or negative effect on genes linked to sites that would normally open as endogenous PU.1 declines (“regions opening”; Fig. 4E, red arrow). Thus, acute transcriptional changes caused by PU.1 in pro-T cells were tightly linked with its engagement at non-promoter sites where chromatin accessibility normally follows PU.1 expression. This supports a normal mechanism of PU.1 action via chromatin accessibility.

**PU.1 requires its non-DNA binding domains to occupy sites in closed chromatin**

To assess the domains needed for pioneering activity within the PU.1 protein, we mapped the genomic sites occupied by the isolated PU.1 DNA binding domain alone (PU1ETSHA) as compared to full-length PU.1 (PU1WTHA). To relate this binding to function comparable to PU1WTHA, we also tested a dominant negative PU1ETSHA derivative, PU1ENGHA (constructs...
diagrammed in Supplementary Fig. S6A), which primarily repressed targets rather than activating them (Supplementary Fig. S6B). Both truncated forms bound to DNA with site quality criteria similar to those of PU1WTHA (Supplementary Fig. S6C), and in primary pro-T cells, PU1ENGHA exerted its effects preferentially on sites that would normally close from DN1 to DN3 (Supplementary Fig. S6D), like sites preferred for function by PU1WTHA (cf. Fig. 4E).

However, when PU1WTHA, PU1ETSHA, and PU1ENGHA were introduced into Scid.adh.2C2 cells, both truncated constructs bound quite differently from full length PU.1 (Supplementary Fig. S6E, F), with much greater biases to promoter sites and reduced binding at non-promoter sites. Thus, whereas PU1WTHA bound both to normal sites of PU.1 occupancy in pro-T cells and some additional ones, the truncated constructs in these cells bound well only to a subset of natural PU.1 sites (Supplementary Fig. S6G, Group B).

The sites that were poorly bound by PU1ETSHA and PU1ENGHA in Scid.adh.2C2 cells were not poor-quality in sequence, for in primary pro-T cells these sites (Supplementary Fig. S6G,H, Group A sites) could be bound by PU1ENGHA as well as the sites that were accessible in the Scid.adh.2C2 cells (Group B sites). In primary cells, also, the Group A sites were even better at mediating the repressive effect of PU1ENGHA (Supplementary Fig. S6I) than the Group B sites, which were constitutively open and promoter-enriched. The difference, however, was that Group A sites were in much less accessible chromatin in Scid.adh.2C2 cells (Supplementary Fig. S6G). Fig. 5A-D show Cd34, Robo1, Syk, and Ffar2, all positively regulated by full-length PU.1 and repressed by PU1ENGHA in primary cells (Supplementary Table S3), which exemplify this context-dependent differential binding (highlighted) at Group A-type sites. Supplementary Fig. S7 shows additional examples: Cd44, Vav1, Elovl5, Flt3, Notch2, and Myd88.

The failure of the isolated PU.1 DNA binding domain (or its derivative) to interact with these sites in the context of the DN3-like cell line suggested that PU.1 without its native trans-
activation and protein-interaction domains could be more sensitive to chromatin state for access to its binding sites than full-length PU.1. We tested whether the truncated constructs really have a qualitative requirement for open chromatin, or whether they simply have lower affinity or reach lower effective protein concentrations. First, we compared binding success of PU1WTHA and PU1ENGHA in primary CD25+ cells at sites of different PWM quality scores with open vs. closed ATAC status. Here, PU1ENGHA bound comparably to PU1WTHA at open sites (Fig. 5E). However, whereas PU1WTHA showed the expected affinity cost for entry into closed chromatin, PU1ENGHA showed much less binding at closed sites, even those with very high-quality motifs (Fig. 5E). Wildtype and truncated constructs also showed sharply different binding to target sites in SCID.adh.2C2 cells depending on whether they were ATAC-open or ATAC-closed. Fig. 5F shows the occupancies of the same open and closed sites by PU1WTHA, PU1ENGHA, or PU1ETSHA, all compared to PU1WTHA (detected by a different antibody). In these graphs, identical binding falls on the diagonal, as seen when the same PU1WTHA was detected with αPU.1 or with αHA antibodies. Global DNA-binding efficiency differences between a truncated construct and the full-length form should shift the whole trend line downward on the log/log plot or change its slope. Instead, Fig. 5F shows that the truncated constructs gave a split pattern. Both truncated constructs closely matched PU1WTHA on open sites (red), but were specifically penalized, within the same cells, with lower binding slopes and high dispersions at closed sites (blue). Thus, the non-DNA binding domains of PU.1 strongly and selectively affected the ability of the PU.1 DNA binding domain to establish occupancy in closed chromatin.

**DISCUSSION**

PU.1 is known to act as a pioneer in the role of a lineage determining factor that initiates and sustains identity of myeloid cells (Natoli et al. 2011; Barozzi et al. 2014). In this study we have asked whether its inherited high activity in the earliest pro-T cells also shapes the epigenetic landscape in this context, even though its activity in this lineage is hit and run and many of its
known partners are not expressed. Criteria for pioneering involve the ability to open closed chromatin and to initiate occupancy of a cis-regulatory site by a complex of transcription factors (Zaret and Carroll 2011). Logically, this implies that pioneer factors can (1) find and bind to sites in closed chromatin; (2) bind to target sequences based on their own specificity, even before other factors are available to collaborate; and (3) initiate the opening of chromatin as new partners are recruited. In the myeloid system, PU.1 often plays these roles as part of a partnership with C/EBP family factors, where either PU.1 or the C/EBP factor can help nucleate binding by the other (Laiosa et al. 2006; Feng et al. 2008; Heinz et al. 2010; Heinz et al. 2013).

As we show here, PU.1 also fulfills most of the criteria for pioneering in pro-T cells. It can bind closed chromatin as well as open. Its binding is primarily guided by its own well-defined specificity, although its binding to closed chromatin sites in these cells requires a consistently higher affinity of site recognition than binding to open chromatin. Its binding preferences as its concentrations drop during T-cell development are consistent with mass-action in which the dissociation constant is dominated simply by PU.1’s own specificity. Finally, it can trigger chromatin opening, and is required continuously to maintain accessibility at many of its target sites. These functions are exerted especially at a major subset of its non-promoter sites, where PU.1 can rapidly induce transposase accessibility followed by recruitment of histone acetyltransferases. It may cooperate with RUNX1 in causing chromatin to open and to activate its positive target genes (Hosokawa et al. 2018), but does not require RUNX1 for its own binding. This is summarized in Fig. 6.

ChIP-seq analysis, short-term forced expression and acute, synchronized CAS9-mediated deletion tests have robustly defined the positive regulatory targets of direct PU.1 binding in early pro-T cells. A core group of about 250 genes is positively regulated by PU.1 based on gain and loss of function in pro-T cells (Supplementary Table S6), and these genes are linked to non-promoter sites of PU.1 binding that depend on PU.1 for ATAC accessibility and lose
accessibility when PU.1 levels decline. We have also identified a minority of negative regulation targets that are also likely to be direct. These high-confidence target genes of PU.1, both positive and negative, show direct binding, chromatin features at PU.1 sites and developmental expression all implying that normal endogenous PU.1 activity is a major controller of their site accessibilities during normal pro-T cell development.

The high developmental resolution possible in this system sheds light on features of PU.1 action that have much broader implications. The first is that motif quality of sites, magnitudes of occupancy, promoter-association, and immediate degrees of ATAC accessibility are useful but not sufficient criteria to identify loci of actual PU.1 regulatory action. Promoters are by far the most accessible sites for PU.1 binding: not only are they constitutively open as measured by ATAC-seq, but also they offer an exceptionally permissive affinity threshold for PU.1 engagement, and they do not require the PU.1 transactivation domains for efficient PU.1 binding. In myeloid cells, PU.1 is commonly bound at promoter-proximal regulatory elements of functional target genes (Gonzalez et al. 2015). However, although PU.1 is frequently bound to promoters of active genes in pro-T cells as well, in this cell context the actual functional impact of its activity at these promoters is often weak or null, unless supplemented by local binding to non-promoter sites as well. Instead, it is those dynamic distal elements, even those with less-pronounced PU.1 binding, that are best associated with function.

PU.1 binding is excluded by H3K27me3-marked repressive chromatin (Zhang et al. 2012), but modestly elevated PU.1 can also enter other regions that appear “inaccessible” by criteria of ATAC-seq, and upon binding can mediate rapid chromatin opening and local gene activation. However, we have shown that the ability to establish binding in such closed sites depends on a function of PU.1 structurally distinct from its site recognition. As in the case of EBF1 (Boller et al. 2016), although the PU.1 DNA-binding domains define its nucleotide sequence specificity, the
non-DNA binding domains of PU.1 are required for its access to closed sites. Thus, the DNA binding domain alone is not only deprived of discrete transactivation or protein interaction functions, but also of access to a large subset of potential genomic targets. This effect explains some of the functional specificity of the obligate-repressor PU1ENGHA form as previously reported (Champhekar et al. 2015), which can compete with endogenous PU.1 at open binding sites but cannot gain access to those sites once they have developmentally closed. The non-DNA binding domains of PU.1 are important for its interactions with protein partners, at least including RUNX1 and SATB1 in early pro-T cells (Hosokawa et al. 2018), IRFs (Escalante et al. 2002), and factors important in erythroid development (Zhang et al. 2000; Stopka et al. 2005). Although RUNX1 itself may not explain this specific binding requirement, other interacting proteins (Hosokawa et al. 2018) remain as candidates to assist PU.1 binding in closed chromatin of pro-T cells. Thus, the full site-selectivity of PU.1 as a pioneer depends not only on its ability to find high-affinity sites, but also on the ability of its protein-interaction domains to convert recognition of sites in closed chromatin into stable, functional occupancy.

Thus, despite PU.1’s fulfillment of simple criteria of pioneer function, its impact on early T-lineage cells is determined by the intersection of its own powerful binding activity and its dynamic interaction with other determinants of epigenetic state. The effect of closed chromatin on full-length PU.1 appears to be quantitatively compensated by the higher binding affinities at nearer-optimal sites, but the transcriptional effect of this PU.1 binding on neighboring genes depends on other factors that influence whether the site bound is constitutively open, constitutively closed, or may be dynamically opening or closing in development. This reconciles the biochemical pioneering-like activities of PU.1 with its distinctive lineage-specific occupancy patterns and functional impacts in the earliest stages of T-cell development.

METHODS
Full methods and a full reagent list are provided in Supplemental Material. Briefly:

**Mice and cells.** As a source of primary cells, C57BL/6 mice and mice with *Cas9* and *Bcl2* transgenes on a C57BL/6 background were used as described previously (Hosokawa et al. 2018). Fetal liver precursors (Zhang et al. 2012; Del Real and Rothenberg 2013; Champhekar et al. 2015), and bone marrow precursors for the CAS9-mediated deletion experiments (Hosokawa et al. 2018) were prepared as described. All mouse husbandry and procedures were reviewed and approved by the Caltech Institutional Animal Care and Use Committee.

Scid.adh.2C2 cells (Dionne et al. 2005; Del Real and Rothenberg 2013) were cultured as in (Hosokawa et al. 2018). *In vitro* T-lineage development using OP9-DL1 cocultures and analysis by flow cytometry were described previously (Champhekar et al. 2015; Hosokawa et al. 2018). Details of flow cytometric staining, marker terminology, antibodies, and culture conditions in each experiment are detailed in Supplemental Material.

**Retroviral constructs.** Exogenous PU.1 constructs in LZRS retroviral vectors and PU.1 in a pMXs derivative were previously described (Champhekar et al. 2015; Hosokawa et al. 2018). *Cas9* was cloned into a pMSCV derivative and guide RNAs into an mTurquoise derivative of pQCXIN described in Supplemental Material.

**ChIP-seq, ATAC-seq and RNA-seq.** Standard RNA-seq and ChIP-seq methods were used as in our related report (Hosokawa et al. 2018), and ATAC-seq followed standard procedures (Buenrostro et al. 2013). Data for these studies have been deposited as reported previously (GSE93755, GSE11020). Details of sample processing, antibodies, sequence processing and data analysis are presented in full in Supplemental Material. Analyses of binding patterns and differential gene expression used HOMER (Heinz et al. 2010) and other publicly available packages. Alignments shown are to mm9 (NCBI37) for comparability with previous results (Zhang et al. 2012). All sample types were generated in 2-4 separate biological replicates, with inter-sample correlations as shown in Supplementary Figs. S4 and S8. Detailed methods of statistics and bioinformatics are presented in Supplemental Material.
Acknowledgments

We thank Jeffrey Longmate (Beckman Research Institute of the City of Hope), Hao Yuan Kueh (Caltech and University of Washington), and Barbara Wold (Caltech) for generous advice; Rothenberg group members and previous group members, Marissa Del Real (City of Hope) and Ameya Champhekar (UCLA), for constructs and helpful discussion; Diana Perez, Jaime Tijerina, and Rochelle Diamond for cell sorting and advice; Ingrid Soto for mouse colony care; Vijaya Kumar for library preparation and sequencing; Henry Amrhein and Diane Trout for computational system assistance; and Igor Antoshechkin for sequencing facility management. This research was supported by fellowships from the Swedish Research Council (to JU), from the Manpei Suzuki Diabetes Foundation (to HH), grants from the USPHS to EVR (R01HD076915,R01AI95943), by the L. A. Garfinkle Memorial Laboratory Fund and the Al Sherman Foundation, Facility and Resource Center support from the Beckman Institute at Caltech, and the Albert Billings Ruddock Professorship to EVR.
