ABSTRACT

We report the results of CO $J=1\rightarrow 0$ mapping of portions of the blue outflow lobe of L1551 with $\sim 7''$ (N-S) \times $4''$ (E-W) resolution, obtained with the 3-element OVRO millimeter array. Comparison of our interferometer mosaic with lower resolution single-dish data shows that we resolve the strongest single-dish emission regions into filamentary structures, such as are characteristic of shock fronts mapped via their near-infrared H_2 emission in other outflow sources.

We detect a continuous velocity gradient across the brightest filamentary structure in our maps. The projected, deconvolved, FWHM of this feature is $1-2 \times 10^{16}$ cm, similar to that predicted in theoretical models of C-shocks. Combined with the velocity gradient, this suggests that the emission originates from within a magnetohydrodynamic shock front, possibly resulting from the interaction of a stellar wind with dense, ambient material. In contrast, the discontinuous J-shocks expected in regions with low or no magnetic field should have a thickness $\leq 10^{15}$ cm, which would be unresolved at our spatial resolution. Based on the shock models of Draine and co-workers, the magnetic field strengths required to account for the structure are in the range 10 to 30 μ G. We suggest future high spatial resolution mapping of this feature in its near-infrared CO and H_2 emission, to characterize further the temperature and density structure of the neutral gas within the shock.

A more comprehensive account of this work will be the subject of an article by us which will appear in the 20 May 1993 issue of the *Astrophysical Journal*.

Velocity structure of CO(1-0) filament

Figure 1

This is a first-moment map of the strongest CO ($J=1\rightarrow 0$) emission feature detected in the 20 interferometer fields we mapped. The greyscale and contours depict the values of the LSR velocity, with lighter grey indicating the most blue-shifted gas relative to the cloud rest velocity of $V_{LSR} = 6.5 \text{ km s}^{-1}$, and darker grey indicating velocities progressively closer to the cloud rest velocity. The contours span the velocity interval $1 \text{ km s}^{-1} \leq V_{LSR} \leq 8 \text{ km s}^{-1}$ going from southeast to northwest, spaced at 1 km s^{-1} intervals. Such a coherent, smooth velocity structure is a defining characteristic of magnetohydrodynamic shocks.
