Abstract

The readiness potential (RP)—a key ERP correlate of upcoming action—is known to precede subjects' reports of their decision to move. Some view this as evidence against a causal role for consciousness in human decision-making and thus against free-will. Yet those studies focused on arbitrary decisions—purposeless, unreasoned, and without consequences. It remains unknown to what degree the RP generalizes to deliberate, more ecological decisions. We directly compared deliberate and arbitrary decision-making during a $1000-donation task to non-profit organizations. While we found the expected RPs for arbitrary decisions, they were strikingly absent for deliberate ones. Our results and drift-diffusion model are congruent with the RP representing accumulation of noisy, random fluctuations that drive arbitrary—but not deliberate—decisions. They further point to different neural mechanisms underlying deliberate and arbitrary decisions, challenging the generalizability of studies that argue for no causal role for consciousness in decision-making to real-life decisions.
Significance Statement

The extent of human free will has been debated for millennia. Previous studies demonstrated that neural precursors of action—especially the readiness potential—precede subjects’ reports of deciding to move. Some viewed this as evidence against free-will. However, these experiments focused on arbitrary decisions—e.g., randomly raising the left or right hand. We directly compared deliberate (actual $1000 donations to NPOs) and arbitrary decisions, and found readiness potentials before arbitrary decisions, but—critically—not before deliberate decisions. This supports the interpretation of readiness potentials as byproducts of accumulation of random fluctuations in arbitrary but not deliberate decisions and points to different neural mechanisms underlying deliberate and arbitrary choice. Hence, it challenges the generalizability of previous results from arbitrary to deliberate decisions.
MAIN TEXT

Introduction

Humans typically experience freely selecting between alternative courses of action, say, when ordering a particular item off a restaurant menu. Yet a series of human studies using electroencephalography (EEG) (Haggard & Eimer, 1999; Libet, Gleason, Wright, & Pearl, 1983; Salvaris & Haggard, 2014), fMRI (Bode & Haynes, 2009; Bode et al., 2011; Soon, Brass, Heinze, & Haynes, 2008; Soon, He, Bode, & Haynes, 2013), intracranial (Perez et al., 2015), and single-cell recordings (Fried, Mukamel, & Kreiman, 2011) challenged the veridicality of this common experience. These studies found neural correlates of decision processes hundreds of milliseconds and even seconds prior to the moment that subjects reported having consciously decided.

The seminal research that launched this series of studies was conducted by Benjamin Libet and colleagues (Libet et al., 1983). There, the authors showed that the readiness potential (RP)—a ramp-up in EEG negativity before movement onset, thought to originate from the presupplementary motor area (pre-SMA)—begins before subjects report a conscious decision to act. Libet and colleagues took the RP to be a marker for an unconscious decision to act (Libet et al., 1983; Soon et al., 2008) that, once it begins, ballistically leads to action (Shibasaki & Hallett, 2006). Under that interpretation, the fact that RP onset precedes the report of the onset of the conscious decision to act was taken as evidence that decisions about actions are made unconsciously. And thus the subjective human experience of freely and consciously deciding to act is but an illusion (Harris, 2012; Libet et al., 1983; Wegner, 2002). This finding has been at the center of the free-will debate in neuroscience for almost four decades, captivating scholars from many disciplines in and outside of academia (C. D. Frith & Haggard, 2018; Haggard, 2008; Jeannerod, 2006; Lau, Rogers, Haggard, & Passingham, 2004; Mele, 2006; Wegner, 2002).

Critically, in the above studies, subjects were told to arbitrarily move their right hand or flex their right wrist; or they were instructed to arbitrarily move either the right or left hand (Haggard, 2008; Hallett, 2016; Roskies, 2010). Thus, their decisions when and which hand to move were always unreasoned, purposeless, and bereft of any real consequence. This stands in sharp contrast to many real-life decisions that are deliberate—i.e., reasoned, purposeful, and bearing consequences (Ullmann-Margalit & Morgenbesser, 1977): which clothes to wear, what route to take to work, as well as more formative decisions about life partners, career choices, and so on.

Deliberate decisions have been widely studied in the field of neuroeconomics (Kable & Glimcher, 2009; Sanfey, Loewenstein, McClure, & Cohen, 2006) and in perceptual tasks (Gold & Shadlen, 2007). Yet, interestingly, little has been done in that field to assess the relation between decision-related activity, subjects’ conscious experience of deciding, and the neural activity instantaneously contributing to this experience. Though some studies compared, for example, internally driven and externally cued decisions (Thut et al., 2000; Wisniewski, Goschke, & Haynes, 2016), or stimulus-based and intention-based actions (Waszak et al., 2005), these were typically arbitrary decisions and actions with no real implications. Therefore, the results of these studies provide no direct evidence about potential differences between arbitrary and deliberate decisions.

Such direct comparisons are critical for the free will debate, because it is deliberate, rather than arbitrary, decisions that are at the center of philosophical arguments about free will and moral responsibility (Breitmeyer, 1985; Maoz & Yaffe, 2015; Roskies, 2010). Deliberate decisions
typically involve more conscious and lengthy deliberation and might thus be more tightly
bound to conscious processes than arbitrary ones. Consequently, if the RP is a marker for
unconscious decisions, while deliberate decisions are driven more by conscious than by
unconscious processes, then the RP might be substantially diminished, or even absent, for
deliberate decisions.

Another reason that the RP might be completely absent during deliberate decisions has to do
with a recent computational model (Schurger, Sitt, & Dehaene, 2012). This model claims that
the RP—which has been deemed a preparatory signal with a causal link to the upcoming
movement—actually reflects an artifact that results from a combination of (i) biased sampling
stemming from the methodology of calculating this component and (ii) autocorrelation (or
smoothness) in the EEG signal. The RP is calculated by aligning EEG activity (typically in
electrode Cz) to movement onset, then segmenting a certain time duration around each
movement onset, and finally averaging across all movements. Hence, we only look for an RP
before movement onset, which results in biased sampling (as ‘movement absent’ is not
probed). Put differently, we search for and generally find a ramp up in EEG negativity in Cz
before movement onset. But we do not search for movement onset every time there is a ramp
up in EEG negativity on Cz. What is more, as EEG is autocorrelated, ramps up or down are to
be expected (unlike, say, for white-noise activity).

Schurger and colleagues demonstrated that RPs can be modeled using a mechanistic,
stochastic, autocorrelated, drift-diffusion process that integrates noise to a bound (or threshold;
see Model section in Methods for details). In the model, it is only the threshold crossing that
reflects decision completion and directly leads to action. And thus the beginning of (what is in
hindsight and on average) the ramp up toward the threshold is certainly not the completion of
the decision that ballistically leads to the threshold crossing and hence to movement onset
(Schurger et al., 2012). This interpretation of the RP thus rather takes the sting out of the Libet
argument against free will, as the latter was based on interpreting the RP of an unconscious
decision to act. Importantly for our purposes, within the framework of the model, this artificial
accumulation of stochastic fluctuations toward a threshold is expected to occur for arbitrary
decisions, but not for deliberate ones. Unlike arbitrary decisions, deliberate decisions are
generally not driven by random fluctuations. Rather, it is the values of the decision alternatives
that mainly drive the decision and ultimately lead to action. Therefore, if the RP indeed reflects
the artificial accumulation of stochastic fluctuations, as the model suggests, a key prediction of
the model is that no RP will be found for deliberate decisions (see more below).

Thus, demonstrating the absence of an RP in deliberate decisions challenges the interpretation
of the RP as a general index of internal, unconscious decision-making; if this interpretation
were correct, such a marker should be found for all decision types. What is more, and
importantly, it questions the generalizability of any studies focused on arbitrary decisions to
everyday, ecological, deliberate decisions. In particular, it challenges RP-based claims relating
to moral responsibility (Haggard, 2008; Libet, 1985; Roskies, 2010), as moral responsibility
can be ascribed only to deliberate decisions.

Here, we tested this hypothesis and directly compared the neural precursors of deliberate and
arbitrary decisions—and in particular the RP—on the same subjects, in an EEG experiment.
Our experiment utilized a donation-preference paradigm, in which a pair of non-profit
organizations (NPOs) were presented in each trial. In deliberate-decision trials, subjects chose
to which NPO they would like to donate $1000. In arbitrary-decision trials, both NPOs
received an equal donation of $500, irrespective of subjects’ key presses (Fig. 1). In both
conditions, subjects were instructed to report their decisions as soon as they made them, and
their hands were placed on the response keys, to make sure they could do so as quickly as
possible. Notably, while the visual inputs and motor outputs were identical between deliberate
deliberate blocks, the decisions were meaningful and consequential—reminiscent of important,
real-life decisions—while in arbitrary blocks, the decisions were meaningless and bereft of
consequences—mimicking previous studies of volition.

Results

Behavioral Results

Subjects’ reaction times (RTs) were analyzed using a 2-way ANOVA along decision
type (arbitrary/deliberate) and difficulty (easy/hard). This was carried out on log-
transformed data (raw RTs violated the normality assumption; W=0.94, p=0.001).
As expected, subjects were substantially slower for deliberate (M=2.33, SD=0.51)
than for arbitrary (M=0.99, SD=0.32) decisions (Fig. 2, left; F(1,17)=114.87,
p<0.0001 for the main effect of decision type). A main effect of decision difficulty
was also found (F(1,17)=21.54, p<0.0005), with difficult decisions (M=1.77,
SD=0.40) being slower than easy ones (M=1.56, SD=0.28). Importantly, subjects
were significantly slower for hard (M=2.52, SD=0.62) vs. easy (M=2.13, SD=0.44)
decisions in the deliberate case (t(17)=4.78, p=0.0002), yet not for the arbitrary case
(M=1.00, SD=0.34; M=0.98, SD=0.32, for hard and easy arbitrary decisions,
respectively; t(17)=1.01, p=0.33; F(1,17)=20.85, p<0.0005 for the interaction
between decision type and decision difficulty). This validates our experimental
manipulation and further demonstrates that, in deliberate decisions, subjects were
making meaningful decisions, affected by the difference in the values of the two
NPOs, while for arbitrary decisions they were not. What is more, the roughly equal
RTs between easy and hard arbitrary decisions provide evidence inconsistent with
concerns that subjects were deliberating during arbitrary decisions.

The consistency between subjects’ choices throughout the main experiment and the NPO
ratings they gave prior to the main experimental session was also analyzed using a 2-way
ANOVA (see Methods). As expected, subjects were highly consistent with their own, previous
ratings when making deliberate decisions (M=0.91, SD=0.04), but not when making arbitrary
ones (M=0.52, SD=0.04; Fig. 2, right; F(1,17)=946.55, p<0.0001, BF=2.32*10^29) for the main
effect of decision type. A main effect of decision difficulty was also found (F(1,17)=57.39,
p<0.0001, though BF=1.57), with hard decisions evoking less consistent scores (M=0.66,
SD=0.05) than easy ones (M=0.76, SD=0.03). Again, decision type and decision difficulty
interacted (F(1,17)=25.96, p<0.0001, BF=477.47): subjects were much more consistent with
their choices in easy (M=0.99, SD=0.02) vs. hard (M=0.83, SD=0.64) deliberate decisions
(t(17)=11.15, p<0.0001, BF=3.68*10^6), than they were in easy (M=0.54, SD=0.07) vs. hard
(M=0.49, SD=0.05) arbitrary decisions (t(17)=2.50, p=0.023, BF=2.69). Nevertheless, though
subjects were around chance (i.e., 0.5) in their consistency in arbitrary decisions (ranging
between 0.39 and 0.64), it seems that some subjects were slightly influenced by their
preferences in easy-arbitrary decisions trials, resulting in the significant difference between
hard-arbitrary and easy-arbitrary decisions above, though the Bayes factor was inconclusive.
Finally, no differences were found between subjects’ tendency to press the right vs. left key in
the different conditions (both main effects and interaction: F<1).
Figure 1: Experimental paradigm. The experiment included deliberate (red, left panel) and arbitrary (blue, right panel) blocks, each containing nine trials. In each trial, two causes—reflecting NPO names—were presented, and subjects were asked to either choose to which NPO they would like to donate (deliberate), or to simply press either right or left, as both NPOs would receive an equal donation (arbitrary). They were specifically instructed to respond as soon as they reached a decision, in both conditions. Within each block, some of the trials were easy (lighter colors) decisions, where the subject’s preferences for the two NPOs substantially differed (based on a previous rating session), and some were hard decisions (darker colors), where the preferences were more similar; easy and hard trials were randomly intermixed within each block. To make sure subjects were paying attention to the NPO names, even in arbitrary trials, and to better equate the cognitive load between deliberate and arbitrary trials, memory tests (in light grey) were randomly introduced. There, subjects were asked to determine which of four NPO names appeared in the immediately previous trial. For a full list of NPOs and causes see Supplementary Table 1.

EEG Results: Readiness Potential (RP)

The RP is generally held to index unconscious readiness for upcoming movement (Haggard, 2008; Kornhuber & Deecke, 1990; Libet et al., 1983; Shibasaki & Hallett, 2006); although more recently, alternative interpretations of the RP have been suggested (Miller, Shepherdson, & Trevena, 2011; Schmidt, Jo, Wittmann, & Hinterberger, 2016; Schurger et al., 2012; Trevena & Miller, 2010; Verleger, Haake, Baur, & Śmigasiewicz, 2016). It has nevertheless been the standard component studied in EEG versions of the Libet paradigm (Haggard, 2008; Haggard & Eimer, 1999; Hallett, 2007; Libet, 1985; Libet et al., 1983; Libet, Wright, & Gleason, 1982; Miller et al., 2011; Schurger et al., 2012; Shibasaki & Hallett, 2006; Trevena & Miller, 2010). As is common, we measured the RP over electrode Cz in the different conditions by averaging the activity across trials in the 2 s prior to subjects’ movement.
**Figure 2: Behavioral results.** Reaction Times (RTs; left) and Consistency Grades (CG; right) in arbitrary (blue) and deliberate (red) decisions. Each dot represents the average RT/CG for easy and hard decisions for an individual subject (hard decisions: x-coordinate; easy decisions: y-coordinate). Group means and SEs are represented by dark red and dark blue crosses. The red and blue histograms at the bottom-left corner of each plot sum the number of red and blue dots with respect to the solid diagonal line. The dashed diagonal line represents equal RT/CG for easy and hard decisions; data points below that diagonal indicate longer RTs or higher CGs for hard decisions. In both measures, arbitrary decisions are more centered around the diagonal than deliberate decisions, showing no or substantially reduced differences between easy and hard decisions.

Focusing on the last 500 ms before movement onset for our statistical tests, we found a clear RP in arbitrary decisions, yet RP amplitude was not significantly different from 0 in deliberate decisions (Fig. 3A; F(1,17)=11.86, p=0.003, BF=309.21 for the main effect of decision type; in t-tests against 0 for this averaged activity in the different conditions, corrected for multiple comparisons, an effect was only found for arbitrary decisions (hard: t(17)=5.09, p=0.0001, BF=307.38; easy: t(17)=5.75, p<0.0001, BF=1015.84) and not for deliberate ones; the Bayes factor—while trending in the right direction—indicated inconclusive evidence (hard: t(17)=1.24, p>0.5, BF=0.47; easy: t(17)=1.84, p=0.34, BF=0.97). Our original baseline was stimulus locked (see Methods). And we hypothesized that the inconclusive Bayes factor for deliberate trials had to do with a constant, slow, negative drift that our model predicted for deliberate trials (see below) rather than reflecting a typical RP. As the RTs for deliberate trials were longer than for arbitrary ones, this trend might have become more pronounced for those trials. To test this, we switched the baseline period to -1000 ms to -500 ms relative to *movement* onset (i.e., a baseline that immediately preceded our time of interest window).

Under this analysis, we found moderate evidence that deliberate decisions (pooled across decision difficulty) are not different from 0 (BF=0.332), supporting the claim that the RP during the last 500 ms before response onset was completely absent (BF for similarly pooled arbitrary decisions was 5.07·10^-4).

In an effort to further test for continuous time regions where the RP is different from 0 for deliberate and arbitrary trials, we ran a cluster-based nonparametric permutation analysis (Maris & Oostenveld, 2007) for all four conditions against 0. Using the default parameters (see
Methods), we found a prolonged cluster (~1.2s) of activation that reliably differed from 0 in both arbitrary conditions (designated by horizontal blue-shaded lines above the x axis in Fig. 3A). The same analysis revealed no clusters of activity differing from zero in either of the deliberate conditions.

![Readiness Potentials](image)

**Figure 3: The readiness potentials for deliberate and arbitrary decisions.** (A) Mean and SE of the readiness potential (RP; across subjects) in deliberate (red shades) and arbitrary (blue shades) easy and hard decisions in electrode Cz, as well as scalp distributions. Zero refers to time of right/left movement, or response, made by the subject. Notably, the RP significantly differs from zero and displays a typical scalp distribution for arbitrary decisions only. Similarly, temporal clusters where activity was significantly different from 0 were found for arbitrary decisions only (horizontal blue lines above the x axis). Scalp distributions depict the average activity between -0.5 and 0 s, across subjects. The inset bar plots show the mean amplitude of the RP, with 95% confidence intervals, over the same time window. Response-locked potentials with an expanded timecourse, and stimulus-locked potentials are given in Fig. 6B and 6A, respectively. The same (response-locked) potentials as here, but with a movement-locked baseline of -1 to -0.5 s (same as in our Bayesian analysis), are given in Fig. 6C. (B) Individual subjects’ Cz activity in the four conditions (n=18). The linear-regression line for voltage against time over the last 1000 ms before response onset is designated by a dashed, black line. The lines have slopes significantly different from 0 for arbitrary decisions only. Note that the waveforms converge to an RP only in arbitrary decisions.

In a similar manner, regressing voltage against time for the last 1000 ms before response onset, the downward trend was significant for arbitrary decisions (Fig. 3B; p<0.0001, BF>10^{25} for both easy and hard conditions) but not for deliberate decisions, with the Bayes factor indicating conclusive evidence for no effect (hard: p>0.5, BF=0.09; easy: p=0.35, BF=0.31; all Bonferroni corrected for multiple comparisons). Notably, this pattern of results was also manifested for single-subject analysis (Fig. 4; 14 of the 18 subjects had significant downward slopes for arbitrary decisions—i.e., p<0.05, Bonferroni corrected for multiple comparisons—when regressing voltage against time for every trial over the last 1000 ms before response onset; but only 5 of the 18 subjects had significant downward slopes for the same regression analysis for deliberate decisions; see Methods. In addition, the average slopes for deliberate and arbitrary decisions were -0.28±0.25 and -1.9±0.32 (mean±SE), respectively, a significant difference: t(17)=4.55, p<0.001, BF=380.02. The regression analysis complements the
averaged amplitude analysis above, and further demonstrates that the choice of baseline cannot explain our results. This is because the slopes of linear regressions are, by construction, independent of baseline.

Figure 4: Individual-subjects RPs. Six examples of for individual subjects’ RPs for deliberate decisions (in red) and arbitrary ones (in blue) pooled across decision difficulty.

Control analyses

We further tested whether differences in reaction time between the conditions, eye movements, filtering, and subjects’ consistency scores might explain our effect. We also tested whether the RPs might reflect some stimulus-locked potentials or be due to baseline considerations.

Differences in reaction times (RT) between conditions, including stimulus-locked potentials and baselines, do not drive the effect
RTs in deliberate decisions were typically more than twice as long as RTs in arbitrary decisions. We therefore wanted to rule out the possibility that the absence of RP in deliberate decisions stemmed from the difference in RTs between the conditions. We carried out six analyses for this purpose. First, we ran a median split analysis—dividing the subjects into two groups based on their RTs: lower (faster) and higher (slower) than the median, for deliberate and arbitrary trials, respectively. We then ran the same analysis using only the faster subjects in the deliberate condition (M=1.91 s, SD=0.25) and the slower subjects in the arbitrary condition (M=1.25 s, SD=0.23). If RT length affects RP amplitudes, we would expect the RP amplitudes to be more similar between these two groups. However, though there were only half the data points, a similar pattern of results to those over the whole dataset was observed (Fig. 5A; compare to Fig. 3A). Deliberate and arbitrary decisions were still reliably different (F(1,17)=5.22, p=0.03), with significant RPs found in arbitrary (easy: t(8)=4.57, p=0.0018; hard: t(8)=-4.09, p=0.0035), but not deliberate (easy: t(8)=1.92, p=0.09; hard: t(8)=0.63, p=0.54) decisions. In addition, the RPs for arbitrary decisions were not significantly different between the subjects with above-median RTs and the entire population for the easy or hard conditions (easy: t(25)=0.14, p>0.5; hard: t(25)=0.56, p>0.5). Similarly, the RPs for deliberate decisions were not significantly different between the subjects with below-median RTs and the entire population for the easy or hard conditions (easy: t(25)=0.34, p>0.5; hard: t(25)=0.17, p>0.5). This suggest that RTs do not reliably affect Cz activation for deliberate or arbitrary decisions in our results.

Second, we regressed the difference between RPs in deliberate and arbitrary decisions (averaged over the last 500 ms before response onset) against the difference between the RTs in these two conditions for each subject (Fig. 5B). Again, if RT length affects RP amplitudes, we would expect differences between RTs in deliberate and arbitrary conditions to correlate with differences between RPs in the two conditions. But no correlation was found between the two measures (r=-0.28, t(16)=0.86, p=0.4). We further tried regressing the RP differences on RT differences. The regression did not produce any reliable relation between RT and RP differences (regression line: y = 0.54 [CI -0.8, 1.89] x - 0.95 [CI -2.75, 0.85]; the R² was very low, at 0.05 (as expected from the r value above), and, as the confidence intervals suggest, the slope was not significantly different from 0, F(1,16)=0.74, p=0.4).

While the results of the above analyses suggested that our effects do not stem from differences between the RTs in deliberate and arbitrary decisions, the average RTs for fast deliberate subjects were still 660 ms slower than for slow arbitrary subjects. In addition, we had only half of the subjects in each condition due to the median split, raising the concern that some of our null results might have been underpowered. We also wanted to look at the effect of cross-trial variations within subjects and not just cross-subjects ones. We therefore ran a third, within-subjects analysis. We combined the two decision difficulties (easy and hard) for each decision type (arbitrary and deliberate) for greater statistical power. And then we took the faster (below-median RT) deliberate trials and slower (above-median RT) arbitrary trials for each subject separately. So, this time we had 17 subjects (again, one was removed) and better powered results. Here, fast deliberate arbitrary trials (M=1.63 s, SD=0.25) were just 230 ms slower than slow arbitrary decisions (M=1.40 s, SD=0.45), on average. This cut the difference between fast deliberate and slow arbitrary by about 2/3 from the between-subjects analysis. We then computed the RPs for just these fast deliberate and slow arbitrary trials within each subject (Fig. 5C). Visually, the pattern there is the same as the main analysis (Fig. 3A). What is more, deliberate and arbitrary decisions remained reliably different (t(16)=3.36, p=0.004). Arbitrary trials were again different from 0 (t(16)=4.40, p=0.0005), while deliberate trials were not (t(16)=1.54, p=0.14).
Figure 5: Relations between RTs and RPs between subjects (A&B) and within subjects (C&D). (A) The subjects with above-median RTs for arbitrary decisions (in blue) and below-median RTs for deliberate decisions (in red), show the same activity pattern that was found in the main analysis (compare Fig. 3A). (B) A regression of the difference between the RPs versus the difference between the RTs for deliberate and arbitrary decisions for each subject. The equation of the regression line (solid red) is \( y = 0.54 \ [CI -0.8, 1.89] \ x - 0.95 \ [CI -2.75, 0.85] \) (confidence intervals: dashed red lines). The \( R^2 \) is 0.05. One subject, #7, had an RT difference between deliberate and arbitrary decisions that was more than 6 interquartile ranges (IQRs) away from the median difference across all subjects. That same subject’s RT difference was also more than 5 IQRs higher than the 75th percentile across all subjects. That subject was therefore designated an outlier and removed only from this regression analysis. (C) For each subject separately, we computed the RP using only the faster (below-median RT) deliberate trials and slower (above-median RT) arbitrary trials. The pattern is again the same as the one found for the main analysis. (D) We computed the same regression between the RP differences and the RT differences as in B, but this time the median split was within subjects. The equation of the regression line is \( y = 1.27 \ [CI -0.2, 2.73] \ x - 0.95 \ [CI 0.14, 1.76] \). The \( R^2 \) is 0.18.

We further regressed the within-subject differences between RPs in fast deliberate and slow arbitrary decisions (defined as above) against the differences between the corresponding RTs for each subject to ascertain that such a correlation would not exist for trials that are closer together. We again found no reliable relation between the two differences (Fig. 5D; regression line: \( y = 1.27 \ [CI -0.2, 2.73] \ x - 0.95 \ [CI 0.14, 1.76] \); \( R^2=0.18 \)).

Yet another concern that could relate to the RT differences among the conditions is that the RP in arbitrary blocks might actually be some potential evoked by the stimuli (i.e., the
presentations of the two causes), specifically in arbitrary blocks, where the RTs are shorter
(and thus stimuli-evoked effects could still affect the decision). In particular, a stimulus-evoked
potential might just happen to bear some similarity to the RP when plotted locked to response
onset. To test this explanation, we ran a fifth analysis, plotting the potentials in all conditions,
locked to the onset of the stimulus (Fig. 6A). We also plotted the response-locked potentials
across an expanded timecourse for comparison (Fig. 6B). If the RP-like shape we see in Figs.
3A and 6B is due to a stimulus-locked potential, we would expect to see the following before
the 4 mean response onset times (indicated by vertical lines at 0.98 and 1.00, 2.13, and 2.52 s
for arbitrary easy, arbitrary hard, deliberate easy, and deliberate hard, respectively) in the
stimulus-locked plot (Fig. 6A): Consistent potentials, which precede the mean response times,
that would further be of a similar shape and magnitude to the RPs found in the decision-locked
analysis in the arbitrary condition (though potentially more smeared for stimulus locking). We
thus calculated a stimulus-locked version of our ERPs, using the same baseline (Fig. 6A). As
the comparison between Fig. 6A and 6B clearly shows, no such consistent potentials were
found before the 4 response times, nor were these potentials similar to the RP in either shape or
magnitude (their magnitudes are at the most around 1µV, while the RP magnitudes we found
are around 2.5 µV; Figs. 3A, 6B). This analysis thus suggests that it is unlikely that a stimulus-
locked potential drives the RP we found.

Notably, the stimulus-locked alignment did imply that the arbitrary easy condition evoked a
stronger activity in roughly the last 0.5 s before stimulus onset. However, this prestimulus
activity cannot explain the response-locked RP, as it was found only in arbitrary easy trials
and not in arbitrary hard trials. At the same time, the response-locked RP did not differ
between these conditions. What is more, easy and hard trials were randomly interspersed
within deliberate and arbitrary blocks, and the subject discovered the trial difficulty only at
stimulus onset. Thus, there could not have been differential preparatory activity that varies
with decision difficulty. This divergence in one condition only is accordingly not likely to
reflect any preparatory RP activity.

One more concern is that the differences in RTs may affect the results in the following manner:
Because the main baseline period we used thus far was 1 to 0.5 s before stimulus onset, the
duration from the baseline to the decision varied widely between the conditions. To make sure
this difference in temporal distance between the baseline period and the response to which the
ERPs were locked did not drive our results, we recalculated the potentials for all conditions
with a response-locked baseline of -1 to -0.5 s (Fig. 6C; the same baseline we used for the
Bayesian analysis above). The rationale behind this choice of baseline was to have the time
that elapsed from baseline to response onset be the same across all conditions. As is evident in
Fig. 6C, the results for this new baseline were very similar to those for the stimulus-locked
baseline we used before. Focusing again on the -0.5 to 0 s range before response onset for our
statistical tests, we found a clear RP in arbitrary decisions, yet RP amplitude was not
significantly different from 0 in deliberate decisions (Fig. 6C; ANOVA F(1,17)=12.09,
p=0.003 for the main effect of decision type; in t-tests against 0, corrected for multiple
comparisons, an effect was only found for arbitrary decisions (hard: t(17)=4.13, p=0.0007;
easy: t(17)=4.72, p=0.0002) and not for deliberate ones (hard: t(17)=0.38, p>0.5; easy:
t(17)=1.13, p=0.27). This supports the notion that the choice of baseline does not strongly
affect our main results. Taken together, the results of the six analyses above provide strong
evidence against the claim that the differences in RPs stem from or are affected by the
differences in RTs between the conditions.
Figure 6: Stimulus- and response-locked Cz-electrode ERPs with different baselines and overlaid events. (A) Stimulus-locked waveforms including the trial onset range, baseline period, and mean reaction times for all four experimental conditions. (B) Response-locked waveforms with mean stimulus onsets for all four conditions as well as the offset of the highlighting of the selected cause and the start of the next trial. (C) Same potentials and timeline as Fig. 3A, but with a response-locked baseline of -1 to -0.5 s—the same baseline used for our Bayesian analysis.

Eye movements do not affect the results

Though ICA was used to remove blink artifacts and saccades (see Methods), we wanted to make sure our results do not stem from differential eye movement patterns between the conditions. We therefore computed a saccade-count metric (SC; see Methods) for each trial for all subjects. Focusing again on the last 500 ms before response onset, we computed mean (±s.e.m.) SC values of 1.65±0.07 and 1.67±0.06 saccades for easy and hard deliberate decisions, respectively, and 1.69±0.07 and 1.73±0.07 saccades for easy and hard arbitrary decisions, respectively. We found no reliable differences between the number of saccades during deliberate and arbitrary trials (F(1,17)=2.56, p=0.13 for main effect of decision type).
We further investigated potential effects of saccades by running a median-split analysis—dividing the trials for each subject into two groups based on their SC score: lower and higher than the median, for deliberate and arbitrary trials, respectively. We then ran the same analysis using only the trials with more saccades in the deliberate condition (SC was 2.02±0.07 and 2.04±0.07 for easy and hard, respectively) and those with less saccades for the arbitrary condition (SC was 1.33±0.07 and 1.31±0.08 for easy and hard, respectively). If the number of saccades affects RP amplitudes, we would expect that the differences in RPs between arbitrary and deliberate trials will diminish, or even reverse (as now we had more saccades in the deliberate condition). However, though there were only half the data points for each subject in each condition, a similar pattern of results to those over the whole dataset was observed: Deliberate and arbitrary decisions were still reliably different within the median-split RPs (F(1,17)=16.70, p<0.001), with significant RPs found in arbitrary (easy: t(17)=4.79, p=0.002; hard: t(17)=5.77, p<0.001), but not deliberate (easy: t(17)=0.90, p=0.38; hard: t(17)=0.30, p>0.5) decisions. In addition, we compared the RP data across all the trials with the median-split RP data above. No significant differences were found for arbitrary decisions (easy: t(17)=1.02, p=0.32; hard: t(17)=0.75, p=0.46) or for deliberate decisions (easy: t(17)=1.63, p=0.12; hard: t(17)=1.47, p=0.16). Taken together, the analyses above provide strong evidence against the involvement of eye movements in our results.

Testing alternative explanations

We took a closer look at subjects’ behavior in the easy arbitrary condition, where some subjects had a consistency score that was further above 0.5 (chance) than others. It seems like those subjects had a greater difficulty ignoring their preferences, despite the instructions to do so. We therefore wanted to test to what extent the RP of those subjects was similar to the RPs of the other subjects. Focusing on the 8 subjects that had a consistency score above 0.55 (M=0.59, SD=0.03) and comparing their RPs to those of the 10 other subjects (consistency M=0.50, SD=0.06) in easy arbitrary trials, we found no reliable differences (t(16)=0.94, p=0.36). This is not surprising, as the mean consistency score of these subjects—though higher than chance—was still far below their consistency score for easy deliberate decisions (M=0.99, SD=0.02).

High-pass filter cutoff frequency does not affect the results

Finally, another alternative explanation might rely on our selection of high-pass filter cutoff frequency, which was 0.1 Hz. Though this frequency was used in some studies of the RP (e.g., Lew, Chavarriaga, Silvoni, & Millán, 2012; MacKinnon, Allen, Shiratori, & Rogers, 2013), others opted for lower cutoff frequencies (e.g., Haggard & Eimer, 1999). Arguably, a higher cutoff frequency for the high-pass filter might reduce the chances to find the RP, which is a low-frequency component. And this might have affected the RP for deliberate decisions more than the RP for arbitrary ones, given the slower RTs there. To examine this possible confound, we reanalyzed the data using a 0.01 high-pass filter. This reduced the number of usable trials for each subject, as it allowed lower-frequency trends to remain in the data. Given that our focus was on arbitrary vs. deliberate decisions (with decision difficulty serving mostly to validate the manipulation), we collapsed the trials across decision difficulty, and only tested RP amplitudes in arbitrary vs. deliberate decisions against each other and against zero. In line with our original results, a difference was found between RP amplitude in the two conditions (t(13)=2.29, p=0.039), with RP in the arbitrary condition differing from zero (t(13)=5.71, p<0.0001), as opposed to the deliberate condition, where it did not (t(13)=0.76, p=0.462). This provides evidence against the claim that our results are due to our choice of high-pass filter.

EEG Results: Lateralized Readiness Potential (LRP)
The LRP, which reflects activation processes within the motor cortex for action preparation after action selection (Eimer, 1998; Masaki, Wild-wall, Sangals, & Sommer, 2004), was measured by subtracting the difference potentials (C3-C4) in right-hand response trials from this difference in left-hand responses trials and averaging the activity over the same time window (Eimer, 1998; Haggard & Eimer, 1999). In this purely motor component, no difference was found between the two decision types and conclusive evidence against an effect of decision type was further found (Fig. 7; all Fs<0.35; BF=0.299). Our analysis of EOG channels suggests that some of that LRP might be driven by eye movements (we repeated the LRP computation on the EOG channels instead of C3 and C4). However, the shape of the eye-movement-induced LRP is very different from the LRP we calculated from C3 and C4. Also, the differences that we found between conditions in the EOG LRP are not reflected in the C3/C4 LRP. So, while our LRP might be boosted by eye movements, it is not strictly driven by these eye movements.

**Figure 7: Lateralized readiness potential.** The lateralized readiness potential (LRP) for deliberate and arbitrary, easy and hard decisions. No difference was found between the conditions (ANOVA all Fs<0.35). Temporal clusters where the activity for each condition was independently found to be significantly different from 0 are designated by horizontal thick lines at the bottom of the figure (with their colors matching the legend).

**Modeling**

The main finding of this study—the absent (or at least strongly diminished) RP in deliberate decisions, suggesting different neural underpinnings of arbitrary and deliberate decisions—is in line with a recent study using a drift-diffusion model (DDM) to investigate the RP (Schurger et al., 2012). There, the RP was modeled as an accumulation of white noise (that results in autocorrelated noise) up to a hard threshold. When activity crosses that threshold, it designates decision completion leading to movement. The model focuses on the activity leading up to the threshold crossing, when that activity is time-locked to the onset of the threshold crossing (corresponding to movement-locked epochs in EEG). Averaging across many threshold crossings, this autocorrelation activity resembles an RP (Schurger et al., 2012). Hence, according to this model, the threshold crossing leading to response onset is largely determined by spontaneous, subthreshold, stochastic fluctuations of the neural activity. This interpretation...
of the RP challenges its traditional understanding as stemming from specific, unconscious
preparation for, or ballistic-like initiation of, movement (Shibasaki & Hallett, 2006). Instead,
Schurger and colleagues claimed, the RP is not a cognitive component of motor preparation; it
is an artifact of accumulating autocorrelated noise to a hard threshold and then looking at
signals only around threshold crossings.

We wanted to investigate whether our results could be accommodated within the general
framework of the Schurger model, though with the deliberate and arbitrary decisions mediated
by two different mechanisms. The first mechanism is involved in value assessment and drives
deliberate decisions. It may be subserved by brain regions like the Ventromedial Prefrontal
Cortex; VMPFC, (Ramnani & Owen, 2004; Wallis, 2007). But, for the sake of the model, we
will remain agnostic about the exact location associated with deliberate decisions and refer to
this region as Region X. A second mechanism, possibly at the (pre-)SMA, was held to generate
arbitrary decisions driven by random, noise fluctuations.

Accordingly, we expanded the model developed by Schurger et al. (2012) in two manners.
First, we defined two DDM processes—one devoted to value-assessment (in Region X) and the
other to noise-generation (in SMA; see Fig. 8A and Methods). Both of them were run during
both decision types, yet the former determined the result of deliberate trials, and the latter
determined the results of arbitrary trials. Second, Schurger and colleagues modeled only when
subjects would move and not what (which hand) subjects would move. We wanted to account
for the fact that, in our experiment, subjects not only decided when to move, but also what to
move (either to indicate which NPO they prefer in the deliberate condition, or to generate a
meaningless right/left movement in the arbitrary condition). We modeled this by defining two
types of movement. One was moving the hand corresponding to the location of the NPO that
was rated higher in the first, rating part of the experiment (the congruent option; see Methods).
The other was moving the hand corresponding to the location of the lower-rated NPO (the
incongruent option). We used the race-to-threshold framework to model the decision process
between this pair of leaky, stochastic accumulators, or DDMs. One DDM simulated the
process that leads to selecting the congruent option, and the other simulated the process that
leads to selecting the incongruent option (see again Fig. 8A). (We preferred the race-to-
threshold model over a classic DDM with two opposing thresholds because we think it is
biologically more plausible (de Lafuente, Jazayeri, & Shadlen, 2015) and because it is easier to
see how a ramp-up-like RP might be generated from such a model without requiring a vertical
flip of the activity accumulating toward one of the thresholds in each model run.) Hence, in
each model run, the two DDMs in Region X and the two in the SMA ran in parallel; the first
one to cross the threshold (only in Region X for deliberate decisions and only in the SMA for
arbitrary ones) determined decision completion and outcome. Thus, if the DDM corresponding
to the congruent (incongruent) option reached the threshold first, the trial ended with selecting
the congruent (incongruent) option. For deliberate decisions, the congruent cause had a higher
value than the incongruent cause and, accordingly, the DDM associated with the congruent
option had a higher drift rate than that of the DDM associated with the incongruent option. For
arbitrary decisions, the values of the decision alternatives mattered little and this was reflected
in the small differences among the drift rates and in other model parameters (Table 1).

Therefore, within this framework, C₂-electrode activity (above the SMA) should mainly reflect
the SMA component (Note that we suggest that noise generation might be a key function of the
SMA and other brain regions underneath the C₂ electrode, at least during this specific task.
When subjects make arbitrary decisions, these might be based on some symmetry-breaking
mechanism, which is driven by random fluctuations that are here simulated as noise. Thus, we
neither claim nor think that noise generation is the main purpose or function of these brain
regions in general.) And so, finding that the model-predicted EEG activity resembles the actual
EEG pattern we found would imply that our findings are compatible with an account by which
the RP represents an artifactual accumulation of stochastic, autocorrelated noise, rather than
indexing a genuine marker of an unconscious decision ballistically leading to action.

**Figure 8: Model description and model runs in the SMA and in Region X.** (A) A block
diagram of the model, with its noise (SMA) and value (Region X) components, each
instantiated as a race to threshold between a pair of DDMs (or causes—one congruent with the
ratings in the first part of the experiment, the other incongruent). (B) A few runs of the model
in the deliberate condition, in Region X (green colors), depicting the DDM for the congruent
option. As is apparent, the DDM stops when the value-based component reaches threshold. Red
arrows point from the Region X DDM trace at threshold to the corresponding time in the trace
of the SMA (black and gray colors). The SMA traces integrate without a threshold (as the
decision outcome is solely determined by the value component in Region X). The thick green
and black lines depict average Region X and SMA activity, respectively, over 10,000 model
runs locked to stimulus onset. Hence, we do not expect to find an RP in either brain region. (For
decision-locked activity see Fig. 9B).

For ease of explanation, and because decision difficulty had no consistent effect on the EEG
data, we focus the discussion below on easy decisions (though the same holds for hard
decisions). For arbitrary decisions, the SMA (or Noise) Component of the model is the one
determining the decisions, and it is also the one which we pick up in electrode Cz. Hence, the
resulting activity would be much like the original Schurger et al. (2012) model and we would
expect to see RP-like activity, which we do see (Fig. 9B). But the critical prediction of our
model for our purposes relates to what happens during deliberate decisions in the SMA (Cz
electrode). According to our model, the race-to-threshold pair of DDMs that would determine
deliberate decisions and trigger the ensuing action is the value-assessment one in Region X.
Hence, when the first DDM of the Region X pair would reach the threshold, the decision would be completed, and movement would ensue. At the same time and in contrast, the SMA pair would not integrate toward a decision (Fig. 8B). We modeled this by not including any decision threshold in the SMA in deliberate decisions (i.e., the threshold was set to infinity, letting the DDM accumulate forever). (The corresponding magnitudes of the drift-rate and other parameters are detailed in the Methods and Table 1.) So, when Region X activity reaches the threshold, the SMA (supposedly recorded using electrode Cz) will have happened to accumulate to some random level (Fig. 8B). This entails that, when we align such SMA activity to decision (or movement) onset, we will find just a simple, weak linear trend in the SMA. Importantly, the RP is measured in electrode Cz above the SMA. Hence, we search for it in the SMA (or Noise) Component of our model (and not in Region X). The expected trend in the SMA is the one depicted in red in Fig. 9B for the deliberate easy and hard conditions (here model activity was flipped vertically—from increasing above the x axis to decreasing below it—as in Schurger et al., 2012). In arbitrary decisions, on the other hand, the SMA pair, from which we record, is also the one that determines the outcome. Hence, motion ensues whenever one of the DDMs crosses the threshold. Thus, when its activity is inspected with respect to movement onset, it forms the RP-like shape of Fig. 9B (in blue), in line with the model by Schurger and colleagues (2012). Note that the downward trend for deliberate hard trials is slightly smaller than for deliberate easy (Fig. 9B). While the noise in the empirical EEG signals prohibits reliable statistical differences, the trend in the empirical data is interestingly in the same direction (see the last 500 ms before movement onset in Fig. 3A).

Akin to the Schurger model, we simultaneously fit our DDMs to the complete distribution of our empirical reaction-times (RTs; Fig. 9A) and to the empirical consistency scores (the proportions of congruent decisions; see Methods). The models’ fit to the empirical RTs and consistencies were good (RT & consistency errors for deliberate easy and hard were 0.054 & 0.040 and 0.166 & 0.013 respectively; for arbitrary easy and hard they were 0.053 & 0.002, and 0.055 & 0.003, respectively; Fig. 9A) The averages of these empirical RT distributions were 2.13, 2.52, 0.98 and 1.00 s and the empirical consistency scores were 0.99, 0.83, 0.54 and 0.49 for deliberate easy, deliberate hard, arbitrary easy, and arbitrary hard, respectively.

Once we found the models with the best fit (see Methods for details), we used those to predict the resulting ERP patterns in the SMA—i.e., those we would expect to record in Cz. The ERP that the model predicted was the mean between the congruent and incongruent activities, as both would be picked up by Cz. The result was an RP-like activity for arbitrary decisions, but only a very slight slope for deliberate decisions (Fig. 9B; both activities were flipped vertically, as in Schurger’s model). This was in line with our empirical results (compare Fig. 3A).

Note that the Schurger model aims to account for neural activity leading up to the decision to move, but no further (Schurger et al., 2012). Similarly, we expect our DDM to fit Cz neural data only up to around -0.1 to -0.2 s (100 to 200 ms before empirical response onset). What is more, we model Region X activity here using a DDM for simplicity. But we would get a similar result—SMA RP-like activity for arbitrary decision and only a trend for deliberate ones—for other models of decision making, as long as the completion of deliberate decisions would remain statistically independent from threshold crossing in the DDMs of the SMA.

Further, we make no claims that ours is the only, or even optimal, model that explains our results. Rather, by specifically extending the Schurger model, our goal was to show how that interpretation of the RP could also be applied to our more-complex paradigm. (We refer the reader to work by Schurger and colleagues (Schurger, 2018; Schurger et al., 2012) for more detailed discussions about the model, its comparison to other models, and the relation to conscious-decision completion).
Figure 9: Empirical and model RTs and model prediction for Cz activity. (A) The model (solid) and empirical (dashed) distributions of subjects’ RTs. We present both the data as fitted with gamma functions to the cumulative distributions (see Methods) across the four decision types in the main figure, and the original, non-fitted data in the inset. (B) The model’s prediction for the ERP activity in its Noise Component (Fig. 8A) in the SMA (electrode Cz), locked to decision completion (at t = 0 s), across all four decision types.

Discussion

Since the publication of Libet’s seminal work—which claimed that neural precursors of action, in the form of the RP, precede subjects’ reports of having consciously decided to act (Libet et al., 1983)—a vigorous discussion has been raging among neuroscientists, philosophers, and other scholars about the meaning of the RP for the debate on free will (recent collections include (Mele, 2015; Pockett, Banks, & Gallagher, 2009; Sinnott-Armstrong & Nadel, 2011)). Some claim that the RP is simply a marker for an unconscious decision to act and thus its onset at least reflects an intention to move and ballistically leads to movement (Libet et al., 1983; Soon et al., 2008). Under this interpretation, the onset of the RP before the reported completion of the conscious decision to move effectively removes conscious will from the causal chain leading to action (Haggard, 2005, 2008; Libet, 1985; Wegner, 2002). Others do not agree.
(Breitmeyer, 1985; Mele, 2009; Nahmias, Shepard, & Reuter, 2014; Roskies, 2010). But, regardless, the RP lies at the heart of much of this debate (Kornhuber & Deecke, 1990; Libet et al., 1983).

Notably, the RP and similar findings showing neural activations preceding the conscious decision to act have typically been based on arbitrary decisions (Haggard & Eimer, 1999; Lau et al., 2004; Libet, 1985; Libet et al., 1983; Sirigu et al., 2004; Soon et al., 2008; Soon et al., 2013). This, among other reasons, rested on the notion that for an action to be completely free, it should not be determined in any way by external factors (Libet, 1985)—which is the case for arbitrary, but not deliberate, decisions (for the latter, each decision alternative is associated with a value, and the values the of alternatives typically guide one’s decision). But this notion of freedom faces several obstacles. First, most discussions of free will focus on deliberate decisions, asking when and whether these are free (Frankfurt, 1971; Hobbes, 1994; Wolf, 1990). This might be because everyday decisions to which we associate freedom of will—like choosing a more expensive but more environmentally friendly car, helping a friend instead of studying more for a test, donating to charity, and so on—are generally deliberate, in the sense of being reasoned, purposeful, and bearing consequences (although see Deutschländer, Pauen, and Haynes (2017)). In particular, the free will debate is often considered in the context of moral responsibility (e.g., was the decision to harm another person free or not) (Fischer, 1999; Haggard, 2008; Maoz & Yaffe, 2015; Roskies, 2012; Sinnott-Armstrong, 2014; Strawson, 1994), and free will is even sometimes defined as the capacity that allows one to be morally responsible (Mele, 2006, 2009). In contrast, it seems meaningless to assign blame or praise to arbitrary decisions. Thus, though the scientific operationalization of free will has typically focused on arbitrary decisions, the common interpretations of these studies—in neuroscience and across the free will debate—have often alluded to deliberate decisions. This is based on the implicit assumption that the RP studies capture the same, or a sufficiently similar, process as that which occurs in deliberate decisions. And so, inferences from RP results on arbitrary decisions can be made to deliberate decisions.

However, here we show that this assumption may not be justified, as the neural precursors of arbitrary decisions, at least in the form of the RP, do not generalize to meaningful, deliberate decisions (Breitmeyer, 1985; Roskies, 2010). For arbitrary decisions, we replicated the waveform found in previous studies, where the subjects moved endogenously, at a time of their choice with no external cues (Shibasaki & Hallett, 2006). The RP was also similarly recorded in the Cz electrode and with a typical scalp topography. However, the RP was altogether absent—or at least substantially diminished—for deliberate decisions; it showed neither the expected slope over time nor the expected scalp topography.

Null-hypothesis significance testing (NHST) suggested that the null hypothesis—i.e., that there is no RP—can be rejected for arbitrary decisions but cannot be rejected for deliberate ones. A cluster-based nonparametric permutation analysis—to locate temporal windows where EEG activity is reliably different from 0—found prolonged activity of this type during the 1.2 s before movement onset for easy and hard arbitrary decisions, but no such activity was found for either type of deliberate decisions. A Bayesian analysis found clear evidence for an RP in arbitrary decisions and an inconclusive trend toward no RP in deliberate decisions. Changing the baseline to make it equally distant from arbitrary and deliberate decisions did provide evidence for the absence of an RP in deliberate decisions, while still finding clear evidence for an RP in arbitrary decisions. Further, baseline-invariant trend analysis showed that there is no trend during the RP time window for deliberate decisions (here Bayesian analysis suggested moderate to strong evidence against a trend) while there existed a reliable trend for arbitrary decisions (and extremely strong evidence for an effect in the Bayesian framework). Thus, taken together, there is overwhelming evidence for an RP in arbitrary decisions (in all six
different analyses that we conducted—NHST and Bayesian). But, in contrast, we found no
evidence for the existence of an RP in deliberate decisions (in all six analyses) and, at the same
time, there was evidence against RP existence in such decisions (in five of the six analyses,
with the single, remaining analysis providing only inconclusive evidence for an absence of an
RP). Therefore, when the above analyses are taken together, we think that the most plausible
interpretation of our results is that the RP is absent in deliberate decisions.

Nevertheless, even if one takes our results to imply that the RP is only strongly diminished in
deliberate compared to arbitrary decisions, this provides evidence against drawing strong
conclusions regarding the free-will debate from the Libet and follow-up results. The
assumption in the Libet-type studies is that the RP simply reflects motor preparation (Haggard,
2019; Haggard & Eimer, 1999; Libet, 1985; Libet et al., 1983; Shibasaki & Hallett, 2006) and
in that it lives up to its name. However, in our paradigm, both the sensory inputs and the motor
outputs were the same between arbitrary and deliberate trials. Thus, motor preparation is
expected in both conditions and the RP should have been found in both. Accordingly, any
consistent difference in the RP between the decision types suggests—to the very least—that it
is a more complex signal than Libet and colleagues had assumed. For one, it shows that it is
influenced by cognitive state and that it cannot be regarded as a genuine index of a voluntary
decision, be it arbitrary or deliberate. Further, our model predicted an RP in arbitrary decisions
but only a slow trend in movement-locked ERP during deliberate decisions that is in the
direction as the RP, but is not an RP. Hence, a signal that resembles a strongly diminished RP
but is in fact just slow trend in the same direction is congruent with our model.

Interestingly, while the RP was present in arbitrary decisions but absent in deliberate ones, the
LRP—a long-standing, more-motor ERP component, which began much later than the RP—
was indistinguishable between the different decision types. This provides evidence that, at the
motor level, the neural representation of the deliberate and arbitrary decisions that our subjects
made may have been indistinguishable, as was our intention when designing the task.

Our findings and the model thus suggest that two different neural mechanisms may be involved
in arbitrary and deliberate decisions. Earlier literature demonstrated that deliberate, reasoned
decision-making—which was mostly studied in the field of neuroeconomics (Kable &
Glimcher, 2009) or using perceptual decisions (Gold & Shadlen, 2007)—elicited activity in the
prefrontal cortex (PFC; mainly the dorsolateral (DLPFC) part (Sanfey, Rilling, Aronson,
Nystrom, & Cohen, 2003; Wallis & Miller, 2003) and ventromedial (VMPFC)
part/orbitofrontal cortex (OFC) (Ramnani & Owen, 2004; Wallis, 2007) and the anterior
cingulate cortex (ACC) (Bush, Luu, & Posner, 2000; Carter et al., 1998). Arbitrary,
meaningless decisions, in contrast, were mainly probed using variants of the Libet paradigm,
showing activations in the Supplementary Motor Area (SMA), alongside other frontal areas
like the medial frontal cortex (Brass & Haggard, 2008; Krieghoff, Waszak, Prinz, & Brass,
2011) or the frontopolar cortex, as well as the posterior cingulate cortex (Fried et al., 2011;
Soon et al., 2008) (though see Hughes, Schütz-Bosbach, and Waszak (2011), which suggests
that a common mechanism may underlie both decision types). Possibly then, arbitrary and
deliberate decisions may differ not only with respect to the RP, but be subserved by different
underlying neural circuits, which makes generalization from one class of decisions to the other
more difficult. Deliberate decisions are associated with more lateralized and central neural
activity while arbitrary ones are associated with more medial and frontal ones. This appears to
align with the different brain regions associated with the two decision types above, as also
evidenced by the differences we found between the scalp distributions of arbitrary and
deliberate decisions (Fig. 3A). Further studies are needed to explore this potential divergence
in the neural regions between the two decision types.
Therefore, at the very least, our results support the claim that the previous findings regarding
the RP should be confined to arbitrary decisions and do not generalize to deliberate ones. What
is more, if the ubiquitous RP does not generalize, it cannot simply be assumed that other
markers will. Hence, such differences clearly challenge the generalizability of previous studies
focusing on arbitrary decisions to deliberate ones, regardless of whether they were based on the
RP or not. In other words, our results put the onus on attempts to generalize markers of
upcoming action from arbitrary to deliberate decisions; it is on them now to demonstrate that
those markers do indeed generalize. And, given the extent of the claims made and conclusions
derived based on the RP in the neuroscience of free will (see again Mele, 2015; Pockett,
Banks, & Gallagher, 2009; Sinnott-Armstrong & Nadel, 2011), our findings call for a re-

re-examination of some of the basic tenets of the field.

It should be noted that our study does not provide positive evidence that consciousness is more
involved in deliberate decisions than in arbitrary ones; such a strong claim requires further
evidence, perhaps from future research. But our results highlight the need for such research.
Under some (strong) assumptions, the onset of the RP before the onset of reported intentions to
move may point to there being no role for consciousness in arbitrary decisions. But, even if
such conclusions can be reached, they cannot be safely extended to deliberate decisions.

To be clear, and following the above, we do not claim that the RP captures all unconscious
processes that precede conscious awareness. However, some have suggested that the RP
represents unconscious motor-preparatory activity before any kind of decision (e.g., Libet,
1985). But our results provide evidence against that claim, as we do not find an RP before
deliberate decisions, which also entail motor preparation. What is more, in deliberate decisions
in particular, it is likely that there are neural precursors of upcoming actions—possibly
involving the above neural circuits as well as circuits that represents values—which are
unrelated to the RP (the lack of such precursors is not merely implausible; it implies dualism:

Note also that we did not attempt to clock subjects’ conscious decision to move. Rather, we

instructed them to hold their hands above the relevant keyboard keys and press their selected
key as soon as they made up their mind. This was to keep the decisions in this task more
ecological and because we think that the key method of measuring decision completion (using
some type of clock to measure Libet’s W-time) is highly problematic (see Methods). But, even
more importantly, clock monitoring was demonstrated to have an effect on RP size (Miller et
al., 2011), so it could potentially confound our results (Maoz et al., 2015).

Some might also claim that unconscious decision-making could explain our results, suggesting
that in arbitrary decisions subjects engage in unconscious deliberation or in actively inhibiting
their urge to follow their preference as well as in free choice, while in deliberate decisions only
deliberation is required. But this interpretation is unlikely because the longer RTs in deliberate
decisions suggest, if anything, that more complex mental processes (conscious or unconscious)
took place before deliberate and not arbitrary decisions. In addition, these interpretations
should impede our chances of finding the RP in arbitrary trials (as the design diverges from the
original Libet task), yet the RP was present, rendering them less plausible.

Aside from highlighting the neural differences between arbitrary and deliberate decisions, this
study also challenges a common interpretation of the function of the RP. If the RP is not
present before deliberate action, it does not seem to be a necessary link in the general causal
chain leading to action. Schurger et al. (2012) suggested that the RP reflects the accumulation
of autocorrelated, stochastic fluctuations in neural activity that lead to action, following a
threshold crossing, when humans arbitrarily decide to move. According to that model, the
shape of the RP results from the manner in which it is computed from autocorrelated EEG:

averaged over trials that are locked to response onset (that directly follows the threshold
crossing). Our results and our model are in line with that interpretation and expand it to
decisions that include both when and which hand to move. They suggest that the RP represents
the accumulation of noisy, random fluctuations that drive arbitrary decisions, Whereas
deliberate decisions are mainly driven by the values associated with the decision alternatives
(Maoz et al., 2013).

Our drift–diffusion model was based on the assumption that every decision can be driven by a
component reflecting the values of the decision alternatives (i.e., subjects’ support for the two
NPOs we presented) or by another component representing noise—random fluctuations in
neural activity. The value component plays little to no role in arbitrary decisions, so action
selection and timing depend on when the accumulation of noise crosses the decision threshold
for the congruent and incongruent decision alternatives. In deliberate decisions, in contrast, the
value component drives the decisions, while the noise component plays little to no role. Thus,
in arbitrary decisions, action onset closely tracks threshold crossings of the noise (or SMA)
component. But, in deliberate decisions, the noise component reaches a random level and is
then stopped; so, the value component drives the decision. Hence, as we record from the SMA
(the noise component)—locking the ERP to response onset and averaging over trials to obtain
the RP leads to a slight slope for deliberate decisions but to the expected RP shape in arbitrary
decisions. This provides evidence that the RP does not reflect subconscious movement
preparation. Rather, it is induced by threshold crossing of stochastic fluctuations in arbitrary
decisions, which do not drive deliberate decisions; accordingly, the RP is not found in
deliberate decisions. Our model therefore challenges RP-based claims against free will in both
arbitrary and deliberate decisions. Further studies of the causal role of consciousness in
deliberate versus arbitrary decisions are required to test this claim.

Nevertheless, two possible, alternative explanations of our results can be raised. First, one
could claim that—in the deliberate condition only—the NPO names act as a cue, thereby
creating a stimulus-response mapping and in that turning what we term internal, deliberate
decisions into no more than simple responses to external stimuli. Under this account, if the
preferred NPO is on the right, it is immediately interpreted as “press right”. It would therefore
follow that subjects are actually not making decisions in deliberate trials, which in turn is
reflected by the absence of the RP in those trials. However, the reaction time and consistency
results that we obtained for deliberate trials provide evidence against this interpretation. We
found longer reaction times for hard-deliberate decisions than for easy-deliberate ones (2.52
versus 2.13 s, on average, respectively; Fig. 2 left) and higher consistencies with the initial
ratings for easy-deliberate decisions than for hard-deliberate decisions (0.99 versus 0.83, on
average, respectively; Fig. 2 right). If the NPO names acted as mere cues, we would have
expected no differences between reaction times or consistencies for easy- and hard-deliberate
decisions. In addition, there were 50 different causes in the first part of the experiment. So, it is
highly unlikely that subjects could memorize all 1225 pairwise preferences among these causes
and simply transform any decision between a pair of causes into a stimulus instructing to press
left or right.

Another alternative interpretation of our results is that subjects engage in (unconscious)
deliberation also during arbitrary decisions (Tusche, Bode, & Haynes, 2010), as they are trying
to find a way to break the symmetry between the two possible actions. If so, the RP in the
arbitrary decisions might actually reflect the extra effort in those types of decisions, which is
not found in deliberate decisions. However, this interpretation entails a longer reaction time for
arbitrary than for deliberate decisions, because of the heavier cognitive load, which is the
opposite of what we found (Fig. 2A).
In conclusion, our study suggests that RPs do not precede deliberate decisions (or at the very least are strongly diminished before such decisions). In addition, it suggests that RPs represent an artificial accumulation of random fluctuations rather than serving as a genuine marker of an unconscious decision to initiate voluntary movement. Hence, our results challenge RP-based claims of Libet and follow-up literature against free will in arbitrary decisions and much more so the generalization of these claims to deliberate decisions. The neural differences we found between arbitrary and deliberate decisions as well as our model further put the onus on any study trying to draw conclusions about the free-will debate from arbitrary decisions to demonstrate that these conclusions generalize to deliberate ones. This motivates future investigations into other precursors of action besides the RP using EEG, fMRI, or other techniques. It also highlights that it would be of particular interest to find the neural activity that precedes deliberate decisions as well as neural activity, which is not motor activity, that is common to both deliberate and arbitrary decisions.

### Materials and Methods

#### Subjects

Twenty healthy subjects participated in the study. They were California Institute of Technology (Caltech) students as well as members of the Pasadena community. All subjects had reported normal or corrected-to-normal sight and no psychiatric or neurological history. They volunteered to participate in the study for payment ($20 per hour). Subjects were prescreened to include only participants who were socially involved and active in the community (based on the strength of their support of social causes, past volunteer work, past donations to social causes, and tendency to vote). The data from 18 subjects was analyzed; two subjects were excluded from our analysis (see Sample size and exclusion criteria below). The experiment was approved by Caltech’s Institutional Review Board (14-0432; Neural markers of deliberate and random decisions), and informed consent was obtained from all participants after the experimental procedures were explained to them.

#### Sample size and exclusion criteria

We ran a power analysis based on the findings of Haggard and Eimer (1999). Their RP in a free left/right-choice task had a mean of 5.293 µV and standard deviation of 2.267 µV. Data from a pilot study we ran before this experiment suggested that we might obtain smaller RP values in our task (they referenced to the tip of the nose and we to the average of all channels, which typically results in a smaller RP). Therefore, we conservatively estimated the magnitude of our RP as half of that of Haggard & Eimer, 2.647 µV, while keeping the standard deviation the same at 2.267 µV. Our power analysis therefore suggested that we would need at least 16 subjects to reliably find a difference between an RP and a null RP (0 µV) at a p-value of 0.05 and power of 0.99. This number agreed with our pilot study, where we found that a sample size of at least 16 subjects resulted in a clear, averaged RP. Following the above reasoning, we decided beforehand to collect 20 subjects for this study, taking into account that some could be excluded as they would not meet the following predefined inclusion criteria: at least 30 trials per experimental condition remaining after artifact rejection; and averaged RTs (across conditions) that deviated by less than 3 standard deviations from the group mean.

Subjects were informed about the overall number of subjects that would participate in the experiment when the NPO lottery was explained to them (see below). So, we had to finalize the overall number of subjects who would participate in the study—but not necessarily the overall number of subjects whose data would be part of the analysis—before the experiment began. After completing data collection, we ran only the EEG preprocessing and behavioral-
data analysis to test each subject against the exclusion criteria. This was done before we looked at the data with respect to our hypothesis or research question. Two subjects did not meet the inclusion criteria: the data of one subject (#18) suffered from poor signal quality, resulting in less than 30 trials remaining after artifact rejection; another subject (#12) had RTs longer than 3 standard deviations from the mean. All analyses were thus run on the 18 remaining subjects.

Stimuli and apparatus

Subjects sat in a dimly lit room. The stimuli were presented on a 21” Viewsonic G225f (20” viewable) CRT monitor with a 60-Hz refresh rate and a 1024×768 resolution using Psychtoolbox version 3 and Mathworks Matlab 2014b (Brainard, 1997; Pelli, 1997). They appeared with a gray background (RGB values: [128, 128,128]). The screen was located 60 cm away from subjects’ eyes. Stimuli included names of 50 real, non-profit organizations (NPOs). Twenty organizations were consensual (e.g., the Cancer Research Institute, or the Hunger project), and thirty were more controversial: we chose 15 causes that were widely debated (e.g., pro/anti guns, pro/anti abortions), and selected one NPO that supported each of the two sides of the debate. This was done to achieve variability in subjects’ willingness to donate to the different NPOs. In the main part of the experiment, succinct descriptions of the causes (e.g., pro-marijuana legalization, pro-child protection; for a full list of NPOs and causes see Supplementary Table 1) were presented in black Comic Sans MS.

Study Design

The objective of this study was to compare ERPs elicited by arbitrary and deliberate decision-making, and in particular the RP. We further manipulated decision difficulty to validate our manipulation of decisions type: we introduced hard and easy decisions which corresponded to small and large differences between subjects’ preferences for the pairs of presented NPOs, respectively. We reasoned that if the manipulation of decision type (arbitrary vs. deliberate) was effective, there would be behavioral differences between easy and hard decisions for deliberate choices but not for arbitrary choices (because differences in preferences should not influence subjects’ arbitrary decisions). Our 2 x 2 design was therefore decision type (arbitrary vs. deliberate) by decision difficulty (easy vs. hard). Each condition included 90 trials, separated into 10 blocks of 9 trials each, resulting in a total of 360 trials and 40 blocks. Blocks of different decision types were randomly intermixed. Decision difficulty was randomly counterbalanced across trials within each block.

Experimental Procedure

In the first part of the experiment, subjects were presented with each of the 50 NPOs and the causes with which the NPOs were associated separately (see Supplementary Table 1). They were instructed to rate how much they would like to support that NPO with a $1000 donation on a scale of 1 (“I would not like to support this NPO at all) to 7 (“I would very much like to support this NPO”). No time pressure was put on the subjects, and they were given access to the website of each NPO to give them the opportunity to learn more about the NPO and the cause it supports.

After the subjects finished rating all NPOs, the main experiment began. In each block of the experiment, subjects made either deliberate or arbitrary decisions. Two succinct cause descriptions, representing two actual NPOs, were presented in each trial (Fig. 1). In deliberate blocks, subjects were instructed to choose the NPO to which they would like to donate $1000 by pressing the <Q> or <P> key on the keyboard, using their left and right index finger, for the NPO on the left or right, respectively, as soon as they decided. Subjects were informed that at
the end of each block one of the NPOs they chose would be randomly selected to advance to a
lottery. Then, at the end of the experiment, the lottery will take place and the winning NPO
will receive a $20 donation. In addition, that NPO will advance to the final, inter-subject
lottery, where one subject’s NPO will be picked randomly for a $1000 donation. It was
stressed that the donations were real and that no deception was used in the experiment. To
persuade the subjects that the donations were real, we presented a signed commitment to
donate the money, and promised to send them the donation receipts after the experiment. Thus,
subjects knew that in deliberate trials, every choice they made was not hypothetical, and could
potentially lead to an actual $1020 donation to their chosen NPO.

Arbitrary trials were identical to deliberate trials except for the following crucial differences.
Subjects were told that, at the end of each block, the pair of NPOs in one randomly selected
trial would advance to the lottery together. And, if that pair wins the lottery, both NPOs would
receive $10 (each). Further, the NPO pair that would win the inter-subject lottery would
receive a $500 donation each. Hence it was stressed to the subjects that there was no reason for
them to prefer one NPO over the other in arbitrary blocks, as both NPOs would receive the
same donation regardless of their button press. Subjects were told to therefore simply press
either <Q> or <P> as soon as they decided to do so.

Thus, while subjects’ decisions in the deliberate blocks were meaningful and consequential,
their decisions in the arbitrary blocks had no impact on the final donations that were made. In
these trials, subjects were further urged not to let their preferred NPO dictate their response.
Importantly, despite the difference in decision type between deliberate and arbitrary blocks, the
instructions for carrying out the decisions were identical: Subjects were instructed to report
their decisions as soon as they made them in both conditions. They were further asked to place
their left and right index fingers on the response keys, so they could respond as quickly as
possible. Note that we did not ask subjects to report their “W-time” (time of consciously
reaching a decision), because this measure was shown to rely on neural processes occurring
after response onset (Lau, Rogers, & Passingham, 2007) and to potentially be backward
inferred from movement time (Banks & Isham, 2009). Even more importantly, clock
monitoring was demonstrated to have an effect on RP size (Miller et al., 2011), so it could
potentially confound our results (Maoz et al., 2015).

Decision difficulty (Easy/Hard) was manipulated throughout the experiment, randomly
intermixed within each block. Decision difficulty was determined based on the rating
difference between the two presented NPOs. NPO pairs with 1 or at least 4 rating-point
difference were designated hard or easy, respectively. Based on each subject’s ratings, we
created a list of NPO pairs, half of each were easy choices and the other half hard choices.

Each block started with an instruction written either in dark orange (Deliberate: “In this block
choose the cause to which you want to donate $1000”) or in blue (Arbitrary: “In this block
both causes may each get a $500 donation regardless of the choice”) on a gray background that
was used throughout the experiment. Short-hand instructions appeared at the top of the screen
throughout the block in the same colors as that block’s initial instructions; Deliberate: “Choose
for $1000” or Arbitrary: “Press for $500 each” (Fig. 1).

Each trial started with the gray screen that was blank except for a centered, black fixation
cross. The fixation screen was on for a duration drawn from a uniform distribution between 1
and 1.5 s. Then, the two causes appeared on the left and right side of the fixation cross
(left/right assignments were randomly counterbalanced) and remained on the screen until the
subjects reported their decisions with a key press—<Q> or <P> on the keyboard for the cause
on the left or right, respectively. The cause corresponding to the pressed button then turned
white for 1 s, and a new trial started immediately. If subjects did not respond within 20 s, they received an error message and were informed that, if this trial would be selected for the lottery, no NPO would receive a donation. However, this did not happen for any subject on any trial.

To assess the consistency of subjects’ decisions during the main experiment with their ratings in the first part of the experiment, subjects’ choices were coded in the following way: each binary choice in the main experiment was given a consistency grade of 1, if subjects chose the NPO that was rated higher in the rating session, and 0 if not. Then an averaged consistency grade for each subject was calculated as the mean consistency grade over all the choices. Thus, a consistency grade of 1 indicates perfect consistency with one’s ratings across all trials, 0 is perfect inconsistency, and 0.5 is chance performance.

We wanted to make sure subjects were carefully reading and remembering the causes also during the arbitrary trials. This was part of an effort to better equate—as much as possible, given the inherent difference between the conditions—memory load, attention, and other cognitive aspects between deliberate and arbitrary decisions—except those aspects directly associated with the decision type, which was the focus of our investigation. We therefore randomly interspersed 36 memory catch-trials throughout the experiment (thus more than one catch trial could occur per block). On such trials, four succinct descriptions of causes were presented, and subjects had to select the one that appeared in the previous trial. A correct or incorrect response added or subtracted 50 cents from their total, respectively. (Subjects were informed that, if they reached a negative balance, no money will be deducted off their payment for participation in the experiment.) Thus, subjects could earn $18 more for the experiment, if they answered all memory test questions correctly. Subjects typically did well on these memory questions, on average erring in 2.5 out of 36 memory catch trials (7% error) and gaining additional $16.75 (SD=3.19). Subjects’ error rates in the memory task did not differ significantly between the experimental conditions (2-way ANOVA; decision type: F(1,17)=2.51, p=0.13; decision difficulty: F(1,17)=2.62, p=0.12; interaction: F(1,17)=0.84, p=0.37).

ERP recording methods

The EEG was recorded using an Active 2 system (BioSemi, the Netherlands) from 64 electrodes distributed based on the extended 10–20 system and connected to a cap, and seven external electrodes. Four of the external electrodes recorded the EOG: two located at the outer canthi of the right and left eyes and two above and below the center of the right eye. Two external electrodes were located on the mastoids, and one electrode was placed on the tip of the nose. All electrodes were referenced during recording to a common-mode signal (CMS) electrode between POz and PO3. The EEG was continuously sampled at 512 Hz and stored for offline analysis.

ERP analysis

ERP analysis was conducted using the “Brain Vision Analyzer” software (Brain Products, Germany) and in-house Mathworks Matlab scripts. Data from all channels were referenced offline to the average of all channels (excluding external electrodes), which is known to result in a reduced-amplitude RP (because the RP is such a spatially diffuse signal). The data were then digitally high-pass filtered at 0.1 Hz using a Finite Impulse Response (FIR) filter to remove slow drifts. A notch filter at 59-61 Hz was applied to the data to remove 60-Hz electrical noise. The signal was then cleaned of blink and saccade artifacts using Independent Component Analysis (ICA) (Junghofer, Elbert, Tucker, & Rockstroh, 2000). Signal artifacts were detected as amplitudes exceeding ±100 µV, differences beyond 100 µV within a 200 ms
Sections of EEG data that included such artifacts in any channel were removed (150 ms before and after the artifact). We further excluded single trials in which subjects pressed a button that was not one of the two designated response buttons (<Q> or <P>) as well as trials where subjects’ RTs were less than 200 ms, more than 10s, or more than 3 standard deviations away from that subject’s mean in that condition (mean number of excluded trials =7.17, SD=2.46, which are 1.99% of the trials). Overall, the average number of included trials in each experimental cell was 70.38 trials with a range of 36-86 out of 90 trials per condition. Channels that consistently had artifacts were replaced using interpolation (0-6 channels, 1.95 channels per subject, on average). No significant differences were found in the number of excluded trials across conditions (2-way ANOVA; decision type: F(1,17)=3.31, p=0.09; decision difficulty: F(1,17)=1.83, p=0.19; interaction: F(1,17)=0.42, p=0.53).

The EEG was segmented by locking the waveforms to subjects’ movement onset, starting 2s prior to the movement and ending 0.2s afterwards, with the segments averaged separately for each decision type (Deliberate/Arbitrary x Easy/Hard) and decision content (right/left hand). The baseline period was defined as the time window between -1000 ms and -500 ms prior to stimulus onset, that is, the onset of the causes screen, rather than prior to movement onset. In addition to the main baseline, we tested another baseline—from -1000 ms to -500 ms relative to movement onset—to investigate whether the baseline period influenced our main results (see Results). Furthermore, we segmented the EEG based on stimulus onset, using the same baseline, for stimulus-locked analysis (again, see Results).

To assess potential effects of eye movements during the experiment, we defined the radial eye signal as the average over all 4 EOG channels, when band-pass filtered to between 30 and 100 Hz. We then defined a saccade as any signal that was more than 2.5 standardized IQRs away from the median of the radial signal for more than 2 ms. Two consecutive saccades had to be at least 50 ms apart. The saccade count (SC) was the number of saccades during the last 500 ms before response onset (Keren, Yuval-Greenberg, & Deouell, 2010) (see also (Croft & Barry, 2000; Elbert, Lutzenberger, Rockstroh, & Birbaumer, 1985; Shan, Moster, & Roemer, 1995)).

**Statistical Analysis**

EEG differences greater than expected by chance were assessed using two-way ANOVAs with decision type (deliberate, arbitrary) and decision difficulty (easy, hard), using IBM SPSS statistics, version 24. For both RP and LRP signals, the mean amplitude from 500 ms before to button-press onset were used for the ANOVAs. Greenhouse–Geisser correction was never required as sphericity was never violated (Picton et al., 2000).

Trend analysis on all subjects’ data was carried out by regressing the voltage for every subject against time for the last 1000 ms before response onset using first-order polynomial linear regression (see Results). We first added a 25 Hz low-pass filter for anti-aliasing and then used every 10th time sample for the regression (i.e., the 1st, 11th, 21st, 31st samples, and so on) to conform with the individual-subject analysis (see below). For the individual-subject analysis, the voltage on all trials was regressed against time in the same manner (i.e., for the last 1000 ms before response onset and using first-order polynomial linear regression). As individual-trial data is much noisier than the mean over all trials in each subject, we opted for standard robust-regression using iteratively reweighted least squares (implemented using the `robustfit()` function in Mathworks Matlab). The iterative robust-regression procedure is time consuming. So, we used every 10th time sample instead of every sample to make the procedure’s run time manageable. Also, as EEG signals have a 1/f power spectrum, taking every 10th sample further better conforms with the assumption of i.i.d. noise in linear regression.
Furthermore, we conducted Bayesian analyses of our main results. This allowed us to assess
the strength of the evidence for or against the existence of an effect, and specifically test
whether null results stem from genuine absence of an effect or from insufficient or
underpowered data. Specifically, the Bayes factor allowed us to compare the probability of
observing the data given $H_0$ (i.e., no RP in deliberate decisions) against the probability of
observing the data given $H_1$ (i.e., RP exists in deliberate decisions). We followed the
convention that $BF < 0.33$ implies substantial evidence for lack of an effect (that is, the data is
at least three times more likely to be observed given $H_0$ than given $H_1$), $0.33 < BF < 3$ suggests
insensitivity of the data, and $BF > 3$ denotes substantial evidence for the presence of an effect
($H_1$) (Jeffreys, 1998). Bayesian analysis was carried out using JASP (ver. 0.8; default settings).

In addition to the above, we used the cluster-based nonparametric method developed by Maris
and Oostenveld to find continuous temporal windows where EEG activity was reliably
different from 0 (Maris & Oostenveld, 2007). We used an in-house implementation of the
method in Mathworks Matlab with a threshold of 2 on the $t$ statistic and with a significance
level of $p = 0.05$.

**Model and Simulations**

All simulations were performed using Mathworks Matlab 2018b. The model was devised off
the one proposed by Schurger et al. (2012). Like them, we built a drift-diffusion model (DDM)
(Ratcliff, 1978; Usher & McClelland, 2001), which included a leaky stochastic accumulator
(with a threshold on its output) and a time-locking/epoching procedure. The original model
amounted to iterative numerical integration of the differential equation

$$\delta x_i = (I - kx_i)\Delta t + c\xi_i \sqrt{\Delta t}$$

where $I$ is the drift rate, $k$ is the leak (exponential decay in $x$), $\xi$ is Gaussian noise, and $c$ is a
noise-scaling factor. $\Delta t$ is the discrete time step used in the simulation (we used $\Delta t = 0.001$).
The model integrates $x_i$ over its iterations until it crosses a threshold, which represents a
decision having been made.

In such drift-diffusion models, for a given $k$ and $c$, the values of $I$ and the threshold together
determine how quickly a decision will be reached, on average. If we further fix the threshold, a
higher drift rate, $I$, represents a faster decision, on average. The drift rate alone can thus be
viewed as a constant “urgency to respond” (using the original Schurger term) that is inherent in
the demand characteristics of the task, evidenced by the fact that no subject took more than 20
s to make a decision on any trial. The leak term, $k$, ensures that the model would not be too
linear; i.e., it prevented the drift rate from setting up a linear trajectory for the accumulator
toward the threshold. Also, $k$ has a negative sign and is multiplied by $x_i$. So, $kx_i$ acts against the
drift induced by $I$ and gets stronger as $x_i$ grows. Hence, due to the leak term, doubling the
height of the threshold could make the accumulator rarely reach the threshold instead of
reaching it in roughly twice the amount of time (up to the noise term).

When comparing the model’s activity for the SMA and Region X, we needed to know how to
set the drift rates for the DDM in the two regions for deliberate decisions. We made the
assumption that the ratio between the drift rate in Region X and in the SMA during deliberate
decisions would be the same as the ratio between the average empirical activity in the SMA
and in the rest of the brain during arbitrary decisions. Our EEG data suggested that this ratio
(calculated as activity in $C_z$ divided by the mean activity in the rest of the electrodes) is 1.45.
Hence, we set the drift rates in the SMA to be 1.45 times smaller than those of Region X for deliberate decisions (see Table 1 for all parameter values).

Our model differed from Schurger’s in two main ways. First, it accounted for both arbitrary and deliberate decisions and was thus built to fit our paradigm and empirical results. We devised a model that was composed of two distinct components (Fig. 8A), each a race to threshold between 2 DDMs based on Eq. (1) (see below), but with different parameter values for each DDM (Table 1). The first component accumulated activity that drove arbitrary decisions (i.e., stochastic fluctuations (Schurger et al., 2012)). Such model activation reflects neural activity that might be recorded over the SMA by the Cz electrode. We term this component of the model the Noise or SMA component. The second component of the model reflects brain activity that drives deliberate decisions, based on the values that subjects associated with the decision alternatives. We term this second component the Value or Region X component. Our model relied on its noise component to reflect arbitrary decisions and on its value component to reflect deliberate decisions.

A second difference between our model and Schurger and colleagues’ is that theirs modeled only the decision when to move (during arbitrary decisions), as those were the only decisions that their subjects faced. But our subjects decided both when and which hand to move. So, we had to extend the Schurger model in that respect as well. We did this using a race-to-threshold mechanism between the decision alternatives. In our empirical paradigm, the difference in rating of the two causes was either 1 (for hard decisions) or 4-6 (for easy decisions; see “Experimental Procedure” in Methods), so there was always an alternative that was ranked higher than the other. Choosing the higher- or lower-ranked alternative was termed a congruent or incongruent choice with respect to the initial ratings, respectively. Hence, we modeled each decision the subjects made as a race to threshold between the DDMs for the congruent and incongruent alternatives in the noise component (for arbitrary decisions) or value component (for deliberate ones).

We found the reaction time (RT) distribution and consistency score for each subject (as detailed above). The model’s RT was defined as the overall time that it took from the onset of the simulation until the first threshold crossing in the race-to-threshold pair (between the congruent and incongruent DDM; for Δt = 0.001 s). To determine the RT error, we ran a similar procedure to Schurger et al. (2012). We computed the empirical, cumulative RT distribution for each subject and fit a gamma function to it. We then averaged those gamma-fitted distributions across all subjects and designated that the empirical distribution. Then, we computed the RT for the model for each parameter set from 1000 model runs and fitted a gamma function to that too. Finally, we computed the ratio of the intersection of the two cumulative distributions and their union; and the RT error was defined as 1 minus that ratio. The consistency error was computed as the absolute difference between the empirical and model consistencies. Finally, the overall error was defined as mean of these two errors.

To find the parameter values that minimize this overall error, we ran an exhaustive grid search over all the parameters. To do this, we fixed the threshold at 0.3 and found the values of the congruent and incongruent drift rates as well as the leak and the noise scaling factors that, at the same time, best fit the empirical distribution of the RTs and the consistency scores (with equal weights) for (easy, hard) x (deliberate, arbitrary) decisions (Table 1) in the manner described below. We had 4 parameters to fit: the congruent drift rate (I_congruent), the incongruent drift rate (I_incongruent), the leak (k), and the noise-scaling factor (c). We first explored the 4D space of those 4 parameters to test how smooth it was and to find the range in which to run the exhaustive grid search. We found that I_congruent was minimized between 0.05 and 0.4 and that I_incongruent was minimized somewhere between the value of the I_congruent and 5 times smaller than...
that. Then $k$ was found to lie between 0.2 and 0.55, and $c$ between 0.01 and 0.3. Based on our
tests and specifically the smoothness of the search space, we found that we could divide each
parameter range into 5 equal parts. So, we then tested the model in each of the $5 \times 5 \times 5 \times 5$ (=
625) entries in the grid by running the model 1000 times and computing its error by comparing
its RT distribution and consistency rate to the empirical ones. Once we found the minimum
point in that 4D grid, we zoomed in on the range between the grid value to the left of the entry
were the minimum error was found and the one to the right of that minimum. (We chose the
initial range such that the minimum error was never achieved on the smallest or largest point
for all parameters.) We continued this process of finding the minimum and zooming in until
each parameter reached a range that was smaller than 0.025 or the error was less than 0.025.

Once we found the parameters that minimized the mismatch between the empirical and model
RTs and consistencies for each decision type, we ran the model with those parameters 1000
times again. For each run of the model, we identified the first threshold crossing point (for the
congruent or incongruent DDM), which made that model the “winning” DDM. We then
extracted the activity in both the winning and losing DDM in the last 2 s (2000 steps) before
the crossing. And we averaged across the activity of the two DDM (because an electrode over
the SMA or Region X would be expected to pick up signals from both DDMs). If the first
crossing was earlier than sample no. 2,000 by $n > 0$ samples, we padded the beginning of the
epoch with $n$ null values (NaN or “not-a-number” in Matlab). Finally, we averaged across all
1000 model runs to calculate the model’s RP. Note that NaN values did not contribute to the
average across simulated trials, so the simulated average RP became noisier at earlier time
points in the epoch. Hence, our model was similarly limited to the Schurger model in its
inability to account for activity earlier than the beginning of the trial (see Results).

**Table 1: Values of the model’s parameters across decision types and decision
difficulties.** Values of the drift-rate parameter, $I$, for the congruent and incongruent
options; for the leak rate, $k$; and for the noise scaling factor, $c$. We fixed the threshold at
the value of 0.3. The values in the table are for the component of the model where the
decisions were made. Hence, they are for Region X in deliberate decisions and for the
SMA in arbitrary ones. Note that, for deliberate decisions, drift-rate values in the SMA
were 1.45 times smaller than the values in this table for each entry.

Our model describes the mechanism we propose for subjects’ decisions. We therefore now
examine how the values in Table 1 relate to the experimental design and actual results. As
discussed above, we view $I_{\text{congruent}}$ and $I_{\text{incongruent}}$ as reflecting the values of the decision
alternatives that were rated higher and lower in the first part of the experiment, respectively.
We thus expect $I_{\text{congruent}}$ and $I_{\text{incongruent}}$ to be more different (similar) for easy (hard) deliberate
decisions. And we indeed find an almost 4-fold differences between $I_{\text{congruent}}$ and $I_{\text{incongruent}}$ in
deliberate easy versus only 2-fold difference for deliberate hard. For arbitrary decisions, be
ey they easy or hard, we do not expect the values of the decision alternatives to matter much. And
this is reflected in the similar values of $I_{\text{congruent}}$ and $I_{\text{incongruent}}$ there.

The leak values ($k$) were similar across all conditions. In contrast, the values of the noise-
scaling factor ($c$) for deliberate decisions were only 35% to 45% of those in arbitrary decisions.
As decision types were blocked, this appears to indicate that subjects adopted different
decision parameters across blocks. One reason for the larger levels of noise in arbitrary trials
might be the difference in consistency scores. The noise-scaling factor provides the
randomness to our model. Hence, the lower the noise factor, the more deterministic the result
of the model’s simulation—and thus the higher the chance that the consistent DDM (i.e., with
$I_{congruent}$, which is larger than $I_{incongruent}$) would win the race against the inconsistent DDM. The
consistency scores for deliberate easy, deliberate hard, arbitrary easy, and arbitrary hard, were
0.99, 0.83, 0.54 and 0.49, respectively. And these are nicely anti-correlated with the respective
increase in the noise levels: 0.08, 0.11, 0.22, and 0.23 ($r = -0.99$, p = 0.007).

It should be noted that, when minimizing the error in the deliberate-hard condition, we found
two disjoint regions within the parameter space ($I_{congruent}$, $I_{incongruent}$, $k$, $c$) where the error
reached relatively similar local minima. The parameter values corresponding to the smaller
among the two errors are listed in Table 1 (deliberate hard row). The parameter values at the
other local minimum are ($I_{congruent}$, $I_{incongruent}$, $k$, $c$) = (0.15, 0.07, 0.21, 0.09).

**Acknowledgments:** We thank Ralph Adolphs for his invaluable guidance and support in designing and running the experiment as well as for very useful discussions of the results. We thank Ram Rivlin for various conceptual discussions about deliberate versus arbitrary decision-making and about the initial experimental paradigm design. We thank Caitlin Duncan for her help in patiently and meticulously gathering the EEG data. We thank Daw-An Wu for discussions about EEG data collection and preprocessing and for his help with actual data collection. We thank Daniel Grossman for his help in carefully preprocessing the data and suggesting potential interpretations of it. We thank Aaron Schurger and Ueli Rutishauser for various discussions about the model and its simulations. We thank Shlomit Yuval-Greenberg and Leon Deouell for important discussions about EEG processing and analysis. Last, we thank the anonymous reviewers for their invaluable comments, which greatly improved this manuscript. **Funding:** This publication was made possible through the support of a joint grant from the John Templeton Foundation and the Fetzer Institute to U.M., L.M. and G.Y.. The opinions expressed in this publication are those of the author(s) and do not necessarily reflect the views of the John Templeton Foundation or the Fetzer Institute. This research was also supported by Florida State University's Big Questions in Free Will Initiative, funded by the John Templeton Foundation, to U.M., G.Y., and C.K.; by the Ralph Schlaeger Charitable Foundation to U.M.; by the Bial Foundation – Grant number 388/14 to U.M. and L.M.; and by the German-Israeli Foundation for Scientific Research and Development to L.M.. C.K. thanks the Allen Institute founders, Paul G. Allen and Jody Allen, for their vision, encouragement, and support. **Author contributions:** U.M, L.M, G.Y., and C.K. conceived the project and designed the experiments. L.M. and U.M. analyzed the results. U.M. designed and simulated the model. L.M. and U.M. wrote the manuscript. G.Y. and C.K. suggested revisions to the manuscript. **Competing interests:** The authors declare that they have no competing interests. **Data and materials availability:** All data needed to evaluate the conclusions in the paper are present in the paper. Additional data related to this paper may be requested from the authors.
Neural precursors of decisions that matter—an ERP study of deliberate and arbitrary choice
